cover. The furnace usually is used for processing material which requires special surface protection from oxidation or decarburization. The furnace shell is removed by a crane and set aside while the hearth of the furnace is charged. The shell is then replaced, as was shown in Figure 21—16. Furnaces of this type, used for annealing sheet, strip, rod and wire, usually are called **box annealing, pack annealing, coil annealing, or cover annealing furnaces**. In these, the material is stacked on a permanent base or stand, a light inner cover is placed over the stack, sealed with sand at the bottom and provided with a constant supply of prepared gas atmosphere, and then the portable heating unit is lowered over the assembly. The heating covers are square, rectangular or cylindrically shaped. Loads vary from 35 to 400 tons per charge, distributed on one to eight stands per base. In most instances, a number of bases and inner covers are provided with one or more covers for heating. After heating of each charge is completed on a base, the heating cover is moved to another base, leaving the charge protected by the atmosphere under the inner cover which is left in place. The covers may be direct fired or equipped with radiant tubes for indirect firing, or they may be heated by electrical resistance units. The heating elements are attached to the inside of the heating cover, which is built of steel and lined with a refractory insulating material and braced substantially in order that it can be moved from base to base with an overhead crane. Many inner covers are made of heat-resisting alloys. All are sealed to the base at their bottom edges with a powdered refractory. The heating time in a cover annealing furnace for coils of sheet or tin plate range from 24 to 44 hours for the larger sized furnaces, depending upon the length of soaking period required. The soaking period usually is about 4 to 12 hours. In furnaces of 150 to 300 tons capacity, the average production is about 5.5 tons per hour, the fuel consumption about 1,000,000 Btu per ton, the maximum fuel-burning capacity about 12,000,000 Btu per hour, and the atmosphere-gas consumption about 1,200 cu. ft. per hour. In pack or box annealing furnaces, natural gas or some inert gas is used to surround the charge; the circulation of gases inside the inner cover is by natural or forced convection. In cover fur-

naces for annealing coils, separators are placed between each coil to aid in distribution of the gas inside the inner cover. The circulation of this gas in a number of modern installations is forced. The fan is located in the base below each stand. The trend in annealing sheet and tin plate has been towards the greater use of coils and heating by forced convection rather than by the former pack method of annealing, in order to obtain higher production and improved uniformity of heating.

4. **Pit furnaces** are furnaces of cylindrical or rectangular shape in which the material is charged and withdrawn through an opening in the furnace top. The larger furnaces are installed usually with at least part of their work chambers below floor level, while many of the smaller and shallower furnaces rest on the working floor, for convenience in handling material. The material to be processed usually is suspended by a fixture or loaded into a basket and set into the working chamber, which resembles a "pit." Pit furnaces employ either direct firing or electrical heating, in either case with natural or forced circulation. They may or may not be equipped with special facilities for atmosphere control. Pit furnaces are used for normalizing, hardening, annealing, tempering, and carburizing.

5. A **salt-bath or lead-bath furnace** is another type of heat-treating furnace. It is designed to hold a bath of molten salt or lead in which the material is immersed for treatment. These furnaces are usually small pot-like affairs used in batch operations, but some large furnaces have been constructed of rectangular shape with depths of 15 feet to suit the shape and size of the material to be handled, with conveyors or other means for carrying out continuous operations. They are equipped usually with a hinged cover or a ventilating hood for minimizing fumes. Such furnaces are used to obtain uniform temperature distribution and close temperature control of the work piece. The bath is heated and maintained at proper temperature either by electrical resistance or by combustion of a fuel. Furnaces with a molten bath for heat treating are called **pot furnaces** when the bath is contained in a pot or crucible constructed of a heat and corrosion-resistant metal, usually externally heated by suitable burners. Other bath-type furnaces may be heated by electric current passing through the (salt)

FIG. 21—20. Continuous disc-roller-hearth type of normalizing furnace, divided lengthwise into zones each having individual automatic temperature control.

bath between immersed electrodes, or by immersed resistance coils or fuel-fired tubes.

Continuous Furnaces—In continuous furnaces, the material moves through the furnace, and two basic types of these are recognized. In one, the furnace is circular with a rotating hearth which carries the charge. The walls and roof are stationary, and the furnace enclosure is made by contacting the walls with the periphery of the moving hearth through a sand or liquid seal. In the other type, the furnace is composed of a single, long straight chamber, or series of chambers, through which the material is moved. Differentiation of continuous furnace types may be made according to the way the material is moved, such as the rotary-hearth, the roller-hearth, the pusher, the conveyor, the walking-beam, the tunnel, the continuous-strand and the monorail types. Modern production methods, dealing with ever increasing tonnages of material of identical size and treatment, favor the continuous-furnace type best suited to the nature of material to be heat treated.

Continuous furnaces are designed with and without auxiliary equipment for atmosphere control. Heat may be applied by direct or indirect firing or electrically. They are especially suited for zone heating and cooling. A brief description of continuous furnace types and their application is given below.

1. **Rotary-hearth furnaces** are used generally for heating pieces that are to be handled individually. Typical applications are the heating of gears, shells, cylinders, billets, etc., that are to be fixture-quenched or handled individually for scale-free hardening without decarburization, for normalizing or drawing. This furnace type is used also for heating smaller parts loaded in lightweight trays, and for pack carburizing. Charging and discharging are accomplished at the same location. Rotary-hearth furnaces are built in a wide range of hearth sizes, to heat from a few hundred pounds up to 60 tons per hour. A typical rotary-hearth furnace for heat treating steel is shown in Figure 21—19.

2. **Roller-hearth furnaces** are high production, continuous-type units, especially suited for uniform treatment of large orders of identical material. This type of furnace is used widely for bright annealing of tubes, stampings, drawn parts, etc.; for normalizing, annealing, hardening and drawing steel bars; for annealing malleable iron, small steel and iron castings, and forgings; and for normalizing flat-rolled products. Roller-hearth furnaces are constructed as a single furnace or as a line of furnaces for zone heating and cooling, and sometimes have an intermediate section with a tank for quenching.

In some modern furnaces used for continuously treat-

ing short lengths of sheet, disc rollers made of heat-resisting alloys with polished surfaces are utilized to reduce the cooling effect of full contact with the ordinary type of roller and to avoid scratching of the piece. The discs are staggered and mounted upon water-cooled shafts, which are driven by variable-speed motors either through a chain and sprocket system or shafts and gears. A gas-fired normalizing furnace with automatic pyrometric control is shown in Figure 21—20. Furnaces of this type are built up to 100 inches in width and vary from 120 to 200 feet in length, the larger ones having capacities for normalizing up to 300 tons per 24-hour day. Sheets undergoing treatment in roller-hearth furnaces may be protected further from contact with rollers of whatever type by the use of rider sheets, which are placed on the rollers and support the work. Cover sheets on top of the work also may be used to further increase protection. Rider and cover sheets may be used repeatedly before they must be scrapped, since they generally are made of alloy steel.

3. **Pusher-type furnaces** are of two general types. In one type the parts are pushed against each other, as in the continuous reheating furnace. In the other type, the parts are loaded in trays or other types of carriers which are pushed through the furnace.

4. **Conveyor-type furnaces** are constructed similarly to roller-hearth furnaces except that belt conveyors are used to carry the material through the furnace. They are suitable for accurately heat treating small miscellaneous pieces which would not ride properly on a roller hearth. Belt conveyors are made of alloy material of sufficient strength to carry the load and are resistant to heat, oxidation, corrosion and abrasion. A number of different designs of conveyors are utilized to satisfactorily meet the requirements. Some conveyors consist of several individual chains held on constant centers by spacer bars provided with suitable projecting lugs upon which the load, such as sheet or plate cut to length, rests. Many other belts are constructed of open mesh or woven chain to permit free circulation of hot furnace gases or protective atmosphere, while another construction utilizes pans or trays connected to a roller chain to carry the material. The production rate or heating cycle in this furnace type is controlled both by the temperature setting and by varying the speed of the conveyor.

5. **Walking-beam furnaces** employ a special mechanism within the furnace, known as a "walking beam" to move the material through the furnace. The walking beam consists of a number of alloy supports or beams which are arranged in rows of two or more beams to the row, throughout the length of the furnace. The beams are staggered with the one immediately ahead, and are

FIG. 21—21. Tower-type furnace in a continuous annealing line in a tin mill. The furnace proper, surrounded by structural-steel operating platforms, is 64 feet in height, and is heated by a combination of gas-fired and electric heating units. It has an annual rated capacity of approximately 136,000 tons.

placed in longitudinal slots in the furnace hearth. They are attached from below to toggles or cams that intermittently raise the beams, move them forward, and then lower them, thus depositing the material on the beams ahead. By this step action the material is moved

through the furnace at the desired rate. This furnace type is used commonly for tubes, bars, structural shapes or similar material.

6. In tunnel-type furnaces, the stock to be heated is placed upon cars which then are pushed or pulled

slowly through the furnace. This furnace type was used at one time for continuous box annealing of sheets. Furnaces used for this purpose sometimes reached 300 feet in length and were built in the form of a long tunnel, not necessarily straight, nor with a level bottom. The sheets were piled upon a base and sealed in a box for annealing. The box then was placed upon a small car which was pushed into the furnace. As the furnace was full of these cars, one car was removed as each car entered the furnace.

7. **Continuous strand-type furnaces** have been developed to reduce the extra handling and the long heating and cooling periods required in annealing sheet and tin plate in coil form. Heat treating uncoiled strip provides greater possibilities for the control of the time-temperature requirements for the entire piece and, therefore, a more uniform product. A coil can be processed in a matter of minutes or a few hours compared to the long cycle required in a batch furnace. Another special advantage of this furnace type is that other operations, such as cleaning or coating, may be combined with the heat-treating process to avoid extra handling and the expense of duplicated handling equipment for separate lines. Continuous strand-type fur-

naces are constructed either as horizontal or vertical units. Furnaces of the latter type of construction are sometimes referred to as **tower-type furnaces** and are used primarily to conserve floor space. Furnaces of this type utilize either electric or radiant-tube heating or both.

Figure 21--21 shows a modern tower-type furnace for annealing cold-reduced material at one stage in the manufacture of tin plate.

The horizontal type of continuous-strand furnace sometimes utilizes catenary suspension of the uncoiled strip, where neither rolls nor any other type of support are used throughout the heating zone. The heating zone of these furnaces may be from 20 to 50 feet in length. The preheating and cooling zones usually are constructed shorter than in the conveyor type and for some kinds of work are omitted entirely.

8. In **overhead monorail furnaces**, the material undergoing heating is suspended from rods that serve as hangers or even may be welded to the suspension rods. The suspension rods are attached at their upper ends to the carriers that operate on the monorail. If the rods are welded to the work pieces, they are removed after the assembly leaves the heating furnace.

Chapter 22

CONSTRUCTION AND OPERATION OF ROLLING MILLS

SECTION 1 TYPES OF MILLS

General Classification—The three principal types of rolling mills used for the rolling of steel are referred to as **two-high**, **three-high**, and **four-high** mills, shown schematically in Figure 22—1. As the names indicate, the classification is based on the manner of arranging the rolls in the housings, a two-high stand consisting of two rolls, one above the other; a three-high mill has three rolls, and a four-high mill has four rolls, arranged similarly. When rolling is in one direction only on **two-high** mills, and the piece is returned over the top of the rolls to be rerolled in the next pass, the mill is known as a **pull-over** or **drag-over** mill. This type of mill formerly was used mainly for production of light sheets and tin plate; it still is used by merchant mills for rolling of tool and high-alloy steels. On **two-high reversing** mills, the direction of rotation of the rolls can be reversed, and rolling is alternately in opposite directions, with work done on the piece while traveling in each direction. The long mill tables of reversing mills make it possible to handle heavy pieces in long lengths that would be impractical to roll on ordinary two-high mills, or to handle on the lift tables of a three-high mill (see below). The reversing two-high type of mill occupies an important position in the industry and, with the use of manipulators, it is possible to produce on it slabs, blooms, plates, billets, rounds, and partially-formed sections suitable for later rolling into finished shapes on other mills. In all three-high mills, each roll revolves continuously in one direction; the top and bottom rolls in the same direction and the middle roll in the opposite direction. The piece is lifted from the bottom pass to the return top pass by mechanically-operated lift tables, or by inclined approach tables. Usually the large top and bottom rolls are driven, while the smaller middle roll is friction driven. This latter roll is about two-thirds the size of the other two rolls, in order to permit removal through the housing windows. **Four-high** mills are used for rolling flat material, like sheets and plates, and represent a special type of two-high mill for both hot and cold rolling, in which large (idler) **backing-up** rolls are employed to reinforce the smaller (driven) **working** rolls. The use of four-high mills resists the tendency of long working rolls to deflect, and permits the use of small-diameter working rolls for producing wide plates, and hot- or cold-rolled strip and sheets of uniform gage. These mills often consist of a number of stands spaced closely together in one continuous line and are known then as **tandem** mills; the product passes in a straight line from one stand to the next. In **cluster** mills, each of the two small working rolls is supported by two (or more) **backing-up** rolls. This latter type of mill is used for the rolling of thin sheets.

ARRANGEMENT OF MILLS

A single stand mill, which may be either two-, three- or four-high, and either reversing or non-reversing, represents the most common arrangement for rolling a wide range of products, including blooms, slabs, plates, sheets, and various sections. **Guide**, **loop**, and **cross-country** mills are made up of several two- or three-high stands, or a combination of both, and are used for rolling of merchant-bar sections. **Guide** mills are small hand mills consisting of several stands of rolls in a **train**. Mills in train have the rolls of separate stands in the same line, the rolls of one mill being driven from the end of the rolls of an adjacent stand. Guide mills take their name from the metal guides which support the piece in the correct position during its passage through the grooves of the various passes. For example, it is possible to roll from an oval section to a round in one pass, provided the oval is supported by metal guides. In many guide mills it is the practice of the catchers, in order to save time, to start the piece through each of the passes before it is through the preceding one, thus forming a loop, resulting in this arrangement being called a **looping** mill. The layout of a mill of this type is shown in Chapter 30. There originated in Belgium the plan of setting up an independent roughing stand preceding the finishing train of the looping mill. This arrangement became known as a **Belgian** mill. On looping mills, it was found that the loop could be made mechanically by a tube or horse-shoe type trough, called a **repeater**, and thus dispense with the hand catchers. Prior to the looping mill, the piece was rolled throughout the entire length in one pass before it could be entered in the next pass. The looping arrangement eliminates the temperature difficulties encountered with long lengths. The shapes produced range from simple rounds and squares to intricate special shapes, but must be relatively small in cross-section. The **cross-country** mill is so named because of the scattered location of its roll stands, and was developed for rolling sections that, due to size or shape, are not adaptable to loop rolling. These mills involve the continuous idea, but the stands are placed so far apart that the piece must leave one set of rolls before entering the next (see Chapter 30). To save space and to avoid complicating the drives, the stands usually are arranged in two or more parallel lines, and the direction of travel of the piece is reversed during the rolling by employing transfer and skid tables. This arrangement results in a high-production mill of great flexibility, which may be used for a wide range of products, including structural shapes, rails, and splice bars. A continuous mill consists of several stands of rolls ar-

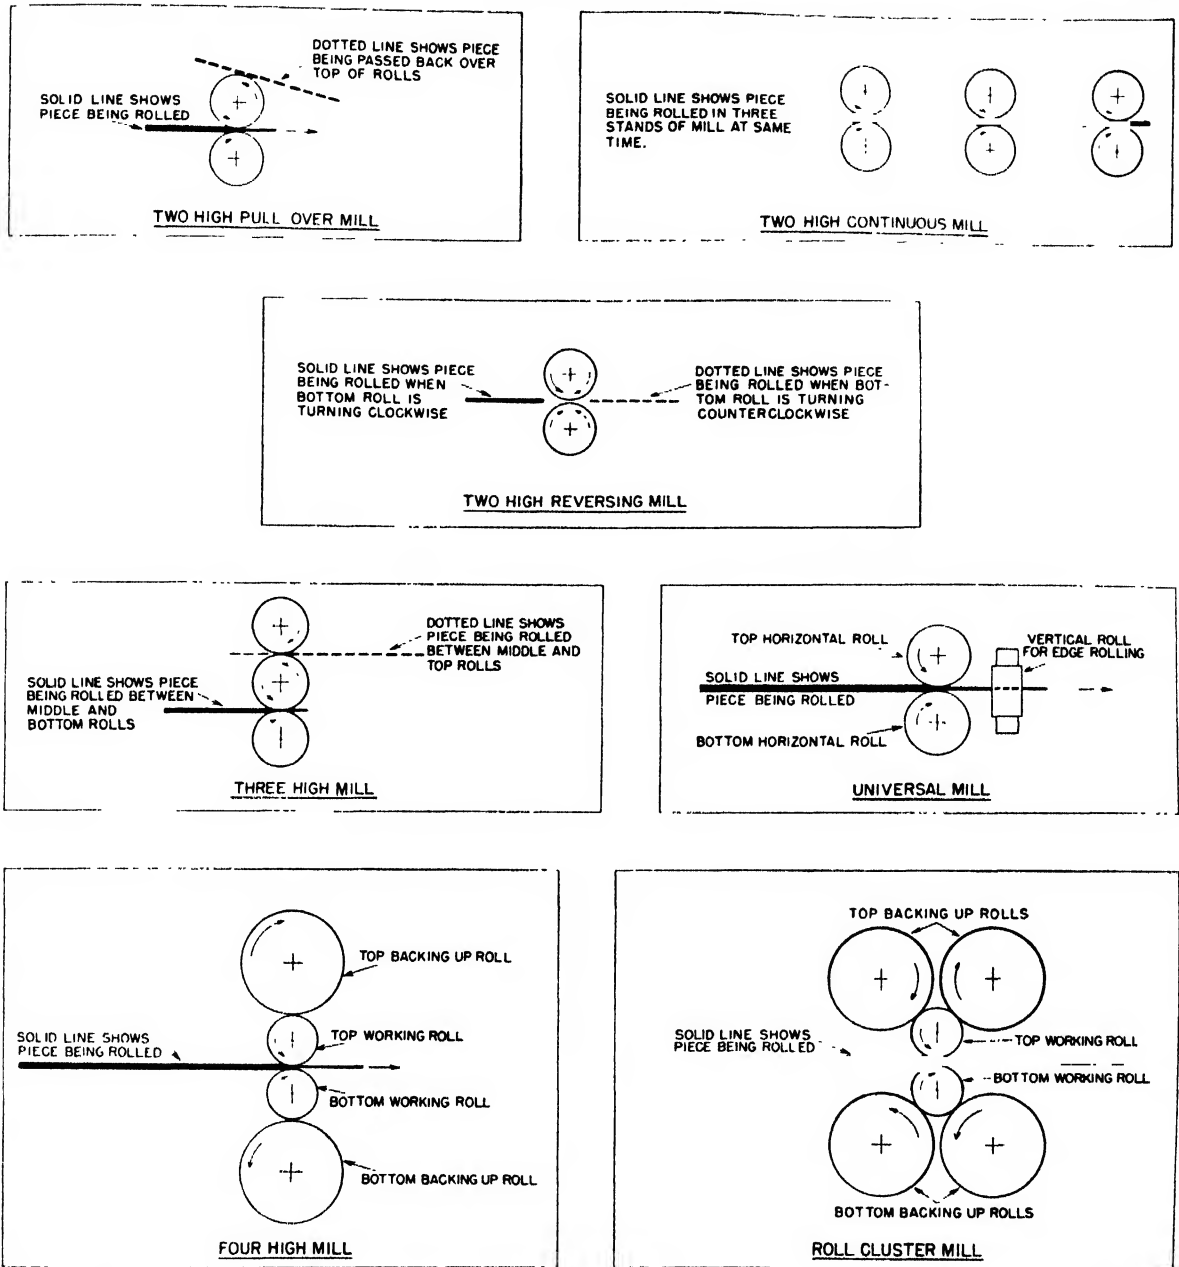

FIG. 22-1. Schematic representation of roll arrangements in the principal types of rolling mills.

ranged in a straight line (in tandem), with each succeeding stand operating with roll surface speed greater than its predecessor. Such a mill is illustrated diagrammatically in Part 2 of Chapter 25. Reduction takes place in several passes at the same time until the piece emerges as a finished shape from the last roll stand. This type of mill is in very common usage for rolling strip, sheet, billets, bars, rods, etc. A semi-continuous mill comprises also a four-high reversing roughing stand for reducing the piece prior to entering the continuous mill for reduction to the finished shape. This arrangement gives moderately high production with lower first cost than a continuous mill. Combination mills are those in which the roughing or major part of the reduction is

performed in a continuous mill, and the shaping in a guide or looping mill.

SPECIALTY MILLS

The universal mill is a combination of horizontal and vertical rolls, usually mounted in the same roll stand (Figure 22-1). The mill is made up of two-high (and occasionally three-high) horizontal rolls, with vertical roll sets on either or both sides of the horizontal stand. The vertical rolls also usually are driven. The direction of the piece is reversed after each pass in the mill. The universal mill is used to a limited extent also for plate product that requires rolled edges (see Figure 22-2). A special type of universal mill, known as the Gray

FIG. 22 -2. Diagrammatic layout of the principal parts of a universal mill for rolling plates.

mill is well adapted for rolling beams and H-sections of great width and depth without taper on flanges (see Figure 22-3). The horizontal rolls work on the web and flange thickness, while the idler vertical rolls in the same stand work simultaneously on flange thickness only. The roughing stands and intermediate stands are of the reversing type, and each has a separate stand of driven horizontal edging rolls which work on the flange height only. The finishing stand consists of the horizontal and vertical rolls in which the beams are given one pass only.

The **Wenstrom mill** is a similar modification of a universal plate mill, designed principally for rolling flats. Instead of acting upon the top and bottom and the two sides at different times, it does this simultaneously. The top roll can be adjusted vertically, and the bottom roll transversely, whereby pieces of different thickness and width can be produced with the same set of rolls. The **Sack universal mill**, designed principally for rolling cruciform sections, has horizontal and vertical rolls which act upon the piece simultaneously, the general arrangement being much like that of the Wenstrom mill. A somewhat similar principle is employed in the **Schoen mill** for rolling of railroad car wheels, whereby

the tread and flange are rolled simultaneously with the web, while rotating the forged wheel blank in a vertical position. This is accomplished by a pair of driven web rolls, and an idler tread roll in simultaneous contact with the wheel blank. A pair of idler rim rolls controls the width of rim (see Chapter 31).

For rolling of billets, rods, and narrow slabs, a continuous mill called a **Morgan mill** may be used (see also Chapter 40). It consists of a series of horizontal roll stands arranged one after the other, so that the piece is being rolled in a number of stands at the same time. The drive for each stand is through bevel gearing, with roll speed of each stand so proportioned that each set of rolls travels at a greater speed than necessary merely to compensate for the increase in speed due to elongation of the piece in the preceding pass, in order to keep the piece under tension at all times. Twist guides may be used to turn the piece 90° between passes. The **Garrett mill** (see also Chapter 40) is used for rolling small rods; it reduces the billet section in a roughing mill, which may be a looping train of three stands, or two or more stands arranged in tandem, followed by two trains of four or five stands each, lying end to end along two parallel lines in close prox-

ROLLING MILLS

FIG. 22-3. (Above) The rolls and their functions in forming an H section by rolling in two-high and Gray mills. (Below) Flow diagram showing layout of the mill utilizing the rolls shown above.

imity to each other, and so placed that the first intermediate pass is in line with the last roughing pass, and far enough away to give proper clearance for the pieces. Generally, catchers are employed on the oval side, while repeaters are used only on the opposite (or square) side of the intermediate and finishing trains.

Another hot-rolling mill for billets, rounds and squares is the ingenious **Lamberton mill**, developed to avoid the need for a reversing motor. This mill is a two-high unit, with the motor turning in one direction only. The roll housing has two horizontal rolls in the usual position, but the shafts of the mill pinions are in the same horizontal plane. The mill housing is arranged to revolve through 180° , so that the rolls exchange positions after each pass, thus reversing the rolling direction. The bottom roll becomes the top roll, and vice versa, without changing their directions of rotation; thus, bars may be rolled in either direction without reversing the motor.

For the cold reduction of strip with a high degree of reduction in one pass, the **Krause mill** has had some application in the brass industry, and consists of a rolling head with the pinch taken between two small work

rolls, backed up by so-called cam plates for backing-up support. During reduction the strip is kept still, and the work rolls and the pinch are given the motion. The rolling head is reciprocated, taking a succession of short bites as the head goes back and forth, and as the thick stock is fed into the machine. A reciprocating type of machine for the incremental cold reduction of seam-rolled steel tubing is described in Chapter 41; this is the **Rockrite machine**. The **Sendzimir cold strip mill** for wide thin strip uses no backing-up rolls. The mill may have two, three, four or more caster shafts per work roll and may use one or more sets of intermediate rolls, between the casters and the small work rolls. The intermediate rolls transmit the pressure from the work rolls onto the casters, always in a plane perpendicular to the work rolls. The **Unitemper mill** is used as one means for temper rolling or skin rolling of finished cold-reduced strip. This mill consists of two stands of two-high mills, but with the second stand above the first in the same mill housing, to provide closer spacing between the two stands. With the motor of the first stand acting as a generator, and the motor of the second stand acting as a motor, the strip can be elongated a con-

trolled amount between passes with only a very slight reduction in each stand due to rolling.

Die rolling is the process of rolling a string of blanks, each of which has varying cross-sectional area produced by heavy reductions, and specified center to center length. When sheared to length the blanks are of identical shape. Products such as automobile axles and crankshafts are produced satisfactorily by die rolling. The blanks are rolled with or without flashing, depending upon the particular product section.

For producing seamless tubing, the types of piercing mills include the **Mannesmann** or parallel-axis barrel-type roll piercing mill, the **60° cone-roll** piercing mill, and the **Stiefel** or **180° disc** mill. For the operating principles of these piercing mills, refer to Chapter 41. A **continuous tube rolling mill**, built in 1948 by National Tube Division of United States Steel Corporation, consists of nine tandem individually powered stands of two-high grooved rolls. The rolls in the consecutive stands have their axes at 90° with each other. A cylin-

drical mandrel extends entirely through the pierced billet and passes through the mill with the work piece. The reheated tubes are processed in a tension reducing mill consisting of sixteen two-high roll stands, without the use of a mandrel. For producing butt-weld pipe the **Fretz-Moon tube mill** may be used. The skelp on leaving the furnace enters the first pair of rolls which form the piece downward, with the edges still apart. The second pair form the complete circle and bring the edges of skelp together, and the welding of the edges by their own heat takes place. The mill actually consists of three pairs of horizontal rolls and three pairs of vertical rolls. The last four pairs reduce and size the pipe, and furnish traction for pulling the skelp through the furnace and forming rolls.

Opportunity will be given in later sections to become better acquainted with the operating details of most of these mills. The types of rolls used in the more common mills, and their manufacture, will be discussed in Chapter 23.

SECTION 2

ROLLING-MILL ACCESSORIES

Many of the accessories of rolling mills are common to all types of mills, differing in design and operations to conform with the conditions in a particular mill. In addition to the rolls (described in Chapter 23), essential parts include the **mill drive**, **lead spindle**, **pinions** and their housings, **spindles** and **coupling boxes**, **chock bearings**, **screws** and **screw-down mechanism**, **edgers**, **front and back mill tables**, **manipulators** and **side guards**, **entering and delivering guides** and **roll-changing devices**. The newer mills may be equipped also with various control devices, such as pressure meters and automatic roll-setting devices. Many of these parts are discussed in the description of particular types of mills in later chapters. In the following, a discussion is presented of those parts essential to the operation of the rolls. To aid in locating some of the various parts described below, Figure 22-4 shows a cross-sectional diagram of a high-lift reversing blooming mill.

Lead Spindle—The lead spindle is used to connect the prime mover with the pinions, and may be of the universal type, either short-coupled, or long with carrier bearings, depending on the position of the motor in the layout. If short-coupled, standard flexible couplings can be used. The lead spindle is attached to the bottom pinion of two-high mills, and to the center pinion of three-high mills. If the pinions are of the universal type, they can be of generous proportions, as their diameter is not limited by the space available. Lubrication of all working surfaces is important. Grease usually is applied through a system of holes drilled in the jaws, and connected to various designs of spring-loaded cavities in the spindle body. The connection at either end of the spindle may be made by a **coupling box**, which is a hollow cylindrical casting corresponding in section to the wobbler, with one end fitting the spindle and the other the pinion (see Figure 23-1 of Chapter 23). The coupling box usually is made deliberately as the weak spot of the mill, either on the lead spindle or the spindles on the roll end. In the event of extreme overloading of the mill, the box breaks and disconnects the motor from the mill. The minimum length of spindle is slightly over twice the length of the coupling box that is used.

Pinions—The pinions are gears serving to divide the

power transmitted by the drive between the two or three rolls, driving the adjacent rolls in opposite directions. If twin-motor drives are used, no pinions are required, since the power is transmitted directly to each roll. The earlier pinions had either spur teeth or a divided face and staggered spur-type teeth, but the present practice is to use double helical teeth. The helical gears give a smoother drive, as some parts of the teeth are in contact at all times, making the transmission of power continuous. When rolling certain grades of materials, operation of the old type of pinion with spur teeth was characterized by jarring of the meshing teeth. This mechanical jarring was transmitted to the rolls and produced marks on the product being rolled. Pinions are made of cast or forged steel. They are mounted in babbit bearings and set in housings similar to those used for roll stands. The pinion stand must be of adequate strength to withstand the overturning effect of the full and maximum torque of the drive motor. Housings should be sealed to eliminate dirt and scale, and forced lubrication should be provided for the pinions. Except in plate, direct-drive and universal mills, the distance from center to center of pinions determines the size of the mill. The pinions absorb about 6 per cent of the power transmitted.

Spindles are used to connect the pinions with the rolls if the mill is not a direct-driven type; in the latter case the spindle is connected directly to the motors. Spindles are made of cast or forged steel and are fitted at each end with wobblers similar to those on the rolls (Figure 23-1), or with the universal couplings, depending upon the type of mill. The bottom spindle runs in spring-balanced carriers, and the top spindle is supported at its center of gravity by carrier bars balanced hydraulically or by counterweights (Figure 22-4). The spindles are supported by babbit or composition bearings, and should operate as nearly level as possible to prevent excessive power loss. It is very difficult to operate with a spindle more than 15 degrees out of level. This angle may be kept within the desired limits by increasing the length of the spindles. If the angularity is greater than 6 degrees or 7 degrees, a universal coupling should be used, in which case the ends of the wobbler are cut from a section of a sphere to give them the rounded form necessary to permit

FIG. 22-4. Schematic cross-sectional diagram of a hydraulically balanced high-lift reversing blooming mill, indicating location and nomenclature of principal parts. (Compare with the schematic diagram of a similar blooming mill equipped with mechanical counterbalances for the top rolls and spindles in Chapter 25.)

them to work at different angles, and the spindle is supported by saddle bearings in a carrier which rises and falls with the top roll and holds the spindle in place (see Figure 22-4).

The Bearings—The bearings, which support the roll necks and align the rolls, may be of two general types; roller bearings or the older chock-type bearings. One type of roller bearing is illustrated diagrammatically in Figure 22-5.

FIG. 22-5. Horizontal section through the center-line of a bottom work-roll chock on a plate mill equipped with roller bearings.

Roller bearings first were used for rolling mills in Czechoslovakia in 1921 and in Sweden in 1922, where they were applied to small hot-rolling mills. In America, use of the roller bearing accompanied the development of the cold-reduction mill for strip and sheet, and its adoption has been extensive since 1932. The development of this type of bearing was slow on account of the difficulties that had to be overcome; namely, (1) the roll necks had to be of adequate diameter to withstand the rolling loads; (2) the roll necks had to be kept free from wear; (3) the bearings had to permit quick roll changes; (4) the bearings had to permit adjustments of the roll laterally as well as vertically; (5) the bearings had to be self-adjusting to take care of slight changes in the shape of the rolls caused by heating and bending; (6) the bearings had to have ample carrying capacity; and (7) in case of roll breakage, provisions had to be made to keep the bearings themselves from being damaged. Roller bearings are now common in new mills, although they have not replaced entirely the chock type of bearing, which possesses the advantage of greater simplicity of construction.

Modern roller bearings are showing extremely long life, with resulting lower cost per ton of product. Mills equipped with roller bearings may be expected to use from 15 to 20 per cent less power for the main drives than mills using bronze or conventional bearings. As roller bearings require no adjustment for bearing wear, greater tonnages can be rolled with less variation in section from piece to piece, permitting requirements to be met with greater ease and improved mill yield. Roller bearings also result in a general reduction in

mill maintenance, and, as an automatic greasing system is used for lubrication, a clean mill operation is effected. Figure 22-5 is a horizontal section through the center-line of a bottom work-roll chock (sometimes called chuck) on a 160-inch four-high reversing plate mill.

Chock Bearings—The chocks usually are made in two parts, the bearing with the surface of its lining in contact with the roll neck, and the chock, which holds the bearing in place against the roll neck. The bearings may be lined with babbitt or may be made with babbitt, brass or bronze inserts or they may be non-metallic bearings of the phenolic-resin type.

The alloys used in the bearings vary considerably. Table 22-I gives an approximate composition of some of the more common alloys used for bearings.

Table 22-I. Compositions of Typical Bearing Metals (Per Cent).

The tin in babbitt bearing metals can be replaced satisfactorily in most instances by substituting lead-base babbitts for tin-base babbitts and making, in some cases, additions of silver or arsenic to increase the hardness of the alloy at elevated temperatures.

As bearings made of all of these metals are soft and not very strong, it is necessary to insert them in supporting castings which are set into the housings. These castings are box-like in shape, each one containing on one side a semicircular groove corresponding to, but larger than, the necks of the rolls. In order to reduce weight, the castings are cored out, and may be of either iron or steel.

Reference has been made above to the use of bearings of the phenolic resin type. These composition bearings of a laminated type operate with water as a lubricant and have replaced the bronze and babbitt types of bearings on a number of mills, including some blooming mills, plate mills, bar and billet mills, rod mills, strip mills, skelp mills, tube mills, three-high sheet mills, and structural mills. Bearings of hard wood, with water as a lubricant also have been used successfully for certain mills. The advantages of the composition and wooden bearings include longer life, freedom from greasing, and reduced power requirements. Failure of this type of bearing in some mills may be due to one of several causes. The heat conductivity of such bearings is very low, and heat generated by friction must be removed continuously with adequate cooling water. Roll necks for these bearings must be smooth to prevent excessive bearing wear.

Arrangement of the Chocks—In a two-high mill, a chock is placed under each of the necks of the bottom roll and above each of the necks of the top roll. In case the top roll is adjustable, light bearings must be placed also under the necks of this roll for support; the upward thrust of the top-roll balancing device is exerted against these supporting bearings. The top-roll balance is for the purpose of keeping: (1) the top-roll necks in contact with the upper chock bearings; (2) the chocks tight up against the screw points; and (3) the

screw-thread surfaces in contact. On heavy mills, the counterbalance may be of the overhead hydraulic-cylinder type connected to an accumulator system, or of the underneath counterweight-and-lever type; both types of counterbalances can be compared in Figures 22-4 and 25-8. On small mills, screw bolts extending through the housing serve the same purpose. The exposed half of the necks of the lower roll usually will be covered to protect them from scale, etc.

The arrangement of chocks in three-high mills is more difficult. The simplest way is to place double-groove chocks between the top and middle and the middle and bottom rolls, and then set them in the housings one above the other, so that all the adjusting made necessary by the wearing away of the bearings and the material of the rolls themselves may be made with large screws in the top of the housing that can be turned to move upward or downward. However, this arrangement causes the bottom bearing to wear down rapidly and increases the power required to drive the mill, owing to the additional friction induced on the bottom bearing by the weight of the upper two rolls and their chocks. This fault may be overcome in two ways: (1) by making the bottom roll fixed and supporting the weight of the upper two rolls and their chocks on the shoulders of the chocks themselves, the distance between rolls may then be regulated with shims, or "liners," by adding or removing the shims as the bearings wear down; (2) a better way, and the one most often employed in modern mills, is to make the middle roll fixed, in which case the bottom roll is raised or lowered by an adjusting wedge attached to a screw in the housing which permits it to be moved back and forth with a wrench from the outside of the housing.

In all mills, two-high as well as three-high, the top chocks are held down by two strong screws which work in threaded holes or nuts in the tops of the housings.

The functions of the chocks are not only to furnish vertical bearings for the rolls but also to prevent their movement laterally as well. This lateral displacement of the roll is prevented by the inner edge of the bearing which is formed to fit against the shoulder of the roll. Adjustment for wear in this direction is provided by adjusting screws which extend through the side of the housing and bear on the ends of the chocks. This lateral adjustment is a matter of great importance in rolling sections that require grooved rolls, the reason for which is self-evident.

Housings—There are two housings for each stand of rolls (see Figure 22-6). They may be made either of iron or steel, the choice of materials depending upon the size of the mill and the strength required. Generally they are of annealed cast steel, but housings may be

FIG. 22-6. Diagrams indicating principal parts and their names for (left) a closed-top housing and (right) an open-top housing.

of welded steel construction, heavy plates or slabs. The housings are of an "O" or "U" form, each having an opening called the **window**, which serves as a receptacle for the bearings. Housings may be either closed top (O) or open top (U). In the former, the base, the two legs and the top are all in one piece, while in the latter, the top will form a separate part which can be removed. The base of the housing is cast with a projection on each side to form the feet. In the bottom of each foot is cut a groove which fits over a **shoe**, running parallel to the rolls. Suitably shaped bolts then serve to clamp the foot of the housing to the shoe, which is fastened firmly to the foundation by long bolts. This method permits the housing to be moved laterally, and facilitates the lining up of the mill. The tops of the two housings in a set are prevented from spreading apart by suitable tie rods or, in the case of open-top housings, the top for both housings may be cast in one piece. Similarly, tie rods usually will be placed at the bottom. Recesses or other openings are cast in the inside face of each housing to receive the supports for the guards and guides, these supports being usually in the form of square rest bars which extend from housing to housing in front of the rolls. The immense pressure applied to the rolls between the top and bottom of the housing acts as a stretching force on the uprights of the housings; the degree to which the housings resist this force is an important factor in determining the reduction that can be effected in one pass and also the exactness with which the thickness of the piece is controlled. The uprights of the housings sometimes are referred to as posts.

A screw-down mechanism is used on mills to position the top roll for each pass through the mill, except on continuous and three-high mills where fixed passes are

FIG. 22-7. Schematic diagram of the main operating parts of a typical manipulator, showing motion of the lifting fingers that raise ingot by a corner in the process of turning it 90 degrees.

used. The top roll is adjusted by screws which extend through the top of each housing. The screw-down bearings are of roller or antifriction type. The transmission of power was first accomplished by hydraulic pressure, but in modern mills the speed of the operation has been greatly increased by electric drives. On one recent installation, the maximum rate of raising or lowering the top roll is 38 feet per minute, compared with 2 or 3 feet per minute on the older mills. On small mills where the adjustment is only occasional, the screws will be operated by hand with spanner bars. In all cases, compression of these screws is unavoidable and, combined with the stretch of the housings, produces the spring of the mill, which in some cases is surprisingly large.

Edgers or edging rolls are used to give a universal or rolled edge to the product. The edging unit may be a roll stand separate from the horizontal stands, but in the universal-type mill the edging unit usually is attached to the main-roll housings. The edging unit consists of two vertically-mounted rolls, each manipulated by screws of identical size, so that they move in unison in opposite directions with respect to the centerline of the mill. Each roll is operated through a screw-down mechanism like that used on the top horizontal roll of a reversing or universal-type mill, with the exception that the motion is horizontal instead of vertical.

Front and back roller tables feed and receive the piece during each pass. Their speed should be matched closely to that of the rolls, and the width should be the same. On reversing mills these tables are subject to heavy usage due to impact from turning the piece, and should be of rugged construction. Forged steel generally is used today in making the rollers, which in new mills are mounted in roller bearings and equipped with automatic lubrication. In the older mills, bronze or babbitt bearings are lubricated by hand. The rollers usually are electrically driven by a line shaft through miter gears.

The manipulator consists of a pair of side guards, stroking laterally over the rollers of the front or back mill tables, usually on both sides of the mill (Figures 22-7, 22-8 and 22-9). The manipulators operate to turn the piece between passes, to move it to another pass, and to straighten it when necessary. Most manipulators are constructed so that both horizontal and vertical motion is possible. In most mills, these units are operated by electric or hydraulic power. Depending upon the size of ingot or section to be manipulated, the height of side guards may run up to 48 inches. Lifting fingers, always on the front manipulator and sometimes on the back one also, are incorporated in the guard or guards toward the drive side. These have a vertical or nearly vertical stroke and serve to lift the piece by a corner in the process of turning it 90 degrees.

Guides and Guards—In order to prevent collaring and to insure that the piece enters and leaves the pass in the correct position, guides are employed. These guides vary in form and size to fit the conditions. In some cases, they are merely grooved fore-plates; in others, they are blunt-edged plates set up in front of the collars, dividing the space in front of the rolls into a series of pigeon holes; in large mills rolling heavy sections, they may take the form of grooved rollers; in the smaller mills like the guide mills, they are trumpet-shaped castings that fit close up to the roll and have exit openings to conform to the shape and size of the section of the entering piece; in continuous mills they may be constructed so as to twist and thus turn the piece between two successive passes. Guides may be

employed on both sides of a pass, in which case they are designated as entering guides and delivery guides. They are held in place by means of the rest bars previously mentioned in connection with the housings. Guards are devices employed mainly on the delivery side of the mill to control the direction of the piece after leaving the pass. Reversing and three-high mills are provided with guards on both sides of the mill (see Figure 22—10).

Roll-changing devices are dependent upon the construction of the mill housing. The rolls in an open-top housing are changed by removing the housing cap and picking out the rolls separately or collectively with crane slings. Roll changing in closed-top housings is accomplished through the window of the housing

either: (1) by using a counterweighted porter bar, (2) by a sleeve utilizing the ingoing roll as a counterweight, or (3) by a "C" hook. All of these methods require overhead crane service to remove the rolls one at a time. The rolls are pulled out of the housing by attaching a socket fitting over the protruding roll necks. In some large modern mills, a roll-changing rig is used to remove worn rolls and install new ones. The rig is placed in a permanent mounting, level with the housing sill, and consists of a rack-and-pinion motor-operated crosshead mounted on a rail frame. It withdraws both top and bottom rolls with their respective bearings, all at one time. The old setup is removed from the rig by the crane and the new rolls and bearings are mounted on the rig to be pushed back into the mill.

Chapter 23

ROLLING-MILL ROLL MANUFACTURE

SECTION 1

ROLLING-MILL ROLL DESIGN

Principal Parts of Rolls—Of the essential parts of the rolling mill, the rolls are of the greatest interest, as they control the reduction and shaping of the metal. There are three parts to a roll; namely, the body, or the part on which the rolling is done, the necks which support the body and take the rolling pressure, and the wobblers, where the driving force is applied through loose-fitting spindles and boxes which together form a sort of ingenious universal coupling. These parts are shown in Figure 23—1.

A plain-surface or cylindrically-bodied roll is used (in pairs) for rolling sheets and plates, while for bars and shapes, grooves of suitable design are turned in the roll bodies. Such grooves are called *passes*.

Figure 23—2 shows two examples of grooved rolls:—a three-high set of rolls with 98 degree diamond passes, with the roughing-down operation from a billet indicated by the hatched lines, and a two-high set of rolls with grooves for rounds. Rolls are turned as required for a multitude of shapes. Figure 23—3 shows some of these grooves or passes and their nomenclature. The dotted lines over each pass show the cross-section of the piece leaving the preceding pass and entering the pass in question.

Procedure in Designing—When a new section has been approved for rolling, a detailed drawing of the section is sent to the roll designer, together with instructions to proceed with the design.

In most cases, though not all, a cold-finishing templet of the section is made which is an exact cross section of the bar to be produced by rolling. This is the starting point in the design. The templet work is done by skilled artisans called *templet filers* who must work to very close tolerances. As the bars are finished hot, a certain amount of shrinkage takes place in cooling. To allow for this shrinkage it is necessary to prepare a hot-finishing templet to which the rolls are turned. The shrinkage varies with different finishing temperatures but, on the average, is $\frac{1}{64}$ inch to the inch.

FIG. 23—1. Nomenclature of the parts of a rolling-mill roll and the units that connect it to the motive power driving the mill. The broken lines indicate position of the parts when the roll is raised.

FIG. 23—2. (Above) Set of three-high rolls with diamond passes, showing the seven passes used in roughing down a billet to a round-cornered square section. (Below) Two-high set of rolls with grooves for finish rolling of rounds.

FIG. 23-3. Diagrammatic representation of some common types of roll grooves or passes. The cross-hatched portions are axial sections of the roll bodies. Dotted lines indicate cross section of the piece entering each pass.

FIG. 23—4. This illustration shows the operation of a roll lathe, turning grooves in a shape roll.

The passes in the design are drawn very accurately from the finishing pass to the starting billet, bloom or ingot. Where it is necessary to use a definite size of billet or bloom, the design must be shaped so that the available billet or bloom will be satisfactory.

Plants having primary blooming mills have an advantage in that special sized billets, blooms, or shaped blanks may be made exactly to the size required.

In designing the passes, it is customary to draw each preceding pass, from the finishing pass to the initial pass, over the succeeding one, and the roll designer judges the correctness of the design by this method, drafting the passes in the form which his knowledge and experience has shown to be proper. This part of roll design has been referred to as intuitive ability in design and is a faculty not readily transferred to others.

When the templets have been prepared, drawings are made and roll castings ordered from the drawings. When the castings have been received, the rolls are turned on special lathes to match the drawings and to an exact fit of the templets. As will be learned in Section 2 following, rolls are cast from either iron or steel, with or without alloying elements, depending upon the use to which they are to be put.

Roll lathes are different from the usual machine lathes. They are very rigidly constructed and all tool movements are made by screws and wrenches. Figure 23—4 shows a roll turner at work on a shape roll.

The pass guides usually are designed by the roll department and are a very necessary part of any successful roll design. Many shaped sections are so cut in the rolls that they would have a tendency to wrap around the rolls unless stripped from the pass by guides. Entering and delivery pass guides also serve their purpose in guiding and delivering bars into the proper pass in a straight line. Figure 22—10 illustrated the guide principles.

Elements of Good Roll Design—In the designing of rolls there are many points to be observed if the design is to be satisfactory.

In determining the number of passes, one point to be remembered is that the fewer the passes, the smaller the roll expense. Drafts (amounts of reduction per pass), however, must be suited to roll diameters and plant heating capacity so that roll breakage will be small, and excessive use of power will be avoided.

The passes must be designed with liberal tapers on the various parts so that they may be dressed to templet with the minimum possible reduction in diameter.

A successful design also takes yield into consideration. A minimum of section variation, giving a bar uniform in size from the front to middle and back, insures good yield. Yield is defined as a measure of good product made from a given quantity of starting material.

The tonnage which may be obtained from the rolls also is important. The design which permits the greatest tonnage to be rolled before it is necessary to scrap the rolls because of their reduction in size, due to dressing to eliminate the effects of wear, gives the lowest roll cost.

In roll design, the fact that material being rolled elongates and also spreads in proportion to the draft must be given the most careful consideration, as this is the fundamental principle in rolling, and the proper directing of this elongation and spread is vital to the success of a roll design.

Spread of the various kinds of material must be taken into consideration, as there is a great deal of variation in spread of steels. Roll speeds must be considered in the design. High speeds in many cases restrict spread and low speeds increase it. Low speed permits heavy drafts, while high speed requires lighter drafts.

Temperature of the steel is also a factor. High temperatures permit heavy drafting, while low temperatures call for lighter draft.

Roll diameter also is important. A roll of large diameter is strong and permits heavy drafts without roll breakage, and also, because of the large diameter, the area of contact of roll on bar is large, permitting easy entrance (see Chapter 19). Rolls of small diameter re-

quire less power to drive, reduce spread and increase elongation, but are more easily broken, and heavy reductions cannot be taken readily on them as the area

of contact between the work-piece and roll is small. All these points and many more must be given full consideration in any successful roll design.

SECTION 2

CASTING OF ROLLING-MILL ROLLS

The selection of the proper grade of roll to be used in any of the various stands of the rolling mills is most important. In general, primary mills such as blooming or slabbing mills require a roll in which strength is paramount. Such rolls are subject to tremendous shock and extreme pressures in the rolling of large ingot masses with heavy reductions. The heat from the ingots transmitted to the roll also has a tendency to cause surface or fire cracks through differential expansion of the surface, and the strength and toughness of the rolls must be such as to resist the further development of these cracks. The original plain-carbon steel roll containing 0.30 per cent to 1.50 per cent carbon, used in the past for such applications, now has been supplanted largely by the alloy-steel roll of greater strength and durability.

From the primary mills through the secondary and so on to the finishing mills, the required rolls generally become smaller and harder and any of a variety of roll grades may be used; carbon-steel or alloy-steel rolls for roughing, iron or alloy-steel rolls for intermediate work, and the various grades of iron-base rolls for the finishing stands. Specifically, however, each roll must be custom made to suit the requirements of the individual mill by a procedure within the limits of the manufacturer's equipment. For this reason, no two manufacturers use exactly the same procedure for the same roll and each must apply his own specifications for a given requirement.

Steel-base rolls, as now produced, generally are cast from steel made in acid open-hearth furnaces, while iron-base rolls are usually made from metal melted

in reverberatory-type air furnaces. In some cases, both types of rolls are made of material melted in electric-arc furnaces, either acid or basic. Although the fundamentals for making steel and iron rolls are similar in many respects, important differences exist.

STEEL-BASE ROLLS

In the casting of steel rolls, as indeed in the casting of any shape, the greatest importance must be attached to the control of directional freezing of the molten metal in the mold after casting. To insure soundness in the casting, solidification must occur progressively from the smallest to the largest cross section. Shrinkage occurring in each step of solidification must be compensated for by still-molten metal drawn from adjacent unfrozen regions. Shrinkage of the interior of the largest section, which is last to freeze, is compensated for by a feed-head or sink-head of large volume provided to act as a reservoir for molten metal (see Figure 23-7). To obtain the advantage of gravity feed during this freezing-feeding process, as well as to satisfy mechanical requirements, the feed-head is always placed on top of a roll mold which has been set vertically on end, as shown. The effective cross-sectional pattern thus obtained should approach the shape of an inverted cone. Due, however, to the required design of the roll and the general rule that the drive end is best placed down, this optimum arrangement is often distorted or even inverted. In these cases provision must be made to control the freezing pattern by artificial means. This may be done in several ways, one of which is "padding" or adding extra thickness of metal to

FIG. 23-5. Illustrating use of a sweep in preparing a mold for casting a steel roll. (Courtesy, Pittsburgh Rolls Corporation.)

FIG. 23-6. Assembling the two halves of a mold for a steel roll. (Courtesy, Pittsburgh Rolls Corporation.)

sections which are too small to solidify in the proper manner in relation to the balance of the casting. Increasing the rate of freezing by inserting heavy metal blocks, rings, or segments, called chills, in the mold, close to the surface contacted by the molten metal, is still another means for controlling the freezing pattern. Consideration must be given also to the fact that, in addition to increasing the freezing rate, chilling in the manner described also promotes formation of a dense, refined outer skin of the roll at the contact areas, which

in most cases is very desirable. Although rolls are made with meticulous care in both molding and pouring, particles of the mold sand frequently are entrapped accidentally on the surface and, in order that these or other surface defects will be removed properly during subsequent machining, rolls are cast slightly oversize. The extra stock thus cast on a roll must be of such thickness that, in those instances where heat treatment precedes the other processing, the tough, heat-treated skin will not be removed during subsequent machining.

The initial step in the manufacture of steel rolls is that of examining the blue print of the roll; the composition and heat treatment are determined from the requirements indicated. The pattern is designed after applying the metallurgical and mechanical considerations discussed above. This pattern is generally in the form of a sweep; that is, a flat board carved on one edge to conform to the longitudinal contour of the roll as modified for casting, with provision on the other edge for fastening the sweep securely to a spindle or axle (Figure 23-5). Then the plan of manufacture is given to the operating section.

The steel flasks or containers for roll molds are cylindrical in shape, and designed to separate into two longitudinal halves. Proper molding sand is first rammed into each half, after which the sweep mounted on the spindle is attached to the half flask and rotated, cutting the sand before it to the shape of the sweep contour. The same procedure is used on the second half-mold. Figure 23-5 shows a mold used for casting a large-diameter universal-beam mill roll. After molding, the half-molds are baked in drying ovens at temperatures somewhat above 400° F to drive out moisture and bond the mold thoroughly. Figure 23-6 shows the two halves of a mold being put together. Figure 23-7 shows the vertical section of a mold for an alloy-steel blooming-mill roll in position for pouring. Rolls are bottom poured and the metal enters the bottom neck through a gate tangent to the periphery of the neck. This is to set up a swirling motion of the metal as it enters the mold. This centrifugal action concentrates dirt and foreign particles in the center of the rising molten metal in the roll mold, and as the metal continues to rise, they are carried to the top into the sink-head. The dotted lines seen in Figure 23-7 show the outline

FIG. 23-7. Schematic section of a mold for an alloy-steel blooming-mill roll.

FIG. 23—8. Inserting chilling rings in a mold for a steel roll. (Courtesy, Pittsburgh Rolls Corporation.)

of the finished roll. The excess of metal at the top is either burned off before, or cut off during, the machining operation. The cavity in the sink-head is formed by feeding molten metal in the head to the roll body to compensate for shrinkage during solidification.

Figure 23—8 shows cooling or chilling rings being placed in a roll mold and Figure 23—9 shows the mold being smoothed over and near completion. Figure 23—10 shows some structural-mill rolls having the chills removed. In this type of mold, the chill rings located in the passes play their most important part by imparting a fine-grained structure to those parts of the roll which form the major wearing surface.

After the alloy-steel rolls are taken out of the molds,

by an operation called shaking out, they are ready for heat treatment. An example of this heat treatment is that used for a chromium-molybdenum alloy-steel roll for a blooming mill, containing 0.80 to 0.90 per cent carbon, 0.70 to 0.80 per cent manganese, 0.25 to 0.30 per cent silicon, 1.00 per cent chromium, 0.25 to 0.30 per cent molybdenum, and a maximum each of phosphorus and sulphur of 0.04 per cent. After shakeout, the roll is brought to the heat-treating furnace and placed in the furnace in a manner to allow full access of heat to all parts. It is brought up slowly to 1700° F and allowed to cool in the furnace to 1000° F, and then is reheated to 1550° F. At this point, the roll is removed from the furnace and air-cooled to 1000° F,

FIG. 23—9. Smoothing over the face of one-half of a roll mold, after insertion of chilling rings. (Courtesy, Pittsburgh Rolls Corporation.)

FIG. 23—10. Removing the chilling rings from steel-roll castings after they have been shaken out of the molds. (Courtesy, Pittsburgh Rolls Corporation.)

replaced in the furnace and brought back up to 1250° F, after which it is allowed to cool to 300° F and removed from the furnace. The heat treatment varies with the size and chemical composition of the roll.

After heat treatment, the roll goes to the roll lathe for removal of extra stock on the top neck and thorough testing of the roll body. Any defects which cannot be removed by the rough turning result in rejection and scrapping of the roll.

A special type of alloy-steel roll is the **built-up roll**. These are used for backing-up rolls on four-high plate and strip mills. The solid backing-up roll as used on large four-high mills is a difficult one to cast. The large volume of the casting induces strain during cooling due to the unequal cooling between the roll surface and its center. Due to this unequal cooling, cracks are very apt to occur in the casting. In the built-up roll, the center arbor or mandrel is relatively small in diameter and easier to cast. It also cools more uniformly than a large-diameter solid roll, and is less liable to strain and crack-

ing. The outer shell also is easy to manufacture and, due to its construction, can be heat treated to be much harder than the arbor. Figure 23—11 shows a built-up roll of special construction. In some cases, solid rolls which have been dressed down repeatedly in service are reduced further and fitted with sleeves and returned to service.

Another type of roll is the **forged-steel roll**. This roll is forged from an ingot of suitable size and, after being normalized in a heat-treating furnace, is turned close to the finished size. A hole is then bored longitudinally through the center of the roll to facilitate hardening by quenching after heating to the proper temperature. This type of roll is used mostly for the cold rolling of flat material. One of the favored compositions for a roll of this kind is: carbon, 0.85 per cent, manganese, 0.25 to 0.30 per cent; phosphorus and sulphur, below 0.05 per cent; silicon, 0.25 to 0.30 per cent; chromium, 1.60 to 2.50 per cent; molybdenum, 0.25 per cent; and a trace of vanadium.

FIG. 23—11. Cross-section of a built-up roll.

IRON-BASE ROLLS

The iron-base roll differs from the steel-base roll principally in per cent of carbon, the steel roll containing from 0.30 to 2.50 per cent carbon, whereas iron rolls contain from 2.50 to 3.50 per cent. The material for iron rolls usually is melted in an air furnace using powdered coal as fuel. The flame is less oxidizing than that used in open-hearth operation and there is less loss of elements.

In the manufacture of iron rolls, a wide range of composition is employed to obtain the desired characteristics such as hardness, strength, resistance to spalling, and depth of dense, refined grain structure. Table 23—I summarizes the general range of elements for various types of rolls, and rolling-mill applications.

The normal charge for the melting furnace in the manufacture of iron rolls contains 25 per cent pig iron and 75 per cent worn-out rolls, heads and gate scrap. If lower carbon content is desired, a certain percentage of low-carbon-steel scrap makes up a part of the charge. Alloys, such as nickel, chromium and molybdenum, if required, are also added with the charge.

When the iron is melted and sufficiently hot, two samples are taken, one for chemical analysis and the other for a test block which is cooled and broken. From the chemical analysis and the test coupon, the roll metallurgist determines the necessary additions of alloys for the type of roll being cast. The metal is tapped in a ladle and, when the correct temperature is reached (2425° to 2650° F), poured into previously prepared roll molds. After cooling from one to four days, the rolls are shaken out, heat treated if necessary, and machined to specifications.

FIG. 23—12. Vertical section of mold for casting a plain-bodied roll, or a shape roll in which grooves are machined from the solid (dotted lines).

Chill Rolls—Figure 23—12 shows a roll-mold arrangement for casting a plain-bodied roll, or a shape roll in which the grooves are machined from the solid. The wobblers and necks are cast in sand but the body of the roll is formed by heavy-walled cast-iron cylinders, known as chills. The purpose of these chills is to cool the molten iron quickly after it has been poured into the mold, while the necks and wobblers, being molded in sand, are not subjected to fast cooling. The carbon in molten iron is in solution. If the molten iron is allowed to cool slowly, the carbon in excess of 0.82 per cent separates as graphitic carbon and is distributed throughout the mass. But if iron of the proper composition is cooled rapidly from the liquid state, the carbon combines with the iron to form cementite (Fe_3C), which is very hard and white in color. The depth of case on the body of the roll, induced by the fast cooling of the molten iron in contact with the chill mold, depends upon the chemical composition of the iron (see Chapter 18). As the mold loses its chilling effect, carbon starts to come out of solution to form a mottled area immediately below the hard case. This mottled area consists of a mixture of graphite, cementite and iron. Since the interior of the roll cools slowly, gray iron forms therein. Another factor controlling the depth of chill is the diameter of the roll being cast. As the diameter increases, the chilling rate is retarded due to greater cross-sectional area. On a 30-inch diameter roll, the following composition would give a clear chill about $\frac{3}{4}$ inch in depth, and a mottled area about $\frac{3}{4}$ -inch deep before reaching the portion composed uniformly of gray iron:

Element	Per Cent
Carbon	3.00
Silicon	0.65
Phosphorus	0.40
Manganese	0.25
Sulphur	0.08

To improve the finish of the mill product and reduce spalling and wear, various alloys are added such as: nickel, chromium, molybdenum and vanadium in balanced proportions to control chill depth and roll structure.

Since the case or chill on the rolls is hard and brittle, there is a practical limit to the depth a roll can be chilled without causing failure through breakage. In general, chill specifications will vary between $\frac{1}{2}$ and $1\frac{1}{2}$ inches in depth, depending upon the product to be rolled and the amount of diameter reduction through dressing expected to be permissible before the roll is scrapped.

Grain-Iron Rolls—For certain applications, such as the intermediate stands of some hot-strip, plate, rod and merchant mills, where shock, temperature and extremely heavy loads frequently result in spalling, fire-cracking and breakage, chill rolls are not practical. This applies also to rolls for billet, rail and structural mills, with deep grooves or passes. To meet these requirements, an iron composition commonly referred to as grain iron is used. Sufficient alloys, such as chromium and nickel, are added to control hardness and to increase strength while silicon or other graphitizers are used to resist formation of a definite chill. While these rolls do not give the quality of finish obtained from a true chilled-type roll, they have deeper penetration of the refined structure, with increased strength. The grain-type rolls become softer and the gray iron coarser progressing inward from surface to center, and this less desirable structure is encountered as the deeper

Table 23—I. Types, Compositions and Uses of Iron Rolls

Type	Carbon (%)	Manganese (%)	Silicon (%)	Phosphorus (%)	Sulphur (%)	Chromium (%)	Nickel (%)	Molybdenum (%)	Scleroscope Hardness	Uses
Plain Chill	2.90-3.30	0.20-0.25	0.60-0.70	0.45	0.08	0.25	58-70	Sheet, Merchant, Plate and Rod Mills.
Nickel Chill—Regular	2.90-3.30	0.18-0.25	0.40-0.60	0.35	0.08-0.12	0.25-0.50	2.50-3.00	0.25	65-70	Finishing; Bar, Rod, Skelp and Intermediate Stands of some Strip Mills.

Ductile Iron	3.20-3.40	0.30-0.50	1.50-2.25	0.04-0.15	0.01-0.02	0.75 max.	1.50-2.50	0.25-0.50	40-65	Roughing or Intermediate Stands; Rod, Structural and Bar Mills.

Fig. 23-13. Schematic representation of the vertical section of a mold for casting a composite iron roll.

passes are cut in a roll. To overcome this characteristic, rolls calling for deep working passes are molded similar to steel rolls, as shown in Figures 23-8, 23-9 and 23-10 in Section 1 on steel rolls. The inserted iron rings promote a finer structure and better wearing metal in the passes.

Composite or Overflowed Rolls—High-alloy rolls (1.50 to 2.50 per cent chromium and 4.00 to 5.00 per cent nickel with 75 to 90 Scleroscope hardness) used in cold-reduction mills and finishing stands of some hot-strip mills, would, if cast solid, have hard, unmachinable necks. Casting strains are quite severe in this type of

roll. To overcome these objectionable features, a different method of pouring has been developed as shown in Figure 23-13. The mold is made in the regular manner, except that a spout is connected to the top neck cavity a few inches above the body of the roll. Metal of high-alloy content is poured until the metal reaches the run-off spout. Pouring is stopped and a small amount of metal of a composition that produces much "softer" iron than the first high-alloy metal is poured down the runner to keep the ingate from freezing. After a predetermined time, pouring of the "soft" iron is continued, washing out through the spout connected to the top neck and into a "nugget pot" the still-molten hard roll metal that has not been chilled and solidified by the iron mold which forms the body of the roll. When sufficient "soft" iron has been introduced into the mold to wash out the still-fluid iron in the center of the roll, the pouring is stopped, and a plug inserted in the overflow spout. The same iron used to flush out the molten hard iron from the interior of the roll is introduced into the top neck either by pouring directly down through the neck or through a gate attached to the top neck just above the run-off spout.

A roll poured by this method will have an extremely hard fine-grained structure for a depth of 1 to 2 inches. The necks will be machinable and the central part of the roll will be strong, the hard brittle iron having been replaced or diluted by the soft "flush iron."

Ductile-Iron Rolls—With the recent development of "ductile" or "nodular" cast iron, some manufacturers have produced rolls of this material which is made by the addition of magnesium or rare earth compounds to iron of restricted analysis.

The remarkable strength and toughness of this iron results from the nodular shape of the free graphite in the structure as contrasted with the flake graphite common to gray iron. This iron, if properly made and heat treated, develops properties which approach the strength and ductility of steel.

Chapter 24

MILL DRIVES AND POWER REQUIREMENTS

SECTION 1

INTERRELATION BETWEEN ELECTRIC-POWER SUPPLY AND THE DEVELOPMENT OF MAIN MILL DRIVES

During the first part of the nineteenth century, rolling mills were driven by water wheels and low-pressure steam engines. The power was transmitted to the mills by direct mechanical connection, through suitable shafts, gears and couplings. Because of the low steam pressures used, short steam lines were necessary. As a result, many small boiler houses were built adjacent to the mills. Most of the engines were of the simple non-condensing type and this factor, together with the small, hand-fired boilers used, resulted in high-cost operation. Coal had to be delivered to the boiler houses, ashes disposed of, and steam lines maintained. In some plants, compound condensing engines were used, requiring a supply of cooling water and a sewer system. When the mills were shut down over the weekend, the steam lines had to be kept hot, as the contraction set up by cooling the line resulted in leaks at the joints. Nearly all of these early mills have been replaced, during the last twenty years, with modern electrically-driven mills that, while fewer in number than the mills they replaced, have a much greater combined capacity.

With the development of the electric generator and motor in the latter part of the nineteenth century, a new and more efficient method of driving rolling mills became available. Instead of direct mechanical connection of the mills with the power source, generators could be placed in a convenient central location, and electric power could be transmitted over wires to motors attached to the mills. The generators could be driven either by gas engines, steam engines, or steam turbines.

Shortly after 1890, internal combustion engines were developed to operate on blast-furnace gas. This by-product fuel was available at all blast-furnace installations and at this period either was used for making steam or was wasted. The gas engine could use this fuel direct and thus eliminate the investment for a boiler house required for a steam engine. These gas engines were used as the prime movers for blast-furnace-blowing equipment and also for driving electric-power generators. This type of drive was selected for both the blowing units and the generators at the Gary Steel Works when this plant was designed in 1908. At that time, gas-engine-driven generators were available in sizes having outputs up to 2000 kw, and fifteen such units were installed. A few years later, the size was increased to 3000 kw, which equalled the largest generator driven by a reciprocating steam engine at that time. The gas-engine-driven generator installation at Gary was the first sizeable steel-mill power house in the United States, and made possible the use of 6000-horsepower motors to drive the mills. At a later date, the maximum size of the gas-engine-driven generators was increased to 6000 kw and three units of this

size were installed in the South Works, Chicago, Illinois.

While the development of the gas engine was progressing, another prime mover had entered the field—the steam turbine. Both the steam engine and the gas engine were slow-speed machines and, when used to drive electric generators, the speed limitation resulted in a physical limitation of the generators. The 5000-kw generators, which were about the largest built, had a diameter of over 30 feet. On the other hand, the steam turbine is inherently a high-speed machine and the early generators of 5000-kw capacity that were driven by steam turbines required only a fraction of the space needed by other types of units.

Developments in boiler practice whereby steam pressures could be increased to 250 pounds at first, then 500 pounds and then, by 1948, over 2000 pounds per square inch, all favored development of turbine designs and the size of turbine units increased until 275,000-kw generators now are available. While these developments

FIG. 24—1. Relationship between growth of electric-power generating capacity and installation of main mill drives (1904-1954). Note difference in vertical scale used in plotting the curves.

in electric-power-producing facilities were taking place, iron-silicon alloy steel in sheet form for transformer cores was being developed and improved and better insulating materials developed, with the result that larger quantities of electric power could be produced and, further, it could be transmitted economically over greater distances to the motors that used it.

Such improvements in both the generation and distribution of power were required before electrification of mills became possible. Figure 24—1 shows the relation between the growth of electric-power generation and the installation of main-drive motors in steel mills. The installed generating capacities were obtained from Edison Electric Institute statistics and show a growth from 160,000 kw in 1905 to 102,000,000 kw in 1954. The main drive figures were taken from the Proceedings of the Association of Iron and Steel Engineers, and show a growth from zero in 1905 to 6,700,000 horsepower in 1954.

Many steel plants, especially the smaller ones, are not self-contained in that they have no coke plant or blast furnaces. Such plants buy their electric-power supply from the power companies and, since they may impose large loads such as strip mills create, the power producer has the problem of providing sufficient gen-

erating and distribution capacity to serve such loads.

If a map showing the electric transmission lines in the United States is studied, it will be found that the various utility generating sources are interconnected by high-voltage lines to provide a pooled power supply. These interconnecting systems have many advantages, and are favorable to steel mills in that heavy peak loads caused by electric furnaces or strip mills do not necessarily have to be absorbed by a single generating station but, usually, are distributed among many units that are connected to the system. The growth of these interconnecting systems has followed the growth of electric-power consumption and today, with forecasted arrangements, it is possible to purchase power for all types of steel-mill electric loads.

The growth in generating capacity plus the interconnecting systems have made possible the large motor-driven installations in modern mills. Prior to about 1930, it often was a problem to obtain 6000 kw to drive a proposed blooming-mill reversing motor. Today, purchased-power contracts often cover the supply of power for loads of 100,000 kw, and additions to the supply are limited only by the time required to install additional generating capacity.

SECTION 2

DEVELOPMENT OF MAIN MILL DRIVES

In 1905, two 1500-horsepower, 230-volt, 100/125 r.p.m., direct-current motors were installed on the light-rail mill at the Edgar Thomson Works in Braddock, Pa. They were supplied with power from two 1000-kw, steam-engine-driven, direct-current generators in a nearby power house. In the same year, the first reversing direct-current main-drive motor was installed on the 36-inch universal-plate mill at South Works in Chicago. Power for this latter motor was furnished at 575 volts, direct current, from a 2200-volt, 25-cycle, motor-generator set. Both of these installations were, with some modification, still in operation in 1954.

At about the same time, another type of main drive, suggested by European developments, was installed on the light-rail mill at the South Works. This consisted of two 1500-horsepower, 2200-volt, 25-cycle, 80/120 r.p.m., variable-speed, wound-rotor motors. The rotor windings of these motors were connected to the stator of a second wound-rotor motor on the same shaft; this is known as a cascade connection. By varying the resistance in the rotor circuit of this second motor, the speed of the main drive could be varied between 80 and 120 r.p.m.

About the same time (1908-1910), the Gary Works, designed to be the largest steel plant in the world, planned to use slow-speed, wound-rotor induction motors on the heavy rolling mill drives. Some of these had windings that, by external contactors, could be connected to change the number of poles and thus provide what is known as a two-speed motor. Other

than this, the main drive installations were designed to operate at constant speed, except for the variations that could be obtained by changing the resistance in the secondary circuits of the wound-rotor motors.

This type of drive was satisfactory for some types of mills but, for the merchant mills in particular, greater ranges of speed variation were needed and this led to the development of variable-speed controls. With these systems, speed variations up to 50 per cent were made possible.

The demand for wider speed ranges, better regulation and a more simplified control led to the development of large, variable-speed, direct-current motors, which are now the preferred drives on practically all new installations.

While these developments were progressing, another problem confronted the steel industry—the alternating frequency of the power systems. In the period 1905-1910, practically all steel companies generated their own power and were not interconnected with utility systems. Slow-speed, direct-connected drives were needed, since high-efficiency gears such as now used were not available. For this purpose, 25-cycle motors offered an advantage and were adopted in the mills and, as late as 1910, all main drive motors in the steel industry had a 25-cycle source of power. Today, while there are many 25-cycle drives representing many thousands of horsepower still operating, new installations using 25-cycle power are very few and 60 cycles have become the standard frequency of the industry.

SECTION 3

POWER REQUIREMENTS IN THE STEEL INDUSTRY

According to a report of the American Iron and Steel Institute, the iron and steel industry used 40.7 billion kwh of electric power in 1953. Of this amount, about one quarter was generated in power houses in the industry and the remainder was purchased from utili-

ties. With an ingot production of 111,600,000 tons, the average power consumption per ton of ingots in 1953 was 364.8 kwh.

Power Requirements for Various Operations in the Production of Steel—When new mills are contemplated

in existing works or new plants planned, one of the questions to be answered is the quantity of electric power required to operate the new facilities.

Data on existing mills are the best source for this information. Actual power consumption by certain operations such as coke plants, blast furnaces and open hearths are found to be in accord with estimates based on established data from pre-existing similar units. Requirements of heavy mills such as blooming, slab and rail mills also can be estimated closely if the predicted output of product in tons per hour is matched by actual production. Finishing mills, however, require additional data as to the sections to be rolled and the pass design of the rolls.

In the total demand load of a plant, there are two loads that have the greatest effect on power peaks: those from the electric melting furnaces and the wide-strip mills. There are available data for power requirements of both of these operations, and the total power required for new installations has to be estimated by using these data in conjunction with proposed operating schedules.

The following tabulation gives the average kwh consumption per ton of steel for some of the major operating units in a modern plant.

Operating Unit	Kwh Consumed per Ton of Product
Coke Plant	17, based on coal charged
Blast Furnaces	10, based on pig iron
Open Hearth	8, based on ingots
Bessemer (with motor-driven blowing equipment)	92, based on ingots
Blooming Mill	13-15, based on blooms
Slabbing Mill	10-12, based on slabs
Plate Mill (Reversing) ..	30-40, based on plates
Merchant Mills	40-80, based on product
Wide Strip Mills	45-65, based on product

The preceding tabulation for mills covers the power used by the main drive motors, and does not include that used for auxiliaries such as tables, fans, lighting, and so on. On some mills, this auxiliary power amounts to as much per ton as the power used by the main drive.

The following tabulation indicates how power requirements are increased as the finishing operations are continued. These figures are averages taken from the records of a modern strip mill whose end products are tin plate and sheets:

Facility	Kwh per Ton
80-Inch Mill (including all auxiliaries) ..	63.0
Continuous Pickling	6.3
5-Stand Cold-Reduction Mill (including auxiliaries)	86.0-100.0
Electrolytic Cleaning	8.8

Tin Mill Annealing	20.0
Tin Mill Temper Rolling	18.0
Electrolytic Tinning	100.0
Hot-Dip Tinning	38.0
3-Stand Tandem Mill	35.0
Sheet-Mill Galvanizing	30.0

In addition to the above operations, such a plant has pumps, shops, air compressors, yard lighting and other miscellaneous loads that increase the total power consumption.

Estimation of the total electric-power requirements for a steel plant with the predicted fifteen-minute demand is part of a study required to get a fuel balance for new installations. (The predicted fifteen-minute demand is an estimated figure representing the highest possible peak load expected ever to be encountered for an arbitrarily-selected period of 15 minutes duration.) It is also necessary before arriving at an estimated amount to be used in negotiating purchased-power contracts. The tabulation following is an example of the estimation of the annual kwh requirements for an integrated plant planned to produce 1,500,000 tons of open-hearth ingots per year.

Mill or Department	Annual Production (Tons)	Kwh/Ton of Product	Total Kwh Per Year
Coke Plant	826,000	17	14,042,000
Blast Furnaces	1,000,000	10	10,000,000
Open Hearth	1,500,000	8	12,000,000
Blooming Mill*	1,235,000	26	32,110,000
Billet Mill*	458,000	28	12,824,000
Wheel Mill*	34,000	110	3,740,000
12-Inch Bar Mill*	221,000	65	14,365,000
16-Inch Bar Mill*	200,000	55	11,000,000
Structural and Rail Mill*	353,000	60	21,180,000
Plate Mill*	244,000	87	21,288,000
Splice Bar and Mine Tie. Miscellaneous (Pumps, Air Compressors, Lighting, Etc.; due load 7000 kw x 8760 hours)	37,000	70	2,590,000
Total			216,399,000

*Including auxiliaries.

The above represents an average consumption of 18,000,000 kwh per month or, in a 720-hour month, of 25,000 kw per hour. In this example, however, it is not the average power consumption in any hour but the peak hour that has to be determined, as this latter quantity determines the size of the generators required if a power house is to be built, or the peak demand that will be made on the utility system if power is to be purchased.

SECTION 4

FACTORS WHICH AFFECT THE SIZE AND TYPE OF MAIN-DRIVE MOTORS

The selection of the proper motor to be used on mill drives is a very important item in the design of a mill. Its size and characteristics must be based not only on tonnage requirements and rolling schedules, but also on displacement, reductions, temperatures, composition of product, speed of rolling, and finish. The accepted methods for calculating loads when rolling a product at

a specific speed and definite temperature, with specified reductions per pass, are based on data taken from tests on existing mills.

The most common main-drive motor is that used on reversing primary mills. For these drives, the size and shape of the ingot are known, also the size of the finished bloom or slab, the composition and temperature of the

FIG. 24-2. Curves showing amount of work for displacement of one cubic inch of metal including all increases in friction during the pass in a single-motor-driven reversing blooming mill. (13, 34)

steel, the roll size, and the efficiency of the machinery. It has been determined from existing reversing primary-mill units that the total power required is divided approximately into the following components:

Power Required for Rolling	59.00%
Friction of Pinions and Mill	5.90
Loss in Reversing Motor	10.84
Loss in Electrical Connections	0.75
Loss in Generators	11.44
Loss in Flywheel	1.32
Loss in Slip Regulator	2.69
Loss in Induction Motor	6.40
Loss in Exciters, Blowers, Etc.....	1.66

Total 100.00%

The part of the total torque required of the motor shaft of a single-motor drive for a reversing blooming mill that is used in (1) deforming the metal being rolled; (2) overcoming the increase in roll-neck bearing friction during rolling; and (3) other mechanical losses, may be approximated from the following formula (see References 13 and 34 on Page 462):

$$(1) \quad T = 275 \times C (A_1 - A_2) \times D \frac{A_2}{A_1}$$

where T = Motor torque in pounds-feet
 C = Factor for cubic inches of metal displaced (ordinate of Figure 24-2).
 A_1 = Area of section in square inches before pass
 A_2 = Area of section in square inches after pass
 D = Diameter of roll at base of pass in inches.

From this formula, which applies only to the type of mill mentioned, the rolling schedule can be calculated pass by pass, and to the figures so obtained must be added the idling friction torque for the mill which may amount to 20,000 to 25,000 pounds-feet.

To obtain the maximum torque requirements for the motor, it is necessary to add the torque required for acceleration. The inertia of the mill parts and the armature for a 7000-horsepower motor is about 4,250,000 lb.-ft.². If the rate of acceleration is 20 r.p.m. per second, and the time required for acceleration is 2 seconds, then from the formula:

FIG. 24-3. Effect of temperature of steel on resistance to deformation. (After Trinks.)

FIG. 24-4. Effect of temperature on power consumption during rolling steels containing 15 and 30 points (0.15 and 0.30%, respectively) of carbon. (Courtesy, Iron and Steel Engineer.)

$$(2) \quad T_a = \frac{0.003255 \times WR^2 \times \text{r.p.m.}}{t}$$

where

T_a = Torque required for acceleration (pounds-feet)

t = Time required for acceleration (seconds)

WR^2 = Inertia of moving parts,

$$T_a = \frac{0.003255 \times 4,250,000 \times 20}{2} = 138,000 \text{ pounds-feet}$$

Another factor to be considered is selection of a motor of ample capacity to prevent excessive heating of the motor during operation.⁽¹³⁾

Figure 24-3 shows a group of curves for five different steels in which the resistance to deformation is plotted against temperature of the steel in degrees F. Figure 24-4 shows similar curves for two grades of carbon steel, where rolling temperatures are plotted in relation to power consumption. From these curves it may be seen that a drop in temperature from 2300° F to 1750° F will double the power requirements for rolling. This indicates the necessity for considering steel temperature when calculations of power for rolling are being made.

Another factor to be considered is the number of horsepower-seconds required per cubic inch of metal displaced during the various passes. Temperature again

FIG. 24-5. Curves showing relation of horsepower-hours per net ton of steel rolled to per cent reduction of cross-section for shapes and flat sections.

must be considered in this case as the bloom or slab cools off during the rolling operation. Figure 24-2 shows curves giving the specific power for motor torque for displacement of metal plus all increases in friction during the pass. From these curves, it will be noted that as the bloom becomes smaller the horsepower-seconds increase rapidly, especially after 25 per cent of the original area is reached. The constant "C" used in formula (1) was taken from this chart.

Another form of these power curves is shown in Figure 24-5. These curves, for flat and structural sections, show that power requirements do not increase in direct proportion to per cent reductions, and that the smaller the section the larger the increase in power in terms of reduction.

The speed at which the piece is rolled affects the

power requirements in two ways. Theoretically, the power requirements should be directly in proportion to speed; however, with increase in speed the temperature of the piece being rolled has less time in which to drop; therefore, the higher the rolling speed, the higher the finishing temperature and, consequently, the lower the power required by the mill. For this reason, it is sometimes possible to increase the speed and not increase the motor loading to any great extent.

In order to meet the surface-quality requirements on certain products, it is necessary to roll them in the finishing pass at relatively low temperatures—sometimes as low as 1400° F. On mills where this practice is to be used, the horsepower requirements for the motor should be determined on the basis of the reduction and temperature required for such sections.

SECTION 5

TYPES OF MOTORS FOR MAIN DRIVES

There are four general classifications of motors that can be used on mill drives: synchronous, squirrel-cage, wound-rotor, and direct-current. All but the last-named operate on alternating current. Each of these has characteristics which make it suitable for definite applications. The cost of each type also differs and is often the factor determining the type to be used.

The synchronous motor, if an exciter is not required, usually costs the least and, in certain speed ranges, may be used interchangeably with the squirrel-cage design. Wound-rotor motors cost more than either the synchronous or squirrel-cage, and direct-current motors are the most expensive of all. With the latter, a supply of direct current is needed, which necessitates the use of a motor-generator set or mercury-arc rectifier to convert the alternating-current power supply of the plant to direct current, and these have to be considered as a part of the installation.

In the following paragraphs, short descriptions of the four general classifications of motors are given, along with suggestions for possible applications. It is assumed that the reader is familiar with the general design of such units; if not, details of their design and construction are available in the literature.

Synchronous Motors—The synchronous motor has the stator or stationary part wound with core and coils in the same manner as the squirrel-cage and wound-rotor motors. However, the rotating part or rotor has salient poles, positive and negative, wound for direct current. The power supply for these poles usually is furnished by a small direct-current generator called the exciter. This may be mounted on the main motor shaft, be belt driven by same, or be driven by a separate motor in a motor-generator set. In addition to the direct-current coils on the pole pieces, another winding which is buried in the pole faces is required. This is called the squirrel-cage winding and controls the necessary starting and pull-in torques of the motor and also the uniformity of the accelerating torques between starting and pull-in. When driving reciprocating machinery, the squirrel-cage winding also develops a damping torque.

This winding consists of a number of round or rectangular rods or bars that pass through the pole shoes in the axial direction. The material used may be copper, brass, or bronze, of such electrical conductivity as to suit best the particular requirements of starting and pull-in torques. The ends of these rods or bars project sufficiently beyond the poles to allow making connections to the short-circuiting end-ring segments to which

they are joined securely by brazing. In some cases, where both high starting torque and high pull-in torque are required, it is necessary to use double cage windings. These consist usually of two sets of damper bars but only one set of end connections.

To conduct the direct current to the field coils, collector rings mounted on the main shaft are required, the terminals for the field circuit being connected to these rings and the direct-current power supply from the exciter is connected to the brushes that contact the rings.

In order to apply a synchronous motor correctly, it is necessary to give consideration to the starting torque, pull-in torque, pull-out torque, operating temperature, power factor and method of starting.

The time required for a synchronous motor to attain full speed depends upon the load, and the power required to pull into step from this speed depends upon the inertia of the revolving parts, so that the pull-in torque cannot be determined without knowing the inertia of the external load as well as the torque required to overcome it.

The permissible starting-power input will vary with different localities, being affected by local power company regulations, capacity of feeders, or the capacities of individual, isolated power stations.

These motors can be designed with considerable range of starting, pull-in and pull-out torques. Some applications require a starting torque of 150 to 200 per cent, a pull-in torque of 110 per cent, and a pull-out torque of 175 per cent.

The efficiency of a synchronous motor usually is higher than that of a comparable induction motor, is less expensive in first cost, and has the ability to correct power factor. They have been built in sizes up to 10,000 horsepower for mill drives. It must be remembered that they are a constant-speed motor and are locked in step with the frequency of the power system. For this reason, there is no cushion afforded by a drop in speed for a sudden peak load, and the pull-out torque must be high enough to handle the highest peak load encountered. Synchronous motors often are used to drive motor-generator sets, air compressors, pumps and other types of equipment where constant load conditions exist.

Squirrel-Cage Motors—Squirrel-cage induction motors are the most simple with respect to design, and can be built in a wide range of sizes and torques. By varying the design resistance in the rotor winding, the

Table 24-I. Main Drive Motors Installed 1939-1954.

Year Installed	Alternating-Current Motors		Direct-Current Motors	
	Number Installed	Total Horsepower	Number Installed	Total Horsepower
1939	9	18,900	54	81,500
1940	13	6,850	72	112,000
1941	31	39,350	93	101,100
1942	14	20,000	97	263,650

starting torque can be low, normal, or high, as desired. It has become customary to start these motors "across the line" in the usual sizes, which necessitates strong bracing for the stator coils to withstand the powerful magnetic forces involved.

In the larger sizes, these motors have been designed for use in certain speed ranges in capacities up to 10,000 horsepower, and for speeds as low as 100 r.p.m., operating on 60-cycle power.

This motor has the lowest initial cost per installation, but its efficiency is less than that of the synchronous induction motor, and at the lower speeds the power factor is lowered. For instance, a 500-horsepower, 60-cycle, squirrel-cage motor has the following efficiencies and power factors at 900 compared with 514 r.p.m.:

R.p.m.	Efficiency (%)		
	½ Load	¾ Load	Full Load
	900 514	91.1 91.3	92.9 92.3
	Power Factor		
	½ Load	¾ Load	Full Load
	900 514	82.0 75.0	88.0 83.0
	½ Load	¾ Load	Full Load
	900 514	82.0 75.0	88.0 83.0

This type of motor is used on fans, pumps, compressors and shears, to name a few common applications, but is not used normally on main drives.

Wound-Rotor Induction Motors—This type of induction motor has a wide range of use in the steel industry. The difference between it and the squirrel-cage type is that the rotor winding consists of coils with the phase connections brought out to collecting rings mounted on the motor shaft. Connections can be made from these rings through external resistance boxes or a slip regulator; hence, the secondary resistance can be varied. By this means, the starting-power input and accelerating time can be controlled and, if the motor is used in connection with a flywheel, various divisions of the load between the motor and the wheel can be obtained.

These motors are available over the complete output and speed ranges required for mill drives, for operation on voltages up to 13,200. As in the case of squirrel-cage

motors, the efficiency and power factor decrease with the base speeds.

Wound-rotor induction motors are standard for flywheel-equipped motor-generator sets, and usually have been designed for a speed of 360 r.p.m. in medium sizes and 300 r.p.m. for the largest sets. However, several recent installations have been designed for 514 r.p.m. One such unit consists of an 8000-hp motor with a 65-ton, 215,000 hp-sec. flywheel, driving four 2500-kw and two 1750-kw direct-current generators.

Direct-Current Motors—Due to the demand for wide speed ranges for mill drives, many large direct-current motors are being used for this purpose. They are designed with flat speed characteristics, to operate usually on 600 volts. The largest size, about 8000 horsepower, has been used on reversing mills. These motors require forced ventilation due to the heat generated by operating conditions involving frequent reversals. The normal speed range is 2:1, but higher ranges can be obtained. On mill drives, it is not uncommon to have a maximum torque of 240 per cent of the full-load torque.

The trend toward the use of variable-speed direct-current motors on main drives began in the 1930's. The operating advantages of this type of drive overbalanced the added cost. Table 24—I, taken from the Proceedings of the Association of Iron and Steel Engi-

neers, shows this trend in motors (over 300 horsepower) installed on main drives from 1939-1954.

Table 24—II shows the trend from 25-cycle to 60-cycle motors.

The speeds of synchronous and induction motors are a function of the number of poles in the motor windings. These speeds are determined by the formula:

$$N = \frac{60 \times F}{\frac{1}{2} P}$$

where,

N = Speed (r.p.m.)

F = Frequency

P = Number of poles

Table 24 -III shows the possible speeds that can be obtained in both 25-cycle and 60-cycle motors. These are synchronous speeds and apply to synchronous motors. For induction motors, the full-load speeds are a few per cent less due to slip.

Although it is possible to build motors with more than 40 poles, they become very expensive, and the above table shows how it was advantageous to build the slow-speed, 25-cycle motors used in some of the early mills and why it would have been necessary to use gear sets if 60-cycle frequency had been specified.

SECTION 6

FLYWHEELS—HOW THEY WORK AND WHERE THEY ARE USED

Many main-drive applications are on mills that have short-time peak rolling loads. Blooming mills, slabbing mills, and reversing plate mills are in this classification. For such mills, it is often economical to use a wound-rotor induction motor having an adjustable secondary resistance in conjunction with a flywheel, to drive the generators that supply direct current to the main mill motors that are subject to peak loads. By this means, it is possible to select a motor having a capacity $\frac{1}{4}$ to $\frac{1}{2}$ of the value of the maximum load requirements of the mill, and so control its "slip" that the flywheel energy supplies the greater proportion of the energy to meet the peak loads. Some typical questions related to motors and flywheels of mill drives, and the methods of finding their answers, are given in the following examples.

1. Energy Stored in a Flywheel—Assume a large flywheel having a momentum (WR^2) = 15,000,000 lb.-ft.² (that is, an effect of 15,000,000 lb. at a radius of gyration of 1 ft., or 3,750,000 lb. at a radius of 2 ft.), and a wheel speed of 83 r.p.m. What is the total amount of energy stored in the wheel?

The energy (E) possessed by any body of weight W lb. moving with a velocity of V ft. per second is:

$$(1) E = \frac{W \times V^2}{32.16 \times 2} \text{ ft.-lb.}$$

In this expression, 32.16 ft. per second per second is the rate of acceleration due to gravity, usually expressed by the symbol, g. The rotating flywheel with a given WR^2 and running at N r.p.m. may be considered as a body with weight W moving with the same velocity as the end of its radius of gyration R; this velocity in feet per second for the case under consideration is:

$$(2) V = \frac{2 \times 3.1416 \times R \times N}{60}$$

Substituting this value of V in (1), it becomes:

$$(3) E = \frac{WR^2 \times N^2}{5865} \text{ ft.-lb.}$$

Then, for the present example,

$$(4) E = \frac{15,000,000 \times (83)^2}{5865} = 17,500,000 \text{ ft.-lb.}$$

This energy is equal to the amount of work required to bring the flywheel from rest to a speed of 83 r.p.m.

Since 1 horsepower-second = 550 ft.-lb.

E = 31,900 horsepower-seconds.

From the foregoing formulas, it may be seen that the stored energy in a flywheel is proportional to the WR^2 of the wheel and to the second power of its speed.

2. Amount of Energy Available for Regulation—The energy calculated above is the total energy stored in the wheel at a certain speed. How much of this energy may be used for load equalization in case this flywheel is installed on a mill drive?

If it is assumed that a speed variation of more than 15 per cent is not permissible, the wheel speed could be varied from 83 r.p.m. to 70.5 r.p.m. At 70.5 r.p.m., the stored energy in the wheel would be:

$$E_2 = \frac{15,000,000 \times (70.5)^2}{3,230,000} = 22,950 \text{ horsepower-seconds.}$$

Thus, the energy given up by the wheel in slowing down from 83 to 70.5 r.p.m. would be:

31,900 — 22,950 = 8,950 horsepower-seconds, or approximately 28 per cent of the total stored energy.

From this it is evident that the per cent of energy given up by the wheel is not directly proportional to the per cent of speed reduction.

Suppose the speed of the flywheel is lowered from N_1 to N_2 r.p.m. The speed reduction (S) expressed as a fraction of the maximum operating speed (N_1) is:

$$S = \frac{N_1 - N_2}{N_1}$$

or, the minimum speed is:

$$N_2 = N_1 \times (1 - S)$$

Now, the total amount of energy stored in the wheel at speeds N_1 and N_2 , respectively, are:

$$E_1 = \frac{WR^2 \times N_1^2}{3,226,000} \text{ horsepower-seconds}$$

$$E_2 = \frac{WR^2 \times N_2^2}{2,226,000} \text{ horsepower-seconds}$$

Hence, the energy given out comprises the following portion of the total:

$$\frac{E_1 - E_2}{E_1} = \frac{N_1^2 - N_2^2}{N_1^2} = \frac{N_1 - N_2}{N_1} \times \frac{N_1 + N_2}{N_1}$$

$$\frac{E_1 - E_2}{E_1} = S \times \left[\frac{N_1 + N_1(1 - S)}{N_1} \right]$$

$$= S \times (2 - S) = 2S - S^2$$

Giving S various values from 0 to 100 per cent, the corresponding values of energy given up by the wheel in slowing down may be calculated. For instance, if the speed reduction is 12 per cent ($S = 0.12$), the flywheel will give up 22.5 per cent of the total energy available at the maximum speed. Further calculations would show that at 50 per cent speed reduction, 75 per cent of the total energy is given up by the wheel.

3. Acceleration and Retardation of the Wheel—Assume that the wheel should be accelerated at a uniform rate from N_2 r.p.m. to N_1 r.p.m. in t seconds; then, the rate of acceleration (a) would be:

$$a = \frac{N_1 - N_2}{t}$$

If the inertia of the wheel is WR^2 lb.-ft.², then there will be required during this period a uniform accelerating torque (T_0), equal to:

$$T_0 = \frac{WR^2 \times a}{308} \text{ ft.-lb.}$$

For instance, if the same wheel as was considered above ($WR^2 = 15,000,000$ lb.-ft.²) is to be brought from rest ($N_2 = 0$) to $N_1 = 83$ r.p.m. in 10 seconds, then the required torque, T_0 , equals:

$$T_0 = \frac{15,000,000}{308} \times \frac{83}{10} = 405,000 \text{ ft.-lb.}$$

If the flywheel is brought up to this speed by an 83-r.p.m. motor, the latter will have to develop during the acceleration a torque (in addition to frictional torque) which corresponds to a load of:

$$\frac{405,000 \times 83}{5250} = 6440 \text{ horsepower}$$

4. Induction-Motor Characteristics—The majority of all mills equipped with flywheels are driven by induction motors. Within the operating range, the speed-torque or the slip-torque curves for these motors are very nearly straight lines. This is the basis for the assumption that the motor torque is proportional to the slip. If the secondary resistance of the motor is changed, the slope of the speed-torque curve is changed, but the breaking-down torque for the motor is not affected.

The torque developed at the motor shaft is proportional to the speed, and the difference in power between the input power and this torque goes into losses in the rotor windings, the core, and external secondary resistance.

The total power, P , can be expressed as:

$$P = \frac{T \times N_s}{5250}$$

where N_s is the synchronous speed and T the torque.

Starting from rest and drawing normal current from the line, the motor at first does not develop any power at the shaft because the speed is zero, but the secondary losses are high. With increasing speed, the losses are reduced and the mechanical power increases.

If the motor is running and more resistance is introduced in the secondary, maintaining constant line input, it will be observed that the speed, N , and the mechanical shaft power, P , both decrease in the same proportion, which means that the torque, T , is not changed.

This is an important conclusion, since it shows that when an induction motor drives a mill without any flywheel, and is called upon to develop a certain torque, nothing is gained by increasing the secondary resistance as long as the torque requirements are the same.

FIG. 24-6. Effect of flywheel energy on load and speed, showing division of load between motor and flywheel. Each horizontal division equals 1 sec. (Courtesy, Iron and Steel Engineer.)

5. Motor Load Curves—Assume a mill with a flywheel being driven by an induction motor of P horsepower, at a speed of N_s r.p.m. (synchronous speed). The mill is running light and the motor is developing only frictional torque, T_0 . Then the metal enters the rolls, and this imposes a combined torque, T_1 . The torque developed by the motor will increase gradually along some curve (Figure 24-6). What will the motor torque be after " t " seconds?

According to an expression called Gasche's formula:

$$T = T_1 - \frac{T_1 - T_0}{e^{At}}$$

where

T = motor torque to be determined

T_1 = combined (external) torque

T_0 = frictional torque

e = 2.718, the base for Napierian or natural logarithms

A = a constant for a given motor and flywheel (provided the secondary resistance is constant), and

equals $\frac{308 T_s}{WR^2 N_s S_n}$, in which latter expression:

T_s = normal torque

S_n = normal slip

N_s = normal speed

W = weight of the flywheel, and

R = radius of gyration of the wheel.

Figure 24-6 shows curves of the division of load between a motor and flywheel, calculated according to the

Electronic Control Elements are used in steel-mill regulating systems when the characteristics of the application are favorable to this type of control. Electronic control is used where great accuracy and speed of response are needed. It is also used when the input signal from the drive must be controlled from a very low power level. On very small drives, electronic equipment may be considerably less expensive, and sometimes there is no other way to solve the problem. In several recent installations, electronic control has been used as an addition to rotating-regulator or magnetic-amplifier equipment. A recent development in electronic controls is the transistor, a tiny simple device that employs the unique electrical properties of germanium crystals for rectifying and controlling the flow of current and that promises someday to replace the electron tube.

Rotating regulators have a broad field of application. The main and auxiliary drives of blooming mills are good examples of applications requiring a large number of rotating regulators. They are used at the Fairless Works, for example, for regulating the drives for the skin-pass or temper mill, a cleaning line, the finishing stands of the hot-strip mill, the main drive and auxiliaries for the 45-inch slabbing mill, and the main drive for the 40-inch blooming mill. On the main drive of a

blooming mill, rotating regulators are used to regulate and reverse the generator voltage, force fast response of the motor fields, limit the main armature currents to predetermined values, and for load-balance control where two or more armatures are operated in parallel.⁽²⁰⁾

The magnetic-amplifier regulating systems show promise of being applied in considerable numbers in the steel industry. Operating experience is somewhat limited since this type of control has begun to be applied only relatively recently. It has been used for controlling tandem cold-reduction mills, reel drives for cold-reduction mills, speed control for high-speed side-trimming line tension reels, speed regulation for the bridle rolls on cleaning lines, tension-reel drives for processing lines, tensiometer-type tension regulators for skin-pass or temper mills and as a voltage regulator for ignition rectifiers.⁽²⁰⁾

Electronic regulators have been used for applications where the regulator has to "see," such as edge control for slitting and cleaning lines, and where very precise and fast-acting regulator components are required, such as rod-mill drop regulators and electric flying-shear regulators. To obtain the required speed regulation, such as required on tube and rod mills, combination electronic-rotating regulating equipment has been used.

SECTION 8

REVERSING-MILL DRIVES

On motor-driven primary mills, such as slabbing, blooming, or single-stand plate mills, it is customary to use a reversing mill drive. About 135 mills of this type are in operation in the United States as this is written, and about 30 per cent of them still are driven by steam engines. These latter are the older mills which retain their engines for economic reasons. Since the installation of the first motor-driven reversing mill in 1915, very few engine drives have been installed and, today, only

motor drives are given consideration. Electric-motor and steam-engine drives for primary mills are compared in some detail in Chapter 25.

For modern reversing-mill service, the main-drive DC motor is of rugged design, with a welded frame of rolled steel, horizontally split. The pedestal for the bearing next to the mill is cast steel and is provided with a thrust bearing. These motors, being connected directly to the mill pinion stand, necessarily must be of slow

FIG. 24-8. Twin-motor drive for a 44-inch slabbing mill (Edgar Thomson Works) consisting of two 5000-horsepower, 40/80 r.p.m., direct-current motors.

speed. One of the normal speed ratings is 0/40/80, which represents speed control from zero to 40 r.p.m., which is the constant-torque range, on voltage control, and from 40 to 80 r.p.m., which is the constant-horsepower range, on field control.

One of the original design problems on these motors was commutation and, in sizes above 4000 horsepower, they were built with two armatures on a single shaft. In recent years, however, the designs have been developed so that an 8000-horsepower, 0/50/100 motor has been built with a single armature. Sizes and speeds of some modern installations of these motors are shown in Table 24—IV.

This table indicates that the most popular size is about 7000 horsepower. Some of the characteristics of such a motor are:

Frame Diameter.....	197 inches
Armature Diameter.....	148 inches

Length of Shaft.....	295 inches
Diameter of Shaft.....	32 inches
Weight of Complete Motor.....	416,000 pounds
Approximate Reversing	

Cycle.....[50-0-50 r.p.m.—2 seconds
[120-0-120 r.p.m.—5 seconds

A motor of this type was installed on the reversing roughing stand of a 132-inch semi-continuous plate mill at Columbia-Geneva Steel Division of United States Steel Corporation. This 7000-horsepower, 0/25/60 r.p.m. motor is really two 3500-horsepower motors mounted as a single unit. The armatures are of unusual construction in that they have no conventional shaft. The spiders are bolted to stub flanged shafts at each end and the complete unit assembled at the mill. This design solved some of the shipping problems for the heavy pieces.

When the power requirements for a reversing mill exceed 7000 horsepower, problems in motor and pinion

SECTION 10

CONTINUOUS-MILL DRIVES

Wide Hot-Strip Mills—The major development of continuous-mill drives was associated with the wide strip mills. There were in 1954 about forty of these mills in the United States, 36 inches and larger, whose combined production was about 40,000,000 tons.

The conventional layout for these mills has a long, narrow motor room paralleling the hot-strip mill, between the mill and the slab yard. This motor room houses all of the main-drive motors, the motor-generator sets, the gear-reduction units, control and switching equipment. Figure 24—10 shows the motor room in one of the modern mills.

The drive motors for continuous mills follow a fairly uniform pattern, with the scale breaker and four roughing stands being driven by wound-rotor induction motors, and the six finishing stands driven by variable-speed DC motors.

The roughing stands are spaced so that the slab is in only one stand at a time.

The time the slab is in the rolls in the scale breaker and in Stands Nos. 1 and 2 is less than three seconds, offering ideal conditions for use of a regulator and flywheel combination.

On the older mills, it was customary to use flywheels on the third and fourth stands also, but with the increased lengths of slabs now being rolled on modern mills, the time the piece is in the rolls often exceeds four seconds, which makes the value of the flywheel questionable. As indicated earlier, the amount of momentum given up by the flywheel decreases rapidly with time, while the proportion of load taken by the motor increases with time. Hence, after three or four seconds, the motor may be driving both the mill and the flywheel. Modern installations of this type use 22-foot long slabs which are in the roughing passes for seven seconds. For this reason, flywheels were omitted and synchronous motors used for the main drives.

The DC motors driving the finishing stands present more interesting features. In the earlier mills, it was thought to be of advantage to have these motors of the same size and speed to simplify stocking of replacement parts. This necessitated gear sets on each stand which

were not only expensive but introduced chatter and extra inertia in the drive. The latest designs call for direct drive on all finishing stands except Nos. 5 and 6, where the speed is too low for economical use of direct-connected motors.

The basic data for calculating the horsepower requirements per stand for a continuous mill are based upon actual test. Composition of the steel, its temperature, speed of rolling, and width are variables in these data. In addition, allowance has to be made for the judgment that has to be exercised by the roller, who is given a certain size slab to be reduced in ten stands to a product meeting close dimensional tolerances and high surface-quality standards. To do this, the theoretical reductions per pass may have to be varied, and it may be necessary to increase or decrease the draft on certain passes as compared with the calculated reductions.

One of the measures used to compare the driving powers of hot-strip mills is the horsepower per inch of roll face. Since the main-drive motors may have different maximum torques or overload ratings, it is customary to use both the normal and overload ratings in such a comparison. Table 24—VI compares the horsepower per inch of roll face for eleven of the hot-strip mills operated by major steel companies.

The DC finishing-mill motors are designed to operate on 600 volts. At this voltage, they will run at the base speed. If lower speeds are required, the DC generator voltage is reduced, which also decreases the horsepower output but does not change the torque. Higher speeds are obtained by weakening the DC fields in the motors by the field rheostats or, in the more modern installations, by changing the field voltage by means of the rotating type of control. The standard speed range for these motors on field control is 2:1 and they are designed to have very flat speed characteristics.

When operating, the six finishing-stand motors must function as a unit and maintain their speed relationship regardless of load. Usually, a master control is installed so that, once this relationship is established, the speed of the six stands can be raised or lowered as a unit.

^ω Twin Drives^ω Triple-Armature Motor^ω Double-Armature Motor^ω One Generator per Drive Motor

These motors are started by the Ward-Leonard system, the generator voltage being increased gradually until the motors are at the base speed. The motor-generator sets to supply these finishing-mill motors have a synchronous motor as the driving unit and two generators mounted on a common bed plate for each stand. Due to the time the strip is in the mill, flywheels would be a detriment and seldom are used. The synchronous motors usually are operated at leading power factor and correct the lagging power factor caused by the inductive load on the other drives.

The top rating for these 600-volt, DC generators is about 4000 kw, due to commutator limitations. The number of these sets required for a mill varies from two to three, and the ratio of generator capacity to total motor-drive horsepower ranges from 0.60 to 1.50. The synchronous motors driving these sets must have a high pull-out torque capable of absorbing the sudden, high power peaks from the finishing stands.

The generators must operate in parallel and receive their excitation from separate exciter sets. It is essential that the voltage on the drive motors be kept constant, which is accomplished by sensitive voltage regulators. The load on the generators varies from frictional load to 200 per cent of the full-load rating. Since the synchronous motors on these sets are used for power-factor correction, it is sometimes necessary to use automatic regulation on the shunt fields to prevent wide fluctuations in the phase angles of the corrective power.

Tandem Cold-Reduction Mills—Another type of continuous mill is the cold-reduction tandem mill. Mills of this type have three, four, or five stands, with a reel to wind up or coil the cold-reduced product. The electrical problem here is more difficult than on the hot-strip mill, because tension maintained in the product between the stands must be controlled within close limits. The speeds on this type of mill have been gradually increased, several mills having a top finishing speed of 6000 feet per minute. Direct-connected motors are used on all stands, and there are a few installations using direct-connected, twin-motor drives on Stands Nos. 4 and 5 on five-stand mills. Table 24—VII gives motor and generator data on some modern tandem cold-reduction mills.

Continuous Billet Mills—Modern continuous billet mills are provided with individual motor drives at each stand. On the 30-inch mill at Fairless Works, each stand (three vertical and three horizontal) is driven through gearing by a 1750-horsepower, 300/600 r.p.m., 600-volt, direct-current shunt motor. They are supplied with power from a motor generator set consisting of four 2000-kw generators driven by an 11,200-horsepower, 514 r.p.m., 13,800-volt synchronous motor. The 21-inch billet mill at the same plant consists of two vertical and two horizontal stands, each individually driven by a 1250-horsepower, 400/600 r.p.m., 600-volt, direct-current shunt motor through gears. The power for these drives is supplied by a motor-generator set consisting of two 2000-kw generators driven by a 5600-horsepower, 514 r.p.m., synchronous motor.

Continuous Bar Mills—Individual motor drives are also provided for the separate stands of modern continuous bar mills. At the 10-inch mill at Fairless Works,

there are 18 two-high stands, all in line. Ten have horizontal rolls and eight have vertical rolls. Each stand is driven by a 600-volt, direct-current motor, in sizes ranging from 400 to 700 horsepower. Power is supplied by a motor-generator set composed of three 2500-kw generators, one 150-kw exciter, and a 10,500-horsepower, 514 r.p.m., 13,200-volt synchronous motor.

Continuous Rod Mills—Continuous rod mills consist of numerous stands arranged, for drive purposes, in groups with an individual motor driving the two or more stands in each group. The selection and distribution of motors in such a mill is dependent upon roll speed, roll diameter, amount of reduction in each stand, the horsepower required, and the degree of flexibility of control of the mill as an operating unit. The new straight-line continuous rod mill at Cuyahoga Works of the American Steel and Wire Division of United States Steel Corporation will roll 3¼-inch square billets, 30 to 34 feet long, into coiled rods from about ¼-inch to 1½-inches in diameter. The motors with their speed ranges were selected as shown in Table 24—VIII.

Table 24—VIII. Motor Drives for Modern Continuous Rod Mill.

	Horse-power	Speed (r.p.m.)
Roughing Train		
Drive No. 1—Stands 1 and 2	600	300–950
Drive No. 2—Stands 3, 4 and 5	1250	225–675
Intermediate Stands		
Drive No. 3—Stands 6, 7, 8 and 9	1750	200–550
Finishing Stands		
Drive No. 4—Stands 10 and 11	1500	225–580
Drive No. 5—Stands 12 and 13	1250	225–620
Drive No. 6—Stands 14 and 15	1250	225–620
Drive No. 7—Stands 16–23, incl.	4500 ^(a)	690–960
Drive No. 8—Stand 16a ^(b)	700	200–690
Drive No. 9—Stand 17a ^(b)	700	250–790

^(a) Motor set consists of one double-armature and one single-armature motor.

^(b) Looping stands 16a and 16b are used for rolling ¾-inch to 1½-inch diameter rods. In this case, Stands 16 to 23 are not used.

Continuous Seamless Tube Mill—In the continuous seamless tube mill at Lorain Works of the National Tube Division of United States Steel Corporation (separate mills of which are described in Chapter 41), the piercing mill is driven by a 4500-horsepower, 225 r.p.m., 13,800-volt, synchronous motor through a reduction gear having a ratio of 2.25:1. The nine continuous stands of the mandrel mill are individually driven by direct-current motors with a combined rated capacity of 8500 horsepower. The product from the mandrel mill, after reheating, is further processed in either the stretch-reducing mill or the sizing mill. The stretch-reducing mill is made up of twelve two-high, overhung roll stands; each roll stand is individually driven by a 200-horsepower, 850/1700 r.p.m., 600-volt, shunt motor. The sizing mill consists of twelve overhung roll stands, each with an individual drive consisting of a 76-horsepower, 850-1700 r.p.m., shunt motor.

SECTION 11

MOTOR-ROOM VENTILATION

A very important feature of the motor rooms for large electrical installations is the ventilating system.

It is necessary to supply sufficient clean air to maintain normal operating temperatures for the equipment.

Several recent installations have been designed with down-draft recirculating systems, where the air which passes into the motors and generators is discharged into the basement, pulled or blown through surface-type water coolers, and sent back to the motor room. Since there is always some leakage, a certain amount of make-up air is required, and this is introduced into the basement through a cleaning system.

Several installations have allowed for only 10 per cent make-up air, which may have been adequate when the building was new but, as cracks developed and loose joints appeared in the structure, this quantity of make-up air was too small and, as a result, outside air infiltrated into the building. These recirculating systems also have the detrimental effect of picking up the carbon dust from the brushes of the motors and generators and, in the recirculating process, this dust is deposited in the windings since no cleaning equipment is included in the indoor system. If a closed system is specified, the make-up air provided for should be at least 25 per cent.

The other type of ventilating system supplies 100 per cent new air which is blown into the basement through a cleaning system, then forced up through the motors into the motor room, where a positive pressure is maintained that prevents infiltration. This system requires larger fans and motors than the recirculating

system, but requires no cooling-water system and is less costly to maintain. Usually, there are three or four fans operated as needed so that, in winter time, the heat from the motors can be used to warm the room.

In the recirculating system, the cooling system has to be designed so that the difference in temperature between the cooling water and the outgoing air is not less than 10° F. Since the air delivered to the machines should not be above 104° F, the cooling water should not be warmer than 94° F. The following table indicates the amount of air required for cooling per kw loss in each machine:

Cubic Feet of Air Per Minute Per KW Loss	Rise in Air Temperature (Degrees F)
100	32.9
110	29.9
120	27.4
130	25.3

For cleaning the air, various types of filters have been used. The oil-immersed traveling-screen type, one of the early designs, did not remove the fine particles of soot and smoke from the air, and the oil was a fire hazard. Later installations favor the electrostatic type of air cleaner that eliminates even the finest foreign particles from the air.

SECTION 12

AUXILIARY DRIVES

The auxiliary drives on mills are as important as the main drives, and require proper application and co-ordination of types and sizes of motors. Both AC and DC motors are used, the former being the accepted ones for driving fans, pumps, and, occasionally, shears and run-out tables. The majority of the motors, however, are mill-type DC units, because of their ruggedness and the many operating characteristics that can be built into them. These mill-type motors were developed by the steel industry in cooperation with the electrical-equipment manufacturers for use in the rough service of driving mill tables, heavy-duty cranes, manipulators, etc. Their ratings and principal dimensions have been standardized by the Association of Iron and Steel Engineers into eleven frame sizes, ranging from 5 horsepower to 200 horsepower, based on the 1-hour rating. They can be obtained with several designs of windings from straight series to shunt, and with various types of ventilation. The designs are very rugged, and the armatures have low inertia in comparison with general-purpose motors. Table 24—IX describes motors for various auxiliary-drive applications.

Table Rollers—The early strip-mill run-out table rollers were equipped with variable-speed AC motors, one per roller, and speed variations were obtained by varying the frequency of the power supply by a variable-speed motor-generator set. Since 1937, the DC mill-type motor has been used for this application.

Schloemann rollers, a German design, in which the movable part of the table roller is the rotor of the motor and the stationary part wound to form the stator of an induction motor, have been used on some mills. When such rollers handle hot products, they must be water cooled. Speed variations are obtained by frequency control from a motor-generator set.

In modern mills, the rollers may be driven by individual, small direct-current motors of 3 to 4 horsepower, or they may be arranged in consecutive groups with

each group driven separately by a direct-current motor of ample size through a line shaft and gearing. Variable-voltage control is used to regulate the speed of the table rollers. The current generally is supplied by a motor-generator set.

Screw-Downs—Proper selection of motors for screw-down drives on the various mills is very important. In some mills, such as blooming and slabbing mills, a maximum roll lift of 66 inches may be required, with lifting speeds of up to 645 inches per minute. On strip mills, a maximum operating lift of only a few inches may be required, but the opening must be controlled within a few thousandths of an inch.

Regardless of the speed or distance involved, the screw-down motor and control must be capable of positioning the rolls within close limits. The inertia of the armature and brake wheel makes this a difficult problem, even with a compound-wound motor, and has resulted in the adoption of the Ward-Leonard system of control. This system has an added advantage in that it limits the amount of torque that can be applied to the motor, thus preventing damage to the screws by jamming.

On primary mills, modern screw-down drives usually consist of two 230-volt, DC motors of 100 to 200-horsepower rating. If operating under variable-voltage control, they are shunt motors with shunt brakes. If magnetic control is used, they are compound wound with reversing, plugging, dynamic braking, series-parallel control. The parallel connection is used to obtain higher speeds for long screw-down travel.

Another feature that can be incorporated in the control is the automatic preset device. In mills rolling fair-sized orders of a given product, this device positions the rolls automatically after each pass to give the correct reduction for each succeeding pass. Thus, the operators can concentrate their attention on the control of the main drive, table and manipulator motors, the screw-

down settings for each pass being made automatically.

Manipulators and Side-Guards—Mill tests have shown that steel being rolled on primary mills is in the rolls only from 25 to 70 per cent of the total rolling time, the remainder of the time being required for screw-down, manipulator, and table operation. In a modern slabbing mill, the maximum opening of the side-guards is 115 inches, with an overtravel of 40 inches to permit changing of the table rollers. Each of the side-guards is driven by a 150- or 250-horsepower motor. Due to the heavy plugging service required for these devices, and the heavy moving mass that has to be controlled, modern installations are using shunt-wound, variable-speed motors with Ward-Leonard control for this service.

The lift fingers on the manipulators are required to make four-foot lifts and complete the cycle in two

seconds. They always must stop below the top of the rollers, and represent another application for variable-voltage control. Where magnetic control is used, compound-wound mill-type motors with reversing, plugging, dynamic-braking features, plus a jamming resistor and arranged to operate two motors in series with series brakes, should be specified.

Blooming-Mill Shears—Blooming-mill shears can be driven either electrically or hydraulically. Many of the older installations were driven by an induction motor with high secondary resistance to allow the flywheel to supply the peak power for the cut. The motor ran continually and the shear was actuated through a clutch. Some of the more recent shears are of a start-stop type, driven by two shunt-wound motors of 200 to 300 horsepower, each equipped with a shunt brake and variable-voltage control.

SECTION 13

FUTURE DRIVES

This résumé on drives for steel mills is indicative of the ever-changing design in electrical apparatus. It is no longer a problem to add loads of many thousands of horsepower to existing systems. Motors have been improved in design and increased in rating so that they can be obtained for all types of service. Improved con-

trols, too, have kept pace with motor improvements, so that it is possible to maintain close relationship between individual large motors on successive continuous-mill stands rolling product at rates up to 6000 feet per minute.

The present trend is toward still greater flexibility in

drives. Recent continuous mills have been designed with separate generators for each drive motor; this allows the greatest range in speed.

Some few mills are introducing the mercury-arc rectifier as a source of DC power to substitute for the motor-generator set. With electronic control, this device can maintain voltage within very close limits and has a higher over-all efficiency than a motor-generator set.

The story of motor drives for mills is one of continual improvement in design to obtain higher speeds and closer regulation, to provide for more and better products from the mills.

Chapter 25

ROLLING OF STEEL INGOTS TO BLOOMS, SLABS AND BILLETS

SECTION 1

PRODUCTION OF BLOOMS AND SLABS

Introductory—Prior chapters have described the several processes for making steel and the production and treatment of steel ingots. This chapter relates to the first stages in forming useful products from ingots by hot rolling. Hot working by other means, such as forging by hammering or pressing, was discussed briefly in Chapter 19.

These early stages consist of a series of operations whereby the ingot cross-section is reduced to a square, oblong, round, or other simple shape, all having rounded corners, and of dimensions approximate to nominal specified size. The length of the ingot is increased, corresponding to the decrease in cross-section. The concluding operations cut a relatively short length called **crop** from each end of the rolled piece as scrap, and cut the remaining long piece, if necessary, into multiples to suit the required lengths or weights for subsequent operations.

These resulting pieces are known by the general names: **blooms**, **slabs**, and **bILLETS**. There is no widely accepted precise definition for any of these terms, and local applications of the terms are used somewhat on a traditional basis. Distinctions are made according to general appearance, influenced by overall size and the proportions of the three linear dimensions, and also by

intended use. The distinction between blooms and billets is principally a distinction of size, billets being smaller than blooms in cross-sectional area, and both having a length several times greater than their maximum cross-sectional dimension. The distinction between blooms and slabs is principally one of cross-sectional dimension proportion, blooms tending to be round, square, or nearly square, and slabs being always oblong and tending to be relatively wide, thin, and (until recently) of short length. There are many exceptions, and there are special names for pieces intended for special uses.

For example, any piece to be rolled into a plate almost invariably is called a slab, regardless of size or of dimension proportion. Likewise, any piece produced on a billet mill is termed a billet, regardless of shape and size, with the exception of round billets. **Round billets** intended for seamless-tube piercing, especially if in short lengths, are usually known as **tube rounds**. **Blooms** in short lengths are sometimes called **blanks**, or **blocks**, and special-shape blooms for structural sections frequently are called blanks regardless of length.

A rude guide using only the cross-sectional characteristics as the distinguishing features, which may serve in place of definitions, is shown schematically in Figure 25—1.

GENERAL FEATURES OF BLOOMING AND SLABBING MILLS

It is possible, and often quite economical, to roll ingots directly through the bloom, slab, or billet stage into more refined and even finished steel products in one mill, of varying numbers of stands from one to about twenty, in a continuous operation, frequently without any reheating. Large tonnages of standard rails, wide-flange beams, and plates, and a lesser proportion of wide hot-rolled coiled strip are produced regularly by this practice from ingots of medium to large size. A few very small plants follow a similar practice in rolling small ingots, such as 4-inch to 6-inch squares, directly into wire rods, concrete-reinforcing bars and other bar products.

However, most of the ingot tonnage is rolled into blooms, slabs, or billets in one mill, following which they are cooled, stored, and eventually rolled in other mills or forged. The reasons for this more common practice are primarily economic; sometimes size or shape of product and certain quality requirements peculiar to the final article to be manufactured determine the steel-rolling method.

A variety of names for mills rolling ingots has come

into common use to differentiate between them in reference to the particular kind of product intended or generally produced, the basic mechanical design features, or the general layout of the mill. For a long time, the term **blooming mill** was used rather commonly for all such mills, but, with the increasing variety, it has come to be restricted by many to a mill producing blooms, and the term **primary mill** is gaining acceptance as a generic term to cover both blooms and slabs. In addition to a name, these mills are designated as to size, expressed in inches, with the result that almost every mill is known by a combination of size and descriptive name which, taken together, with the size always expressed first, indicate a rough mental picture of the mill; for example, 54-inch blooming mill, or 43-inch three-high mill, or 45-inch slabbing mill.

The composite name applies specifically to the roll stand, or to the first roll stand if the mill is a multiple-stand one. However, the name is used as an abbreviation for the entire group of facilities needed to produce blooms, slabs, or billets and for the organization operating them, known more properly as a mill department.

TYPICAL CROSS-SECTION
AND
DIMENSIONAL CHARACTERISTICS*

SLAB

ALWAYS OBLONG
MOSTLY 2 TO 6 INCHES THICK
MOSTLY 24 TO 60 INCHES WIDE

BLOOM

SQUARE OR SLIGHTLY OBLONG
MOSTLY IN THE RANGE 6" X 6" TO 10" X 12"

BILLET

MOSTLY SQUARE
MOSTLY IN THE RANGE 2" X 2" TO 5" X 5"

Primary-Mill Activities—The activities of all primary mills are the same, and it follows that the facilities for carrying out these activities are fundamentally the same in all mills, but they differ in detail according to the particular requirements of each mill. The primary operation is the conversion of a steel casting (the ingot) into a rolled steel product; the secondary function of the rolling operation is to produce this rolled steel product in pieces of the desired cross-sectional dimensions and weights. Auxiliary operations, outlined below, include cropping, conditioning, cutting to length, and the collection and assorting of crops, roll scale and other by-products that are subsequently delivered to the steel-producing and blast-furnace departments.

The primary operation is carried out in a sequence of thermal and mechanical operations:

- (a) Heating the ingots (discussed in Chapters 20 and 21).
- (b) Breaking up the coarse crystalline structure of the ingot into a refined structure by heavy rolling pressure and recrystallization during hot working.
- (c) Closing solidification voids by the same means as in (b).
- (d) Cutting off such portions of steel as are metallurgically (both physically and chemically) unsuited for the intended final purpose.
- (e) Cutting off test specimens.
- (f) Cooling to atmospheric temperature those products not destined for immediate further hot working.

The secondary function is performed in conjunction with operations (b), (c), and (d), above, since they can

be carried out with the same facilities. The essential steps in performing the secondary function are:

- (a) Positioning the rolls, which have been shaped to produce the desired cross-section.
- (b) Cutting the rolled piece to measured length or to specified weight per piece.
- (c) Weighing individual pieces, or weighing and measuring test specimens.

The auxiliary operations pertain to the rolled product and the by-products:

- (a) Conditioning the steel products by removing injurious surface imperfections, removing portions containing injurious internal defects, and by correcting physical conditions by straightening bent pieces, cutting overlength pieces to proper length, and so on.
- (b) Collecting identified crops, other ferrous scrap, roll scale, and cinder and delivering these by-products to steel-producing and blast-furnace departments.

In order to carry out these activities, all primary mills have the same general kind of facilities and all are operated in the same general manner, but no two are exactly alike, although there are a few instances of close similarity. The differences among mills are due to the sizes of ingots and product, the particular kind of product and the quantity required to be rolled in a given time, as well as to the date when the mill was built or subsequently altered, and to the most economical kind of fuel and power available at that time. The differences are in size, in details of design, in the auxiliary equipment provided, and in the arrangement with relation to other facilities, especially those producing the ingots and those rerolling the products of the primary mills.

In a large number of present-day mill arrangements, the primary mill supplies hot steel products either directly or through reheating furnaces to other mills producing semi-finished products such as billets and coiled strip, or finished products such as rails or structural shapes, and the number of such mills supplied by one primary mill is from one to three in various tandem and parallel combinations. When the product coming from the primary mill is rolled, while it is still hot and without reheating, directly in a succeeding mill, rolling capacities must be considered. In the ideal case, the primary mill will just keep the succeeding mill or mills busy, without loss of time in either the primary mill or the succeeding mills. The arrangement of the mills determines the material-handling facilities and the size and location of the mill buildings.

The basic operation in a primary mill is the gradual compression of the steel ingot between the surfaces of two rotating rolls, and the progression of the ingot through the space between the rolls. The physical properties of the ingot prohibit making the total required deformation of the steel in one pass through the rolls, so that a number of passes in sequence are always necessary. There are several ways in which a sequence of passes can be made, and some particular way is selected by choosing one which is suited to the quality of material to be produced and also likely to be the least expensive. This choice determines the general type of mill. The elements of pressure, motion, weight, and time, together with the sizes of ingots and sizes of products, plus the quantity of product desired in a given time period, determine the size and design of the mill.

Each type of mill has been developed to meet a definite need, and, in performing this one task, it is superior to other types. However, mills are expensive to install and are capable of long life, while changing conditions

FIG. 25-2. Diagrammatic representation of the sequence of rolling operations involved in reducing an ingot to a slab on a reversing two-high mill.

in the steel industry sometimes result in a number of changes in the needs to be met by a primary mill during the period of its useful life. This results in adapting existing mills to new needs, frequently with alterations to some of the facilities, and many of the present-day primary mills are rolling ingots and producing products that were not contemplated when the mills were built.

The general characteristics of each of the types of primary mills is outlined below.

Two-High Reversing Mill—In the phrase “two-high reversing mill,” the term “two-high” refers to the fact that the mill consists of two rolls, one over the other, as in Figure 25-2. “Reversing” means that after the piece has gone through the rolls in the direction of the first pass, the rolls are brought to a standstill and then caused to rotate in the reverse direction shown in Pass No. 2, so as to impose the next reduction on the piece (the next pass), and so on until the piece has been reduced the desired amount. This type of mill has maximum flexibility in size range of ingot and product, as well as wide range of adjustment in the amount and rate of steel deformation in any pass. The mill is manually operated in order to permit instant variations in practice, the crew on electrically-driven mills consisting of two men and three on steam-driven mills. A very high degree of skill is essential in each man in his own duties and, in addition, there is the necessity for com-

plete coordination among crew members of all motions of the equipment if the highest production rate is to be attained, since each individual is controlling a part of what is, in effect, one machine working on one piece of steel.

For the same size ingot rolled to the same size product, this type of mill has a lower production rate, in terms of tons per unit of time, than any of the others, and it was due to this relatively low output rate that the other types were devised. However, the two-high reversing mill remains the principal type in use, exceeding in numbers all other types combined, by a wide margin. Its chief characteristic, flexibility, is so valuable that this type of mill is combined frequently with other types to compensate for low production rate, the extreme being two two-high mills of different sizes arranged in tandem. Many such combinations are in operation at this time.

While there is no limit to the size or weight of ingot for which this type of mill is used, there is an economic limit to the length of piece which should be rolled from one ingot on one mill. It is determined by two factors: inertia of moving parts of equipment, and size of building to house the mill. The ingot is a relatively short casting, mostly from five to nine feet long. Mill parlance refers to length of ingots as their height, because they are poured vertically and this dimension is height at first, but the mill operates on the ingot when the latter is in a horizontal position. In the early passes, the length of the piece is so short that one to three revolutions of the rolls is sufficient to complete a pass, and the rolling speed is preferably very slow. Reversals can be rapid, power loss in reversing is relatively slight, and impact among moving parts is light. As the piece becomes longer in successive passes, the rolling speeds must be increased if the steel is not to lose too much heat. At high speed, the motion in one direction is only a few seconds in duration, but reversals at high speed consume excessive power and subject all the moving parts in the mill tables as well as in the mill and the mill drive to severe shock, even with the best electrical controls. The mill table should be as long on each side of the mill as the rolled piece, plus adequate clearance for manipulation. Any appreciable increase in length of the rolled piece requires the combined length of the tables on both sides of the mill stand to be increased by twice that amount and requires a corresponding increase in length of building for proper accommodation. This economic limit of length of an uncropped piece rolled from an ingot seems to be about 90 feet.

The two-high reversing mills in use today are of three forms. The predominating form, known simply as a blooming mill, is provided with one pair of horizontal rolls in which several grooved passes provide the means of controlling the shape of the piece during rolling, and particularly of working the corners of the piece. This form of mill exists in a wide range of sizes and is designed to roll ingots of square or nearly square cross-section with a maximum thickness of about 34 inches, and can edge vertically, in a grooved pass, a piece of about 40 inches maximum width. A typical modern example is the 46-inch blooming mill in the Lorain Works of National Tube Division of United States Steel Corporation, shown in Figure 25-3.

A variation of this form, designed for edging pieces up to about 78 inches wide resting on their narrow edges, is known as a high-lift blooming mill and occasionally as a blooming and slabbing mill. It differs from the more conventional form in being provided with higher mill housings to permit greater elevation of the top roll for the edging passes on wide pieces. The roll body is usually longer and has fewer grooved passes, and the motors

which operate the screws for controlling top-roll elevation are usually larger in order to provide faster raising and lowering of the top roll. This latter feature is provided since edging passes are few in number but require excessive time unless the top-roll travel is accomplished in no longer time than that required for the manipulator to turn the ingot 90 degrees. This form of mill can be provided with interchangeable sets of rolls so that it can produce not only wide slabs but also blooms and, for this reason, it has been installed rather widely since around 1940. It has the greatest range in sizes of ingots and products of all three forms. The 45-inch high-lift blooming and slabbing mill at Geneva Works of Columbia-Geneva Steel Division of United States Steel Corporation, shown in Figure 25—4, is a modern example of this type.

A third form, actually a special-purpose mill limited to the production of wide slab sections, is the universal slabbing mill, often referred to simply as a slab mill. It is designed to increase the production rate for wide slabs by avoiding expenditure of the time required for vertical edging passes in a blooming mill, and is provided with a pair of vertical rolls in addition to the pair of horizontal rolls, the vertical rolls performing the edging. In this arrangement, no grooves are used in either pair of rolls. This lack of grooves prevents support of the ingot corners during rolling, and also limits the mill to production of slab sections, since it is incapable of avoiding consistently the inadvertent production of a diamond-shaped product in square or nearly square sections. The slab product rolled on universal mills has relatively sharp corners compared to that of the other mills. Figure 25—5 illustrates the 45-inch universal slabbing mill at Homestead District Works of United States Steel Corporation.

Rolling a certain size ingot to a certain size bloom is done at the same rate in the conventional and the high-lift blooming mills. The installation cost of the latter is slightly higher. Rolling the same size ingot to the same size slab is done at a somewhat faster rate in the universal slab mill than in the high-lift blooming mill, but the installation cost of the universal slab mill is substantially higher due to the cost of the vertical roll assembly and the additional prime mover to drive it. Before the high-lift mill was developed, the universal mill was the means for producing wide, heavy slabs for plate mills, and it has been built in sizes to produce widths to about 78 inches, maximum.

Two-High Tandem Mill—This mill consists of several single stands, each containing one pair of rolls, spaced one following another at such distances as to permit the rolled piece to be free between stands. Normally, the piece is rolled one pass in each stand, but at Edgar Thomson Works a unique arrangement of tables (Figure 25—6) transfers the piece from the second stand back to enter the first stand and second stand again for the third and fourth passes.

Because each stand rolls only one pass, there is no time lost in reversing the travel of the piece, with the result that this type of mill has the maximum output rate of all types. In addition, each stand can be designed for the almost ideal draft and rotating speed for each of the successive rolling passes. This is a great advantage in the early passes where the weakening effect of the ingot crystal structure exists. Opposed to these three very desirable features is the narrow limit of ingot and product cross-sections which the mill can roll without sacrificing the advantages by excessive idle time to change rolls and by compromise on roll-pass designs. For these reasons, the tandem mill is used as a roughing

FIG. 25-6. Unique arrangement of transfer tables at Edgar Thomson Works making it possible to return a rolled bloom from the second stand back to the first stand for another pass in each of the two roll stands. Four passes may be given in the two stands combined, without the necessity for reversing either mill. The arrows indicate the path of travel of the steel. While not indicated in the sketch, the piece is turned end for end before entering No. 1 stand the second time.

mill to supply hot steel to succeeding mills which permit flexibility in product sizes, but is confined to a narrow limit in ingot cross-section dimensions.

Two installations have been built in which a tandem mill was followed by continuous billet mills, and the entire mill in each case sometimes was called a continuous mill. This designation is slightly misleading with respect to the tandem roughing mill.

Due to the large amount of equipment in a tandem mill, it is the most expensive mill to build for a given ingot-to-product reduction but, when scheduled to full capacity, its operating cost per ton of product is lower than that of any other type mill rolling the same-sized ingot to the same product. A tandem mill can roll any size of bloom or slab for which it is designed, but its application has been to the medium and small sizes, at least up until 1955, since these were the only sizes in which sufficient orders could be obtained to provide the quantity of production to match the capacity of a tandem mill designed to roll them.

Three-High Mill—This type of mill consists of one stand containing three horizontal rolls, one above the other, each of which has grooved passes, and an elevating table on each side of the mill so that the piece being rolled can be passed alternately between the bottom and middle rolls and between the top and middle rolls. In order to keep the roll dimensions and mill and table dimensions from being prohibitive in size, a compromise pass design is used wherein the grooves in the middle roll are used for rolling both with the top and with the bottom roll. This method limits the reduction possible

in the second pass through each middle-roll groove to less than that possible in single passes. The rotating speed of the mill is also a compromise, since each pass should be progressively faster than the one preceding, but, with all passes in one set of rolls, that is impossible. The speed selected is usually too fast for the early passes and too slow for the last ones. There are normally five or seven passes, so that it is often necessary to employ heavy ragging in at least the first two passes to prevent slippage of the steel both in entering the pass and during rolling.

Because the rolls rotate in one direction only and at constant speed, a relatively simple and inexpensive constant-speed prime mover, aided by a flywheel, is used as the main drive. No power is lost overcoming inertia as there is no reversing. Raising and lowering the tables to guide the piece into successive passes can be accomplished in less time than the corresponding manipulations in a reversing mill. For these reasons, a three-high mill is less expensive to build and has a higher output rate than a two-high reversing mill rolling the same ingot to the same product.

Opposed to these favorable features are certain disadvantages. Like the tandem mill, the three-high mill with its fixed passes is rather inflexible with regard to size of ingot cross-section and product, except at the expense of serious operating delays due to roll changing. Then, too, its usual rather fast rolling speed in the first few passes makes it less desirable generally for the rolling of ingots in these passes.

The three-high mill is best adapted to a place as an

intermediate stand (Figure 25-7) where it can be supplied with bloomed-down ingots (ingots which have received a few heavy reduction passes), or large blooms, and where it can supply smaller hot blooms of one or two sizes directly to a following mill. Its rather simple design permits a rolling schedule among three mills in sequence which can be balanced within reasonable limits by alterations in the pass design to adjust the

entering bloom and the product bloom sizes to control the production rate of the preceding and following mills.

It finds a use as an ingot-rolling mill in those plants whose standard ingot sizes are very small, on the order of 14-inch square or less in cross-section, and whose total ingot-producing capacity is also quite modest. In these applications, the three-high mill functions more as a billet mill or as a roughing stand for a directly

connected finishing mill. The 43-inch three-high blooming mill at Ohio Works of United States Steel, which uses an ingot of medium size in a large tonnage operation, is an exceptional use of the three-high type.

Operating Units Comprising a Blooming Mill—To avoid frequent digression, the physical layout will be described here for rolling ingots on a two-high reversing mill. Essentially the same auxiliary equipment is used in rolling on other types of primary mills. The main parts of the rolling mill itself are shown diagrammatically in Figure 25-8. One modern mill is the 46-inch blooming mill at the Lorain Works of National Tube Division of United States Steel Corporation in Lorain, Ohio, already illustrated in Figure 25-3, whose layout is shown diagrammatically in Figure 25-30 in Section 2 of this chapter.

Two men are required to operate the controls of an electric-motor-driven two-high reversing mill, the roller and the manipulator, whose functions are defined by their titles; their pulpit, or control station, is placed on a bridge over one of the mill tables. (The steam-engine-driven mill requires a third man in the pulpit, the engineer, to operate the engine controls.)

Rolling—A pot car or ingot buggy (Figure 25-9) transfers a heated ingot from the soaking pits to the ingot receiving table, which delivers it to the mill approach table. The receiving table, in a few mills, is equipped with an ingot turner so the ingot may be rolled butt-end first (Figure 25-10). This practice aids the shearman in cutting the proper discard from the butt end of the rolled piece.

The mill approach table transports the ingot to the front mill table or roller table in preparation for rolling. It can move pieces at speeds of 200 to 400 feet per minute on modern mills. A few mills have a scale in the ingot receiving table or mill approach table for weighing the ingots before rolling (Figure 25-10).

During the complete rolling cycle, the hot steel is transported by reversible, live rollers in the mill tables. These rollers are subjected to high temperatures, heavy loads and impact. Depending upon the size of the mill they serve, rollers range in size from 12 to 21 inches in diameter, of whatever length is required for the particular service, and are spaced 2 to 3 feet apart. Forged steel generally is used in making the rollers which, in new mills, are mounted in roller bearings having a circulating lubricating system. Rollers on modern tables usually are driven electrically through a line shaft by miter gears; in some cases, they may be driven separately. As the pieces move along the tables, or are turned over by the manipulating equipment between passes, any loose scale falls between the rolls into a trough or depression beneath the tables and is removed to a settling pit with the aid of a stream of water.

Front and back roller tables alternately feed and receive the piece during each pass through the rolling mill, and mechanical units called manipulators rotate the piece through 90 degrees as required and move it from pass to pass. Some of the precautions to be observed in rolling are discussed later in this chapter.

Shear approach tables carry the rolled product from the back roller table of the mill to the shear. These tables have side guards that line the piece at right angles to the shear so that square cuts can be made. Some mills have a hot-scarfing machine in the mill delivery table or in the shear approach table for "skinning" the surface of the hot piece to remove, in part, some of the surface defects.

Shearing—The shear, generally called the crop shear, usually is located 100 to 200 feet from the rolls, and in line with the mill. Live rollers transport the rolled pieces

between the mill and the shear. Primary function of the crop shear is to remove from the rolled piece sufficient of the back and front ends (corresponding to the top and bottom of the ingot, or vice versa), so that the sheared piece remaining will meet chemical and metallurgical specifications. Secondary functions are to cut the remaining piece into desired semi-finished lengths and to shear test pieces.

Shears may be operated with electric or hydraulic power. A typical modern slab shear has an 80-inch wide knife, and a cutting-pressure capacity of 1200 tons; it can make straight cuts up to 8 inches thick and 60 inches wide, at a rate of 10 cuts per minute. It is driven by two 350-horsepower air-cooled motors. The top knife comes down to act as a gag and hold the piece while the bottom knife moves upward to make the cut. This principle of operation has caused this type of shear to be designated as a down-and-up-cut shear. The down-and-up-cut shear of a slab mill is shown in Figure 25-11.

The after shear tables which receive the cut product are designed according to the type of shear. Modern down-cut shears have a table that can move vertically to compensate for the action of the material during shearing. Either kind of shear (down-and-up-cut or down-cut) may have a shuttle motion for the after-shear table, which permits it to move back so the scrap may drop onto a conveyor beneath the shear. A crop pusher on the front side of the shear facilitates pushing the last crop end from the shear. Most after-shear tables have adjustable guards for lining up the last piece to insure a straight cut.

The shear gage measures the length of pieces to be cut. It is operated by a motor-driven screw. The gage head stops the bloom or slab at the desired point between the shear knives.

Sheared-off discards are moved by the crop conveyor to transportation facilities for return to the steelmaking departments where they are charged into the furnaces as scrap.

Located adjacent to and operating with the after shear tables are mechanical stamping devices or platforms for hand stampers to mark pieces for exact identification. A scale also usually is provided for weighing sheared pieces.

Transfers move sheared product from point to point, and may be of the continuous chain type with pusher dogs that engage and move the pieces over skid bars, or of the reciprocating-beam type which moves pieces progressively from one set of supports to another. Transfer buggies or cars also are used to move finished products from the runout table onto the pilers or transfer. Mechanical pilers separate the product into desired classifications as to weight, size of piece and type of cut, or other characteristics. Where the type of product permits, the sheared pieces may be moved by roller table from the shear to a piler of the type shown in Figure 25-12, from which the piles may be removed by a "C" hook on an overhead crane, or moved by rollers onto a transfer car.

COMBINATIONS OF CONVENTIONAL-TYPE MILLS FOR SPECIAL PURPOSES

Two Two-High Reversing Mills in Tandem—The most recent installation for the production of a wide range of sizes of square and round billets and narrow slabs at a high production rate is the No. 4 Blooming, Bar and Billet Mill at Lorain Works of National Tube Division of United States Steel Corporation. The 46-inch and 38-inch reversing mills forming part of this installation are described here and illustrated in Figures 25-3 and 25-13, respectively; the continuous billet mills com-

FIG. 25—13. The 38-inch two-high reversing blooming mill forming part of the rolling facilities in the No. 4 Blooming, Bar and Billet Mill in the Lorain Works. Operating in conjunction with the 46-inch mill shown in Figure 25—3, this mill has the position in the production line shown diagrammatically in Figure 25—30.

prising the remainder of the rolling equipment are described in the second section of this chapter. Layout of the combined facilities is shown diagrammatically in Figure 25—30, also in Section 2.

The layout is designed for extreme flexibility, inasmuch as the mill must roll many sizes of blooms, billets, rounds, and skelp slabs with a minimum number of roll changes, and adequate transfer equipment provides several outlets for these products. A battery of 24 modern soaking pits, each of which can accommodate, at one time, ten $32\frac{1}{2}$ by $32\frac{1}{2}$ by 94-inch ingots weighing 22,890 lb. each, constitutes the heating facilities. Ingots from the soaking pits are conveyed to the blooming-mill receiving table by either one of two ingot buggies. A scale for weighing ingots and a turntable for turning them 180 degrees have been provided at the receiving table.

The 46-inch by 100-inch two-high reversing blooming mill is equipped with front and back tables, individually driven feed rollers, double-rack-type manipulators with tilting fingers on both sides, and hydraulic roll changing rig. Mill rolls are equipped with oil-film bearings which are believed to have been the first application of this type of bearing on any blooming mill. The top roll is hydraulically counterbalanced and is positioned by a two-motor screw-down equipped with roller bearings and both mechanical and Selsyn-type roll-opening indicators. Two 15-inch diameter, 2-inch pitch screws provide a maximum roll lift of 45 inches at the rate of 230

to 460 inches per minute. Mill rolls are driven directly through universal spindles and couplings by two 4000-horsepower, 40/80 r.p.m., reversing, direct-current motors. Collar diameter of the rolls is 46 inches, with a 100-inch body length. The roll body contains 34-inch, 20-inch, 15-inch, and 8-inch passes, $3\frac{7}{8}$ inches deep. This roll design avoids the common practice of working an ingot too much in an open bullhead pass, which has a tendency to sharpen corners. By confining the majority of reductions in grooves with large radii, blooms are comparatively free from corner cracks and seams.

This mill rolls the $32\frac{1}{2}$ by $32\frac{1}{2}$ -inch ingot to a 15-inch by 15-inch bloom in 17 passes. This size of bloom is the primary section delivered by the mill runout table to the shear, which is situated in line with the mill and 145 feet distant from it.

Shearing equipment consists of an approach table, a down-and-up-cut motor-driven shear of the start-and-stop type, shear-crop chute, gage, crop-end pusher and crop car, delivery table, bloom pusher, and transfer car and track.

After cropping, the 15-inch bloom is delivered to the 38-inch by 96-inch reversing mill (called locally a bar mill) situated in line and 206 feet from the shear. This is utilized as a secondary mill to further reduce the 15-inch bloom to 9-inch by 8-inch rectangular blooms or to various large tube rounds.

While normal operating practice calls for the 15-inch

bloom from the 46-inch mill to pass to the 38-inch mill for further reduction, the 46-inch mill is required at various intervals to roll smaller sizes down to 9-inch by 8-inch. These may be rolled, cropped, sheared to required length, and removed by transfer car to the bloom yard. These operations may continue while a 15-inch bloom is being rolled on the 38-inch mill to a 9-inch by 8-inch rectangular bloom or a large round, the 15-inch bloom having been received from the 46-inch mill. Or, in the event of a breakdown or roll change on the 38-inch mill (which normally supplies the six-stand continuous billet mill to be described in Section 2 of this chapter), the 9-inch by 8-inch bloom may be rolled on the 46-inch mill, cropped and sheared to required length, then transferred to an auxiliary roller table in line with the continuous mills, thus by-passing the 38-inch mill entirely (see Figure 25—30 of Section 2).

The 38-inch by 96-inch two-high reversing mill is similar in construction to the 46-inch mill, containing all its features with the following exceptions:

The mill is driven by one 5000-horsepower, 65/130 r.p.m., reversing, direct-current motor, through a 38-inch pinion stand.

Feed rollers were eliminated, these not being necessary due to the longer bloom lengths received from the 46-inch mill.

A double-carriage roll-changing rig, hydraulically operated, facilitates rapid roll changes.

Integral guide units, equipped with hydraulically operated releasing clamps and end-screw adjustment through the roll housings, are on both sides of the mill for each set of rolls, facilitating guide changing.

To obtain maximum rolling efficiency, the 38-inch mill rolls are at all times provided with a 9-inch by 8-inch pass to feed the six-stand continuous mill, along with necessary grooves for producing a specified large tube round. The mill thus alternates from bloom to round, or vice versa, according to production requirements. A typical provision of rolls for the 38-inch mill comprises four sets of 40-inch by 96-inch rolls, each to produce one of four order sizes of $8\frac{13}{32}$ -inch, $10\frac{11}{64}$ -inch, $10\frac{1}{4}$ -inch, and $12\frac{29}{64}$ -inch rounds, each set having the necessary grooves to roll the 15-inch square bloom from the 46-inch mill to either the before-mentioned rounds or 9-inch by 8-inch rectangular sections.

The foregoing example of operating requirements, and consideration of possible future sizes this mill may be called upon to roll, shows why it was necessary to provide rapid devices to minimize roll-changing time. All reductions take place in a specific groove, using the screwdown with Selsyn roll-opening indicator for obtaining the proper drafts in each groove. A predeter-

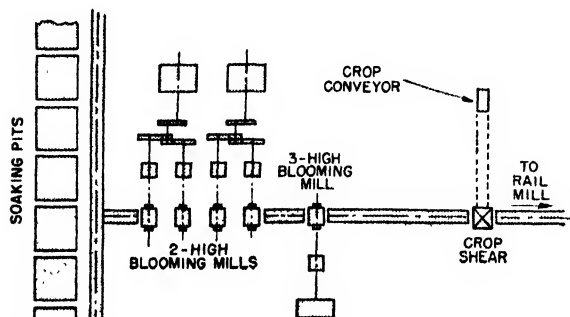

FIG. 25—14. Schematic arrangement of blooming mills in tandem, supplying blooms to the Gary Rail Mill.

FIG. 25—15. Blooming-mill section of the Gary Billet Mill, the world's largest producer of billets, narrow slabs, and small blooms. This illustration is schematic only.

FIG. 25—16. (Left) Arrangement of roll passes in the four 40-inch stands and (right) arrangement of passes in the five 32-inch stands of the Gary Billet Mill, in a typical set-up for producing a variety of shapes from a single ingot size.

mined setting was established for the single pass through the finishing round groove.

Each set of rolls contains 15-inch, 12-inch, and 9-inch passes, plus an octagon leader pass and a round finishing pass, with sufficient collar widths to obtain guide-setting efficiency.

All large rounds are rolled direct in a straight flow line, thus: from ingot through the 46-inch mill, through the 38-inch mill, to saws for cropping and cutting to required lengths, and continuing on to shifting tables.

The shifting tables are equipped with kickout devices for delivering each individual cut to chain-conveyor cooling beds. Upon terminating their travel over the beds, the rounds are removed by an especially designed escapement device to counterweighted chains, which slowly lower them in groups to the cradles from which they are taken by overhead crane to storage bays for conditioning.

As previously mentioned, the 38-inch mill must also deliver 9-inch by 8-inch blooms to the six-stand mill for direct rolling to billets, smaller rounds and skelp slabs. These blooms are rolled from the 15-inch by 15-inch size in 9 passes and conveyed by roller line directly from the 38-inch mill, passing through a continuous

oxy-acetylene hot-scarfing machine situated 150 feet away, then continuing on to the transfer table. Blooms are transferred to the roller line directly preceding the six-stand mill, where they are cropped and divided by a saw.

If the 9-inch by 8-inch bloom is delivered from the 46-inch mill, it must by-pass the 38-inch mill. Therefore, the hot-scarfing machine is mounted on rails for convenience in shifting it to a position suitable for either type of operation. Following scarfing, cropping and dividing operations, the 9-inch by 8-inch bloom enters the six-stand mill.

Tandem and Three-High Mill in Tandem—Figure 25—14 shows the arrangement of blooming mills in tandem supplying blooms to the Gary rail mill. The installation comprises four 40-inch, non-reversing, two-high roll stands, in each of which the ingot receives a single pass, and a three-high mill in which five passes are given, the ingot being turned 90 degrees between passes on the latter mill. Stands Nos. 1 and 2 are driven at 5 r.p.m. by a 2000-horsepower motor, and Nos. 3 and 4 by another 2000-horsepower motor. A 6000-horsepower motor drives the three-high mill. This arrangement provides for reduction of a 23 1/4-inch by 23 1/4-inch ingot

to an approximately 8-inch by 8-inch bloom which, after cropping and cutting to lengths, is rolled directly, without reheating, on the rail mill.

Four-Stand and Five-Stand Tandem Mills in Tandem—The Gary billet mill is the largest tonnage producer of billets, narrow slabs, and small blooms. The blooming-mill section of this mill is described here to illustrate the extreme case of utilization of tandem mills.

The blooming mill, shown in Figure 25—15, consists of four 40-inch, two-high, non-reversing stands, followed in line by five similar 32-inch stands. The first two 40-inch stands are driven by one motor, with the third and fourth stands being driven by a single second motor. All five of the 32-inch stands are driven by a single motor through a line shaft and miter gears. The increasing distance between successive 32-inch stands allows for increase in length of the piece being rolled as it is reduced in each pass. No screw-down mechanism is required on these stands, because all of the passes are fixed. The mill is restricted to practically one ingot size, but can be set up to produce a variety of shapes, as indicated in Figure 25—16. Manipulation is effected by the proper design and application of table rollers, collars, and side guards.

DESIGN OF BLOOMING-SLABBING MILL ROLL STANDS

The design of primary rolling mills is based on the work to be done, the size of material to be handled, and the length, weight, and shape of the sections to be produced. It is necessary in all cases to have all parts of the roll stand designed to survive the severe service conditions imposed by the inherent nature of the operations performed.

Foundations for primary mill stands are proportioned to the size and weight of the mill, and are built to withstand any tendency to settle or distort. On modern units, foundations are anchored to bedrock by piling to increase their ability to withstand the shocks and blows common to primary rolling operations. In counterweight-balanced mills, such as that shown in the diagram represented by Figure 25—8, foundation design is complicated by the space needed for this mechanism. Design of foundations for two-high continuous mills is simplified by the type of housing and roll arrangement used. Three-high mill foundations must provide room under and adjacent to the mill for the mechanisms of lifting and manipulating devices that lift and turn pieces between passes.

Foundation design also must provide for the draining of water, oil, and greases to low spots, or sumps, from which they can be removed by pump or siphon if natural drainage cannot be provided. Passageways giving access to the equipment beneath the mill, sluice ways for handling scale that drops off pieces during rolling, and electric-cable tunnels also must be provided in the foundations of a modern mill.

Stand Design—The essential parts of rolling mills were discussed in Chapter 22, and need not be discussed again here for the particular case of the primary mills. The point should be made, however, that the component parts and auxiliary equipment for primary mills are extremely rugged and of very large size as compared to most other mills. Mention might be made of the fact that, in primary mills, two-high tandem and three-high mills generally are constructed with open-top housings, while two-high reversing mills, high-lift reversing mills, and universal mills are built with closed-top housings.

Front and back feed or housing rollers are required to move the ingot or piece between the mill tables and the horizontal rolls of the mill, because housings of two-

high reversing, high-lift two-high reversing, and universal mills are so bulky in design and the tables for these mills are laid out in such a way that there is an open space between the last roller of the mill tables and the horizontal rolls of the mills. (Post and table construction of two-high continuous and three-high mills make it possible in these cases only for these rollers to be eliminated from their design.) These feed rollers have separate electric motor drives in modern mills. They must be designed with heavy bodies and necks to withstand pressure and impact, and should have carefully designed, well lubricated bearings that are protected from scale and water.

In universal-type primary mills, one of the feed rollers must be omitted between the vertical rolls, since these rolls must move in and out with respect to the center of the table. This one roller is replaced by a short dummy roller. If a piece "stalls" on this dead roller, the vertical rolls must be run in to contact the piece to move it onto the live table rollers on either side of the vertical rolls.

ROLL DESIGN AND ROLLING PROCEDURES

Roll Design—Roll sizes for blooming-slabbing operations are determined by the type and size of mill and the product being rolled. In most two-high reversing mills, roll diameters are usually 2 to 5 inches less than the size of the mill (based on the pinion drive). Rolls for a two-high tandem mill usually are short and heavy, since usually only one pass is made in each roll stand and diamond passes predominate.

In most three-high mills, the train-line diameters of

FIG. 25—17. Schematic representations of rolls for various types of blooming mills. In Sketches A, B, C and F, only part of each roll is shown to indicate the shapes of the pass openings. Sketches D and E show elevations of entire roll bodies.

Fig. 25-18. Schematic representation of rolls for a three-high, single-purpose mill. Only part of each of the top and bottom rolls are shown, sufficient to indicate the shape and size of the pass openings. The diameters of the rolls in the various passes, however, are given, to fix the size of the top and bottom rolls.

the rolls are all different, the bottom roll being the largest, with the middle roll next in size and the top roll the smallest in diameter. These rolls are all of the same length body and neck.

Effect of Pass Design on Rolling Procedures—Drawings of rolls for various types of blooming mills are shown in Figures 25-17 and 25-18. Figure 25-17A shows rolls designed to produce a great number of sizes; this is typical of general practice. Since a large number of sizes must be produced on one set of rolls, it might be supposed that it would be well to roll on flat rolls without grooves. However, such procedure would produce blooms that were far from square. Grooves are provided, therefore, to produce the most popular sizes.

It is best practice to get the ingot into a box (grooved) pass as soon as possible in rolling, since any great amount of reduction of a piece without protection on the sides would cause the steel to crack. The spreading of the metal in these grooves causes wear of the rolls. Therefore, the sides of the grooves are tapered so that, with the dressing of the rolls, the pass may be made to approach its original width. The taper is made as great as possible for this purpose. However, if too much taper is allowed, the piece being rolled will have a tendency to turn down as it emerges from between the rolls. Tapers up to 15 degrees per side have been used effectively.

Figure 25-17B illustrates rolls designed for a more specific purpose, while allowing a certain degree of flexibility. The largest proportion of product made on this set of rolls consists of 4-inch by 4-inch square billets. To use these rolls, it is necessary to provide grooved table rollers for the diamond passes. This also restricts manipulation and, consequently, full use of the roll body.

Rolls for a three-high, single-purpose mill are shown in Figure 25-18. In this case, the ingot size, bloom size, and number of passes is fixed. On this type of mill, much heavier reductions are given in the early passes than would be used in general practice on the two-high mill using the rolls of Figure 25-17A. With the rolls of Figure 25-18, edging occurs after each two passes. Since the ingot is protected on all corners and spreading is somewhat suppressed, and edging is done so frequently, it is possible to roll with the heavy reductions required

to produce a bloom from an ingot in so few passes.

Figure 25-17F illustrates the pass arrangement for the production of shaped blooms called beam blanks. This type of roll, like the blooming-mill rolls of Figure 25-17A, usually lacks the necessary space for the most desirable arrangement of passes. Considerations involved in the design of rolls for beam blanks include: (1) reduction of the ingot to a smaller rectangle or square; (2) provision for an edging pass to aid in the reduction of an ingot; and (3) web and flange proportioning in the beam-blank pass. Available roll length usually limits the design to one pass for each of these three steps in the rolling operation. For the smaller sizes of blanks, it is possible to include a second shape pass in the rolls. Shape blanks to be rolled on universal mills producing beams are made in this type of rolls. For the larger beam sizes, a beam-shaped ingot is used. This permits a more uniform reduction that results in a better flange build-up in rolling.

Figures 25-17C, D, and E show three sets of high-lift blooming-mill rolls. While the method of employing vertical and horizontal rolls is fastest for producing slabs, use of the horizontal rolls for edging, as in Figures 25-17C and D, is advantageous from the standpoint of surface of the semi-finished product of the mill. The edging pass, using horizontal rolls with the piece resting on its narrow edge, cracks the scale from the wide faces of the slab (which are in the vertical position) permitting the scale to fall off the piece and between the table rollers into the sluice-way beneath the mill. With the flat-rolling method using both vertical and horizontal rolls, the piece is not turned and some means must be employed to blow off the cracked scale; various ways are used, which will be discussed later.

Convexity of Passes—The convex shape (belly) of some passes will be noted in the illustrations; this convexity serves a double purpose. One is to prevent the formation of fins. If a straight-sided piece is edged in a succeeding pass, spreading causes the metal to squeeze out between the collars of the roll, as shown by the dotted lines in Figure 25-19A. Convexity of the passes produces a shape with concave sides, allowing considerably more spread in succeeding passes before a fin can occur. Fins, when a piece is turned 90 degrees then rolled in a succeeding pass, are rolled over and produce

FIG. 25-19. (Left) Schematic representation of the effect of concavity of ingot sides in preventing the formation of fins. The large round-cornered shape is that of the piece entering the pass; the smaller shape represents the cross-section of the piece in the pass, with dotted lines indicating fins formed in the openings between the rolls if the ingot is straight-sided or has insufficient concavity. The dot-dash lines indicate extreme concavity which, as indicated at right, also will cause laps during rolling.

what is known as a lap, and no amount of further rolling can eliminate this defect. It is impossible for fins to roll back into the parent metal because an oxide forms on them which prevents clean metal-to-metal contact between the fin and the parent metal that would be essential to welding the two integrally together. Laps (or seams) also may result if the sides of a piece are excessively concave (Figure 25-19). Laps must be chipped or scarfed out before the bloom or billet can be rolled on finishing mills for further conversion.

The permissible amount of convexity is dependent upon the draft. It might seem that the convexity should be made very great to eliminate all possibility of fin formation. However, if the convexity is made too great, as illustrated by the dot-dash lines of Figure 25-19A, the reduction, in penetrating to the center, will not be able to push out the metal in the center and folding will occur that ultimately will form laps, as indicated in Figure 25-19B.

It will be seen from Figure 25-17F, showing the beam-blank roll set, that the box passes have a deep convexity; this is desirable in this case because of the shaping effect which is helpful in producing the shaped bloom.

The second purpose of convexity is to provide a convenient place for the ragging which is put on rolls for primary mills to increase their "bite."

Depth of Passes—The depth of any pass other than the bullhead pass in blooming-mill rolls is governed by two factors: (1) the maximum draft to be taken on any piece rolled in that pass, and (2) the minimum thickness to be produced in that pass. The relationship between the depth of any pass and the bullhead or barrel-pass diameter must be such that the bottom of the bullhead pass is not elevated too high above the table rollers. If the bottom of the bullhead or barrel pass is too high above the table rollers, there would be excessive impact from the piece each time it passed through the mill and was discharged onto the rollers. Passes should be made as deep as possible, consistent with these considerations, however, because deep coverage of the bloom helps to guide the piece and also aids in preventing the formation of fins.

High-lift reversing mills require rolls of extraordinary length; most mills of this type have rolls 100 to 120 inches in body length. This is necessary to provide sufficient width for the grooved edging passes, along with a barrel or bullhead pass at least 6 inches in excess of the maximum width of slab to be rolled. Mills of this

type may operate in conjunction with a separate vertical roll stand having relatively short, heavy rolls, located at the end of the mill runout table, to give a square edge to the finished product.

Universal-mill roll sizes are dependent directly upon the width of material to be rolled, along with the desired product size. In a typical mill, the bodies of the horizontal rolls are 45 inches in diameter and 80 inches in length.

Ragging, or grooves cut into blooming-mill rolls to prevent slippage when using heavy drafts, should be shallow and parallel to the axis of the rolls. Otherwise, it may prove injurious to the surface of the semi-finished steel by causing slivers and laps. Sometimes, ragging will be designed to protrude from the roll, instead of consisting of grooves cut into it. In general, the less ragging the better.

Bearings—Roll-neck bearings of primary mills are, for the most part, babbitted with brass-grid inserts, although many mills are equipped with composition bearings of the laminated-fabric phenolic types. At least one mill uses roller bearings, which represent the latest development. Automatic lubrication of the babbitted bearings adds considerably to their service life, as compared to bearings hand-packed with lubricant. Water is used to lubricate the composition bearings, and care must be exercised to prevent grit from being carried into the bearing with the water.

Roll-Opening Indicators—On mills where the distance between the rolls is varied at the will of the operator to suit the particular rolling operation, some means must be provided for indicating visually the position of (i.e., the distance or opening between) the rolls. The conventional type of indicator is a large, calibrated dial with clock-like hands. The shaft that drives the hands is connected mechanically by rods, gears and cables to some rotating part or shaft on the screw-down mechanism, so that the position of the hands on the dial changes in unison with the movement of the rolls. The dial usually is mounted at the top of the mill, where it can be seen from the pulpit.

More recently, an electrically-operated indicator has been used which utilizes two small, specially-wound (Selsyn) motors. One is connected mechanically to the high-speed shaft of the screw-down and acts as a generator. The current generated by this motor (called the transmitter) is conveyed by wires to the second motor (the receiver) and causes it to rotate in unison with the transmitter. The receiver is connected mechanically to

the shaft driving the hands of an indicator dial which is located in the operators' pulpit.

Roll-Changing Devices—Rolls in open-top housings are changed by removing the housing cap and picking out the rolls separately or collectively with crane hooks.

With closed-top housings, roll changing is effected through a window of the housing by a counterweighted porter bar, by a sleeve using the ingoing roll as a counterweight, or by a "C" hook. Any of these methods requires the use of an overhead crane to remove the rolls one at a time. The rolls are pulled out of the housing by attaching a socket fitted over the protruding roll necks.

In modern mills, a roll-changing rig removes worn rolls and installs new ones. It is set in a permanent mounting, level with the housing sill, and consists of a motor-operated crosshead mounted on a rail frame and driven by a rack and pinion. It withdraws both top and bottom rolls, with their respective bearings, one at a time. The old set-up then is removed from the rig, on which the new set-up is placed and positioned in the mill housings.

Cooling Water—During operation of a blooming or slabbing mill, a liberal supply of cooling water should be distributed carefully and uniformly over the rolls. If possible, the rolls always should be warm, never chilled, since the sudden contact of the surface of a hot ingot with a cold roll will cause too rapid a differential expansion of the roll surface, and cracks called fire cracks may develop. Water should be turned off when the mill is not rolling. If water is kept flowing when the mill is not rolling, the rolls should be kept turning to avoid uneven cooling which is one of the most common sources of cracks in rolls. Rolling without water at first and then putting water on the heated rolls is also a cause of cracking.

In some mills, great care is taken to warm up rolls

before they are used in primary rolling operations. In one plant, the rolls are warmed by steam coils in a special pit before use. This practice minimizes fire cracking and roll breakage.

Manipulators—The rate of rolling steel in the blooming or slabbing mill depends upon the auxiliary equipment to a marked degree, as well as on the speed of the rolls. The importance of the auxiliaries is demonstrated by consideration of the fact that, in normal good rolling practice, a piece being rolled is in actual contact with the rolls only 25 to 40 per cent of the total rolling time. The remaining time is consumed in handling or manipulating the piece, emphasizing the importance of rugged, efficient equipment for performing this work. Transfer of the work from one point to another and away from the mill stand and between the different work stations is performed by the various live-roller arrangements discussed earlier.

Turning of the piece between passes, moving it sideways on the roller tables from one pass to another and, when necessary, straightening it, is the function of the manipulators. Usually, they are built to have both horizontal and vertical motion and, in most mills, are operated by electric or hydraulic power.

Location of blooming-mill and slabbing-mill manipulators depends upon the type of mill. In most three-high mills, the manipulators are located under the table, on the entering side of the rolls, the fingers coming up between the rollers to engage the piece as the table is lowered. The principle of operation is shown in Figure 25-22, as applied to a three-high billet mill. In other mills, they are located on side guards, stroking laterally over the tables on one or both sides of the mill. These side guards are equipped with retractable manipulator fingers or arms, which have a vertical or near vertical stroke and serve to lift the piece by a corner in the process of turning it 90 degrees.

SECTION 2

PRODUCTION OF BILLETS

Development of the Billet Mill—It already has been described how, as the technique of pouring larger and larger ingots progressed, it became necessary to adopt the use of blooming mills to roll blooms of sizes which could be handled by separate finishing mills, either directly, or after reheating. A further step in the trend became necessary as ingot sizes increased still further, in that many reversing blooming mills are capable of producing satisfactory billets in sizes down to 4 inches by 4 inches, but this size is still too large for rolling a great part of the products rolled in finishing mills. About half the steel now produced is rolled into material of small section, and to finish these products with one heating, mills rolling these sections start with small billets. Hence, an intermediate mill between the blooming and finishing mills is required for rolling billets.

Blooms from 6 inches by 6 inches to 10 inches by 10 inches usually are taken to the billet mill from the blooming mill directly without reheating. The ends of the bloom are cropped, and it is often necessary to cut the remainder of the bloom into two or more pieces, as will be explained later. Hot scarfing also may be performed at this time. These operations must be performed rapidly to retain as much heat as possible in the bloom to keep its temperature high enough for good rolling in the billet mill. In this connection, billet mills capable of handling large blooms not only save time on

the blooming mill, but also receive hotter steel, because the smaller surface area per unit of weight exposed by pieces of heavy cross-section lessens heat losses.

Although most billets are rolled directly from blooms without reheating, there are some plants that provide reheating furnaces between the blooming and billet mills (Figure 25-24). The older blooming and billet mills generally did not provide for reheating since the grades of steel then produced could be rolled through a greater temperature range without harmful effects. Since the more critical grades of steel, with their restricted range of rolling temperatures, have become more widely used, some of the newer primary-mill installations provide reheating facilities between the blooming mill and the billet mill. These mills are arranged sometimes so that the ordinary grades of steel can be sent direct to the billet mill without reheating.

Since the billet section is a simple one and the requirements in the way of accuracy as to finish and dimensions of section are not exacting, the first requirement of the billet mill is that it be heavy enough to handle fairly large blooms, and speedy enough to reduce the piece to the desired size before it becomes too cold. Most billets, however, must be straight, square, and free from surface defects. Billets that are twisted, bent, or not square, will not charge into or push through reheating furnaces properly, causing pile-ups in the furnace; this is due to the fact that billets lie on the hearth

Fig. 25-20. Schematic layout for a three-high billet mill, using the rolls shown mounted in their housings in Figure 25-21.

side by side, and depend, for their movement through the furnace, on pushing against the exposed side of the last billet charged to move all the billets forward through the heating chamber. Poor surface causes excessive conditioning or even losses due to rejections.

In this section of the chapter, only the rolling of billets will be discussed. The rolling of sheet bar and skelp will not be considered, for, although these are both considered as semi-finished products, their production on billet mills has been abandoned almost completely in favor of using products of the continuous hot and cold strip mills as raw materials for the production of sheets, welded pipe, and tubes.

TYPES OF BILLET MILLS

Three-High Billet Mills—Billet mills may be of several types. One is the three-high mill with lifting or tilting tables. This type of mill consists of three rolls mounted one above the other in a single roll housing. Billets are rolled in one direction between the bottom and middle rolls, and through the middle and top rolls in the op-

posite direction. The lifting or tilting tables move the billet to the two different pass levels. Mills of this type have fixed drafts, and only a few limited sizes of billets can be rolled with a given combination of rolls. To produce various sizes of billets on this type of mill would necessitate numerous roll changes, which are costly.

Figures 25-20 and 25-21 show the layout for a three-high billet mill and the rolls used in the mill. It can be seen that alternate passes are used in the top and bottom rolls while every pass is used in the middle roll. On this mill, four rolls comprise a set, consisting of a top, bottom, and two identical middle rolls although only three rolls are used at one time. When the middle roll becomes worn to the extent that it must be replaced, the mill is changed; that is, the rolls are removed from the housing and the worn top roll is placed in the bottom position, the fourth roll or second middle is placed in the middle position and the worn bottom roll is placed in the top position. This presents a whole series of new passes and permits the same tonnage to be produced with the set of four rolls that otherwise would require two sets of three, or six rolls. Since the piece is rolled in one direction between the bottom and middle rolls

Fig. 25-21. The rolls (mounted in the housings) of a three-high billet mill. Numerals in the pass openings indicate the sequence of passes used in rolling (see also Figure 25-23).

Fig. 25-22. Diagram showing the action of the fingers of a stationary-type manipulator for advancing the piece from pass to pass, while simultaneously turning it 90 degrees. The fingers remain stationary, and their action is performed by the motion imparted to the piece as the table is lowered from the raised position. The middle diagram represents the lift table in intermediate position.

and in the opposite direction between the middle and top rolls, the use of lifting or tilting tables is necessary to transfer the piece between the bottom and top pass lines. The table on the side of the mill from which the bloom enters (the side nearer the blooming mill) is called the front table, while that on the opposite side of the stand is called the rear or back table. Manipulators must be used in conjunction with these tables to turn the piece between passes and move it into line with the next pass. Both tables on a three-high mill are raised and lowered as a unit. The lift type table is more common and will be described along with only one of the many possible arrangements of manipulators.

Figure 25-22 shows diagrammatically a three-high mill lift table in raised, intermediate and lowered position. The front table contains twelve cast-steel rollers, each of which has five collars for turning the billets. These collars create four grooves extending from end to end of the table. The rollers are driven by an electric motor. There are side guards on the edges of the table and at the front end are side guards for putting the bloom into the proper pass. The front table is equipped with a stationary manipulator for advancing the billets from pass to pass which consists of fingers bolted to a pedestal on the foundation of the mill. These fingers are flat, cast-steel plates mounted vertically and with their tops shaped at an angle giving a 45-degree slope toward the outside of the mill. The fingers do not reach above the level of the roll passes when the table is elevated and the billets run out on the collars of the rolls. When the table is dropped, the billets encounter the stationary fingers and slide down into the grooves in position for the next pass. The rear table is operated through the same shaft as the front table but owing to the fact that it not only must raise the billets from the bottom pass line to the top pass line, but also must advance them one pass toward the outside, it has to travel through an arc in rising to bring the billet in line with the next pass. This is done by causing the table to slide toward the next pass as it is raised, by the use of pull-over rods attached to pedestals on the proper side of the scale pit. When lowered, the table slides back into place again. This table consists of twelve cast-steel rollers driven by a motor similar to the one used on the front table. Three heavy cast-steel side guards between the four passes that are used on the bottom roll divide the table into four grooves. There is a manipulator in the first groove that consists of five forged-steel fingers. The upward motion of the table draws the fingers with it and causes them to turn the piece and, as stated before, the sideward motion of the table advances the billet to the next pass. This manipulator lies below the table when the billet is delivered from the bottom roll and acts only

to turn the billets 90 degrees from the first to the second pass.

The mechanical operation of these tables leads to high maintenance for, when the piece drops into a groove, it causes severe shock to the bearings and other parts of the equipment, and when the tables are lowered, they may strike the stops with rather high speed. These severe service conditions make necessary considerable maintenance and repair work to maintain the tables in good operating condition.

Since the piece being rolled must be entirely out of the rolls for the lift table to transfer it between the top and bottom passes, its length must be limited to that which the tables will accommodate. This requires cutting the blooms from the blooming mill into the correct lengths so that when they are elongated, due to draft in the three-high mill, they can be handled properly on the tables. Cutting the blooms into pieces reduces the yield considerably as the ends of each piece usually are cropped after rolling.

The roll housings generally are cast steel, although some mills use cast-iron housings. The middle roll is not adjusted, but the top and bottom rolls are adjusted toward the middle. Cast-steel guides and side guards are held in guide cages or on rest bars which are bolted to the receiving and delivery sides of the housings. The pinions preferably are made with double helical or herringbone teeth. The three-high mill ordinarily is driven at a constant speed by a steam engine or electric motor. Methods of calculating power requirements for mills were discussed in Chapter 24.

The three-high billet mill shown in Figures 25-20 and 25-21 rolls four sizes of billets, which are reduced further in size on a smaller billet mill. As noted previously, the blooms are turned only once on the rear table and from one to three times on the front table, depending on the number of passes taken in the mill.

Figure 25-23 shows the shape of the piece out of each of these roll passes. The rolls used are cast alloy steel, 30 $\frac{3}{8}$ inches in diameter with a 76 $\frac{1}{2}$ -inch roll body. Box passes, as shown in Figure 25-21, are used generally on three-high mills for rolling billets. Slightly greater reduction can be taken using a diamond and square series but, since in passes of this shape the piece is rolled on the diagonal, the overall height of the piece is greater, requiring a deeper groove in the roll than for box passes. Such deeper grooves weaken the roll and increase the rolling or contact angle. Generally speaking, billets produced in box passes do not have as uniform diagonals as those rolled in diamond passes. If the box pass is narrow enough to restrict spreading, the action of the steel attempting to spread wears the sides of the pass and it rapidly becomes too wide. When the

FIG. 25-23. Cross-sections of the pieces out of each pass when billets are rolled on the mill shown diagrammatically in Figures 25-20 and 25-21.

pass wears wide, the stock entering the pass will "float" to opposite sides in the top and bottom of the pass and, hence, produce a diamond billet. The stock cannot be adjusted very easily to control this condition since the three-high mill is a fixed-draft mill, and any adjustment for one pass affects all passes. Another reason for not using too heavy reductions on the three-high billet mill is that the rolling or contact angle must be small enough to assure the entry of the piece in the roll pass. When several pieces are rolled at once, the failure of one to enter the pass causes the others to be held up until it enters. This delay results in loss of temperature by the steel, with its resultant harmful effects; it also reduces output, since it can affect the production of the blooming mill as well as any mills following the three-high mill.

Billets from a three-high mill usually are cut by stationary shears or, in the larger sizes and for special purposes, by hot saws. This type of mill usually is used where only a few sizes of billets are produced, or in conjunction with smaller billet mills that further reduce the billets from the three-high mill.

Cross-Country Billet Mills—Another design of mill is the cross-country mill. This type of mill is composed of several stands of rolls, so arranged that the piece to be rolled is never in more than one stand at the same time. The roll stands may be placed side by side and the piece transferred to the various roll tables, the direction of rolling being reversed in each stand; they may be arranged with two or more stands rolling in one direction, with the piece transferred to roll tables and then rolled through several other stands in the opposite direction, and so on. This type of mill is faster than the three-high, but as in the three-high, the piece from the blooming mill must be cut into several lengths before entering the mill. The cross-country mill is much more flexible than the three-high billet mill in that, in order to roll a complete range of billet sizes, it not only can take the product of the blooming mill during a greater percentage of the operating time, but also can roll various sizes of billets with only one complement of rolls throughout the mill, with only a few minutes delay necessitated by changing guides for the various passes. Quite frequently, production on the blooming mill is not affected by roll changes on the cross-country mill, except when they occur in the first two stands. Some cross-country mills are so arranged that a single pass is taken in each stand while others are composed of a combination of single-pass and multiple-pass stands.

In contrast to the three-high mill, the finishing pass in the cross-country mill can be faster than the first passes, provided separate drives or gear ratios are used. Since the piece being rolled is only in one stand of rolls at a time on a cross-country mill, tables must be provided to carry the piece from stand to stand. Some mills are provided with diagonal tables to direct the piece from one train to another, while other mills provide transfers at the end of each line of stands for moving the piece over to the next train line. The roll passes of a cross-country mill can be any shape required for good rolling practice and quality of product. The piece can be turned as desired between stands by manipulators, guides, transfers, turn-up rolls, and other devices.

Advantages of Cross-Country Mills—The production of any mill is governed by the speed of the finishing pass and the percentage of the operating time during which it can be kept full. In the cross-country mill, the speed of the finishing pass can be greater than in the three-high mill, but pieces have to be spaced far enough apart in going through the mill so that each table is clear of one piece before receiving the following one. It should

FIG. 25-24. Schematic arrangement (not to scale and not showing all auxiliaries) of the cross-country billet mill in the South Chicago plant of Republic Steel Corporation.

be possible to keep the finishing pass of this type of mill full for more than half the time (as opposed to the three-high mill) and this, together with the higher speed possible, enables such a mill to reach higher production rates than the three-high mill.

Cross-country mills, where the piece can be turned at will after every pass, and particularly those mills where the direction of rolling is reversed after every pass, are admirably suited for the rolling of quality steels.

Figure 25—24 shows the layout of the cross-country billet mill at Republic Steel Corporation's plant at South Chicago, which is part of an integrated installation designed for the production of electric-furnace alloy steels. A 44-inch blooming mill supplies blooms to a 36-inch two-high reversing roughing mill, which in turn feeds three 32-inch two-high stands. The major part of production when this chapter was written was being rolled from hot-topped ingots, 25 inches square, weighing 12,000 pounds, and open-type steels from 23-inch by 25-inch ingots weighing 11,500 pounds. The 44-inch reversing mill produces blooms, for subsequent rolling into billets, bars, etc., in the following sizes: 7 by 7-inch, 8 by 8-inch, 9 by 9-inch, 10½ by 10½-inch, 12 by 12-inch, and 13 by 15-inch, depending on the finished size of the re-rolled product. It is driven by a 7000-horsepower motor at 40 to 100 r.p.m.

Delivery tables, transfers and reheating furnaces of the 44-inch blooming mill are so arranged that the blooms may be disposed of in any one of three ways. They may be sent without reheating directly to the 36-inch roughing mill and then on to the 32-inch and 21-inch mills; they may be kicked off on a transfer and then directed through one of two continuous reheating furnaces from which they are discharged onto the same table that leads directly from the 44-inch mill to the 36-inch mill, or they may be removed from the transfer table and placed in slow-cooling pits after which they are conditioned and shipped or are charged cold into the reheating furnaces and re-rolled on the billet mills.

The 36-inch two-high reversing mill is driven by a 50 to 120 r.p.m., 5000-horsepower motor. It is equipped with 36-inch by 82-inch rolls, laid out to use either 5 or 7 passes in roughing blooms down in preparation for rolling in the 32-inch mill. It is possible, however, to vary this practice by coordinating the work of this mill with that of the 44-inch mill, which is the practice usually followed. Manipulators and side guards on both sides of the 36-inch mill permit turning the blooms after each pass. Delivery tables and transfers are arranged so that, by reversing the 32-inch finishing stand (see Figure 25—24), squares from 5 to 9 inches and some narrow slabs may be finished on the 36-inch mill and sent to the saws, while the 32-inch mill is undergoing a complete roll change, thereby permitting uninterrupted production. The three 32-inch two-high stands are located 225 feet beyond the 36-inch two-high reversing roughing mill. The three stands are placed side by side. The first, or so-called intermediate stand, contains 32-inch by 72-inch rolls; the second, or leader, stand, has 32-inch by 68-inch rolls; and the third, or finishing, stand has 32-inch by 48-inch rolls. The three stands are spaced 14 feet, 6 inches, and 21 feet, 3 inches apart, respectively. All stands are electrically driven, are provided with electric screw-downs, and the roll necks rotate in composition bearings. The first two stands are driven by a single 5000-horsepower reversing motor, while the third stand is driven by a 2500-horsepower motor. The intermediate stand is equipped on either side with an electrically operated manipulator carrying tilting fingers. The leader and finishing stands each have one manipulator on the entry side, incorporat-

FIG. 25—25. Two typical sets of passes used in the mill shown diagrammatically in Figure 25—24. The five passes shown in the top set produce 5½-inch square billets. The lower set of five passes produce 3-inch square billets. In each pass, the dotted line shows the rolled shape which is received from the preceding pass. The solid line shows the new shape produced, which consequently appears dotted in the next pass.

ing a manually operated turning device. Blooms from the 36-inch mill are given one or three passes in the first or intermediate stand of the 32-inch mill, and one each in the leader and finishing stands, depending upon the finished size of the billet (Figure 25—25). The intermediate and leader stands, being coupled together with a common drive, are reversed together from pass to pass. The finishing stand, being separately driven, operates in only one direction. This mill rolls billets 3 inches to 7 inches square, and rounds 3 inches to 9½ inches in diameter, from blooms and billets varying in size from 4½ inches by 5½ inches to 10¼ by 11½ inches. Two tables, each containing a 60-inch hot saw with a 5-foot, 6-inch stroke, parallel the run-out table from the finishing stand of the 32-inch mill. The double saw arrangement enables cutting the billets to standard mill lengths without slowing up the mill.

It will be noted that a 21-inch continuous mill composed of eight horizontal stands is located beyond the first stand of the 32-inch cross-country mill. A 6¼-inch bloom from the first stand of the 32-inch mill can be rolled into square billets ranging in size from 4 by 4 inches to 2 by 2 inches on the 21-inch mill. The bloom is cropped before entering this latter mill, and the finished billets are cut to length by a steam-operated flying shear. The eight stands of the 21-inch mill are driven by a single electric motor through bevel gears from a main drive shaft, and all roll necks rotate in composition bearings. The billets are twisted between stands by twist guides and twist rolls. These devices are discussed in the ensuing section dealing with continuous billet mills.

It has been mentioned previously that some plants are

FIG. 25—26. Sketches illustrating two types of friction driven twist rolls, as used on a continuous billet mill to turn pieces 90 degrees between passes. Twist rolls such as those shown in the bottom diagram are called "cone-type" twist rolls.

equipped to reheat blooms between the blooming and billet mills. The above-described mill is so arranged, as shown in Figure 25—24.

Continuous Billet Mill—The continuous mill consists of a series of roll stands, arranged one after the other so that the piece to be rolled enters the first stand and travels through the mill, taking but one pass in each stand of rolls and emerging from the last set as a finished product. These stands may be all horizontal, and may include one or more vertical edgers, or the stands may be alternately horizontal and vertical. In the continuous mill, where the piece is being rolled in several different stands simultaneously, the peripheral roll speeds must be such that the elongation which occurs as a result of reduction in cross-sectional areas of the piece is taken care of by increasing the speed of each successive roll pass. On mills where all of the various stands are driven through gears by one motor or engine, the

FIG. 25—27. Diagram of oblique roll passes designed to provide a twisting action on billets between stands when being rolled on a continuous mill. In each pass, the dotted line shows the rolled shape which is received from the preceding pass. The solid line shows the new shape produced, which consequently appears dotted in the next pass.

elongation is compensated for in the original design of the mill by choosing gear ratios that drive each set of rolls at a higher speed than the preceding set. The diagram of such a mill appears as part of Figure 25—24, where it is designated a 21-inch continuous billet mill. Any deviation from the originally designed elongation must be compensated for by varying roll diameters and thus changing peripheral speed. The rolls usually are installed in sets and are all dressed together. However, excessive wear on one set of rolls requires excessive dressing on the remaining rolls in the train. Various means have been adopted to gain longer roll life. Some plants will carry extra rolls for those stands that receive the most wear, and thus save excessive dressing on the remainder of the train, while others change the rolls around from stand to stand. As an example of the latter methods, a $2\frac{1}{2}$ -inch square in No. 4 stand can be changed to a 3-inch square without reducing roll diameter, and used on No. 2 stand.

The use of individual drives for each stand in a continuous mill is a great improvement over the single-drive type. With this drive, roll diameters need not be matched and the speeds of the individual motors can be regulated to give the correct peripheral speed for each set of rolls. The speed ratio on continuous mills must be maintained closely to prevent the piece from pushing or pulling between stands.

Since the piece being rolled in a continuous mill is in several stands simultaneously, the piece cannot be turned between passes in successive horizontal stands but, rather, it must be twisted. (The necessity for twisting, however, is eliminated in mills composed of alter-

FIG. 25—28. Schematic arrangement of the roll stands and twist rolls for an eight-stand continuous billet mill.

nate horizontal and vertical stands.) Various methods have been devised for obtaining this twist, one of which incorporates the use of twist delivery guides. These guides are iron or steel castings, and are designed so that the piece is twisted gradually by the action of the guide which is contacted by two surfaces of the piece being rolled; the other surfaces have clearance in the guide. The twist in the guide is designed so that the piece being rolled is rotated to the correct degree for entry into the succeeding roll pass.

Another method uses friction-driven twist rolls, mounted in housings, between the various stands of work rolls. Some plants use twist delivery guides that are designed with a slight over-twist, to start the twisting action, in conjunction with twist rolls. The twist rolls relieve the twisting slightly, thus reducing the pressure on the twist guide and minimizing guide scratches on the product. Two different types of twist rolls are shown in Figure 25—26. A third method accomplishes the twist as shown in Figure 25—27. With this latter method, the passes are cut in the rolls obliquely, and the difference in diameters in the pass causes the twisting action. This method, however, requires the use of twist guides to insure the proper twist, since temperatures and the chemical compositions of steels being rolled are not always constant and can cause a variation in the degree of twist. This method of twisting causes excessive roll-pass wear.

High output is one of the chief advantages of the continuous mill. Scrap losses are low, due to the fact that blooms of any length can be rolled, making it unnecessary to cut the bloom after it leaves the blooming mill, except to discard pipe or any other flaws that might be present. Flying shears are placed after the finishing stand on a continuous billet mill, and are synchronized with the speed of the stand on which the billet is finished.

It should be stated, however, that sometimes breaks occur in the steel due to the twisting of the billet, and that when the billet is deflected from one pass line to another, it is more subject to scratching by the guides. These defects increase the amount of conditioning required by the steel. The continuous mill composed of alternate horizontal and vertical stands, which eliminate twisting and arranged so that it is never necessary to deflect the bar from one pass to another, produces a product with much better surface quality.

Figure 25—28 shows a schematic diagram for a continuous billet mill; Figure 25—29, the passes used on a 14-inch mill for rolling two different sizes of billets.

Six-Stand Continuous Mill at Lorain Works—This modern mill represents one of the major developments in rolling operations and embodies many features uncommon to billet mills. Its relationship to the other facilities of the mill of which it is a part is shown diagrammatically in Figure 25—30.

Designed to produce a wide variety of semi-finished products from 9-inch by 8-inch blooms, the mill is equipped to roll 4-inch square billets, 5½-inch by 4-inch, 7-inch by 4-inch, 8-inch by 4-inch, and 9-inch by 4-inch skelp slabs, 4¾-inch and 5½-inch tube rounds, on the same roll and guide set-up, with the ability to alternate quickly on any of the above sizes by push-button-operated controls. Additional skelp slabs up to 12 inches wide also may be rolled on the same set-up from 12-inch or 14-inch slabs received from either the 46-inch or 38-inch mills described in Section 1 of this chapter.

The mill consists of three vertical roll stands numbered Nos. 1, 3 and 5, and three horizontal roll stands numbered Nos. 2, 4 and 6, set in tandem on 10-foot centers (Figure 25—31). Each stand is powered individually by a 1750-horsepower, direct-current motor (300 to 600 r.p.m.), making a total of 10,500 horsepower for the six

FIG. 25—29. (Above) Six successive roll passes employed in the production of 2-inch square billets from 4-inch square starting material on a 14-inch billet mill. (Below) Method of rolling 1½-inch square billets on the same mill, using the same starting material, in eight passes. In each numbered pass, the dotted line shows the rolled shape which is received from the preceding pass. The solid line shows the new shape produced, which consequently appears dotted in the next numbered pass.

FIG. 25-30. Diagrammatic layout (not to scale) of the No. 4 Blooming, Bar and Billet Mill in the Lorain Works of National Tube Division. Flow of material through this mill is illustrated schematically in Figure 25-34 which also indicates vertical sizes mentioned.

stands combined. Suitable gear reduction sets provide for a finishing speed of 346 to 692 feet per minute at No. 6 stand. All vertical mills are of sufficiently rugged construction to enable drafting equal to the horizontal stands. The main vertical housing containing two 30-inch by 48-inch rolls is a self-contained, integral unit and resembles a horizontal stand laid over on its side. A fixed outer roll held securely by hydraulic pressure against the housing seat, and a movable inner roll hydraulically balanced against motor-driven screws, plus anti-friction roll-neck bearings and thrust units, comprises the roll-adjusting mechanism. Screw speed is 6 inches per minute, and screw travel is sufficient to permit operating the rolls with the distance between their centers set at any point between $35\frac{3}{4}$ and $27\frac{1}{4}$ inches.

Power for the vertical mill rolls is transmitted from the main gear drive (Figure 25-32) through a horizontal shaft to an intermediate bevel-gear drive, through a shaft inclined at 40 degrees to a combination bevel-gear drive and fully-enclosed 30-inch pinion stand. Universal couplings and spindles equipped with anti-friction thrust bearings, suspended and attached beneath the main mill housing, complete the drive. The main housing is enclosed within a secondary housing supported on the shoe plates. The secondary housing carries the screw-up mechanism and guiding slides for controlling the vertical movement of the main housing with respect to the horizontal-mill pass line. The motor-driven screw-up mechanism operates by push-button control at $10\frac{1}{2}$ inches per minute, and provides for a maximum vertical movement of the main housing of 36 inches. Thus, a set of vertical rolls may contain several passes within this range, each of which may be aligned properly with the horizontal mills. The male coupling end, transmitting motive power from 30-inch pinions through universal couplings to the rolls, is forged in one piece with the spline shaft that telescopes with the pinions. This arrangement permits maintaining the drive connection during upward movement of the rolls. The three vertical mills are of similar design, having all parts interchangeable, including intermediate bevel-gear drive. Rolls with complete bearings are changed in pairs, using double roll-changing hooks.

Vertical-mill roll and guide equipment is of such design that changes are unnecessary when rolling any of the previously mentioned sizes. The useful proportion of rolling time on the mill is thus increased, since it is necessary to change rolls only when worn or in the event of possible breakage. The entry guide unit is attached to the secondary housing in a fixed, pre-leveled position, to accommodate the upper pass in the rolls. The remaining passes may be utilized by adjusting the screw-up mechanism upwards, thus positioning the desired pass in front of the guide.

Delivery guides are set up within a swinging integral unit, including guides for all passes in the vertical-roll set. Once set in position, they seldom need adjustment, fixed-roll guides remaining stationary while the movable-roll guides are carried along with the roll during adjustment. Upon changing rolls, the entry guide retracts clear of the rolls by a hydraulically operated mechanism. Delivery guides are manually swung clear of the rolls. The rolling operations of the three vertical mills in conjunction with the three horizontal stands will be described subsequently.

The three two-high horizontal roll stands (Nos. 2, 4 and 6) resemble strip-mill stands in their construction features, having been designed for stability, smoothness of operation, accurate roll settings, and ease in roll changing. Housings are of cast-steel, closed-top construction. The top roll is hydraulically counter-balanced

FIG. 25—31. General view of the six-stand continuous billet mill in the Lorain Works of National Tube Division of United States Steel.

against motor-driven screws. The screw-down permits the screws to function independently or in unison. The bottom roll is fixed, with provision on the outward chuck for endwise adjustment. The top-roll outward chuck is fixed, while both drive-side chucks are free to "float" in the housing. The 28-inch diameter by 48-inch body length rolls are mounted on anti-friction bearings of the radial thrust type, all preassembled with fully-enclosed chucks. Rolls thus can be quickly changed by use of a "C" hook similar to those used in changing strip-mill rolls. Horizontal roll stands Nos. 2 and 4 each are driven independently through a double reduction-gear drive and a 27-inch pinion stand. No. 6 horizontal roll stand is driven through a single reduction-gear drive and 27-inch pinion stand. Universal couplings and spindles mounted on carriers connect the pinion stands with the rolls.

A feature essential to the flexibility of operation of this mill is the endwise movement provided for the horizontal roll and pinion stands. To utilize all the grooves provided in the horizontal rolls for various product sizes, provision was made for rapid alignment of horizontal-roll grooves with respect to vertical-roll grooves to maintain a straight line of product travel throughout the desired grooves of all six stands. This was accomplished by mounting the roll stand, spindle-carrier base, and pinion stand as a unit on the bed plate. By using the bed as sliding ways, the entire unit can be moved endwise horizontally 42 inches through power supplied by a 14-inch diameter hydraulic cylinder operating at 1250 pounds per square inch. To maintain the drive connection during such movement, the main drive shaft telescopes a spline-type flexible coupling at the pinion stand. Hydraulically operated quick-release clamps anchor the assembly to the bed plate, obviating the use of foot bolts.

As in the case of the vertical mills, the roll and guide equipment of the horizontal stands was designed to roll all of the previously mentioned sizes without roll or guide changes. Entry and delivery guides are mounted

as integral units on sliding rest bars which, in turn, are supported by the main rest bar attached securely to the roll housings. All main rest bars are adjustable vertically by jack screws mounted on the housings. Rolls must be changed after excessive wear occurs. To minimize roll-changing time and increase efficiency, all guide equipment is mounted on a retractable mechanism operated hydraulically, which makes it possible to move the guides clear of the housing window to permit rapid and simple removal or insertion of the roll-and-chuck assembly.

To thoroughly understand the functions of all the foregoing features on the six-stand mill, a discussion of a typical roll-pass arrangement and the sequence of operations is advisable. These are as follows:

Vertical roll set V-1 (Stand No. 1) consists of rolls 30 inches in diameter with a 48-inch body. It is provided with three duplicate 8 $\frac{1}{4}$ by 7-inch box passes, all of which are set up complete with the necessary guides. Either pass may be used at any time, the 7-inch dimension varying with finished bar size and adjusted by mechanical screws on the movable roll. In the event of a worn-out pass, the roller may, by push-button control, quickly raise or lower the entire main housing unit to the desired position so that an unworn pass can be utilized. A gage attached to the secondary housing post, and a pointer on the movable housing, indicate within easy view of the operator the proper level of the pass.

Horizontal roll set H-2 (Stand No. 2) has rolls 28 inches in diameter and 48 inches in body length. It has two duplicate passes, 7 $\frac{1}{4}$ by 6 $\frac{1}{4}$ inches, plus a 13-inch wide bullhead pass used when rolling skelp slabs. The normal setting as used for 4-inch by 4-inch, as well as 4 $\frac{3}{4}$ -inch and 5 $\frac{1}{2}$ -inch rounds, is 6 $\frac{1}{4}$ inches and is also subject to variation by use of the top roll mechanical screw-down. All three grooves are completely equipped with the necessary guides. The roller also may select any groove rapidly by operating the hydraulic valve controlling the mechanism which moves the entire roll-housing unit endwise. A gage on the housing shoes

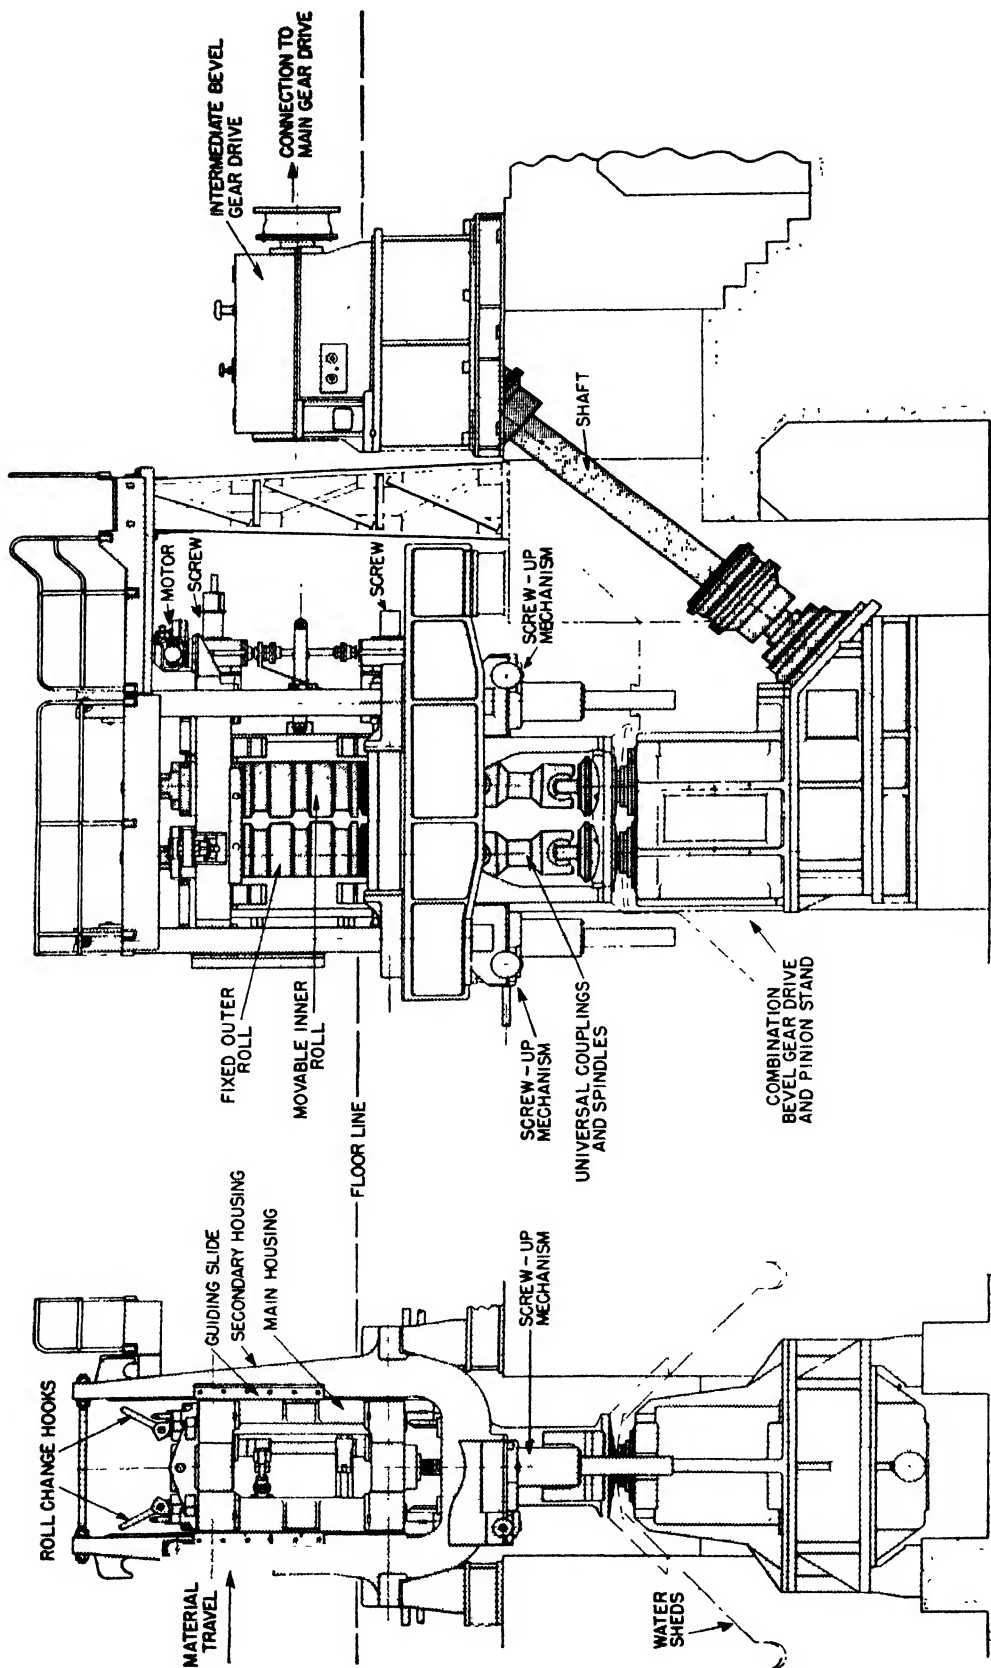

FIG. 25-32. Schematic arrangement of the principal parts of one of the vertical stands of the six-stand continuous billet mill in the Lorain Works of National Tube Division of United States Steel Corporation.

FIG. 25—33. General view of the four-stand continuous billet mill in the Lorain Works of National Tube Division of United States Steel.

indicates the proper position for the horizontal groove with respect to the vertical to assure straight line travel of the piece being rolled through the mill.

Vertical set V-3 (Stand No. 3), with rolls 30 inches in diameter and 48 inches in body length, also has three 6½ by 5-inch duplicate grooves, and functions in a manner similar to the V-1 set. The 5-inch setting is variable for finished product size.

Horizontal sets H-4 and H-6 have rolls 28 inches in diameter with 48-inch bodies. Each has its designated passes for 4-inch by 4-inch squares, and 4¾-inch and 5½-inch rounds, plus a skelp-slab pass, and have operating controls similar to H-2. Vertical set V-5, with rolls 30 inches in diameter and 48-inch body length, which is the leader pass, also has its designated passes. Two leader passes for the 4-inch by 4-inch square, and one each for the two sizes of rounds, have been provided in sets V-5 and H-6. Vertical set V-5 utilizes the 4-inch by 4-inch passes for edging skelp slabs, with operating controls similar to V-1 and V-3.

The run-out table from the six-stand mill delivers all product to transfer equipment designed to handle bar lengths up to 160 feet. Rounds may be delivered direct to either one of two saw lines, each equipped with stationary and movable saws for cropping and cutting to required lengths. Each of the saw lines converges to its own independent chain-conveyor cooling bed. Or, product may be transferred to the double saw line which normally handles product (rounds) from the

38-inch mill (described in Section 1 of this chapter), each line having a single saw with individual cooling bed. Thus, the finishing equipment for tube-round product from the 38-inch mill and the six-stand mill comprises altogether six saws, four saw lines, and four cooling beds. All products 4 inches by 4 inches to 12 by 4 inches delivered from the six-stand mill for skelp conversion are transferred to a roller line that carries them to shearing facilities and inspection and storage. For further reduction to smaller billets and tube rounds, 4-inch by 4-inch or 4½ by 4½-inch billets are delivered from the six-stand mill and transferred to a roller line directly preceding the four-stand continuous mill.

The Four-Stand Continuous Mill at Lorain—This mill (Figures 25—30 and 25—33) is similar in design and employs all the advanced features of the six-stand mill. It comprises four sets in tandem; V-1 vertical, H-2 horizontal, V-3 vertical, and H-4 horizontal. Each set is powered individually by 1250-horsepower, 400 to 800 r.p.m., direct-current motors, with reduction gear drives designed for a finishing speed of 430 to 860 feet per minute. All mill rolls are 20 inches in diameter, with body length of 36 inches, and to meet original requirements, were set up to produce 3¼ to 3¾-inch rounds and 2½-inch square billets, with sufficient space available for rolling other sizes. Billets delivered from the six-stand mill lie flat on the roller feed table and, prior to entering the No. 1 vertical (V-1) pass of the four-stand mill, are turned 45 degrees on the fly, by an air-

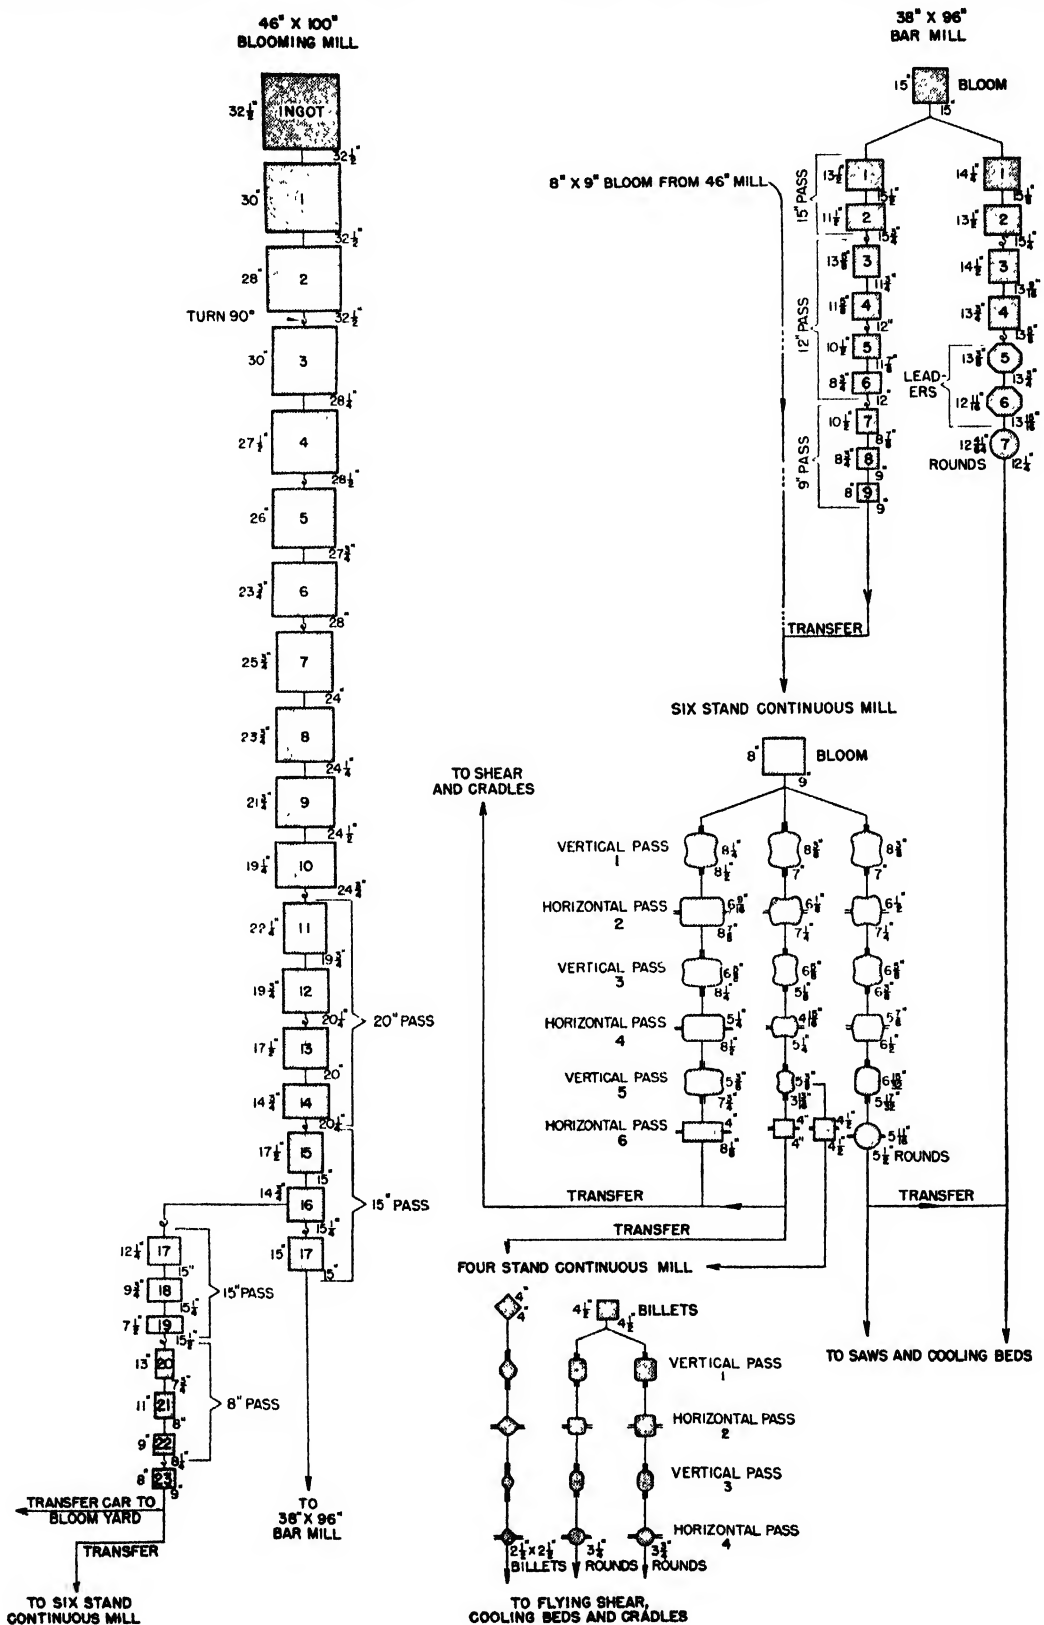

FIG. 25-34. Flow chart summarizing typical series of operations possible due to the extremely flexible arrangement of the modern No. 4 Blooming, Bar and Billet Mill in the Lorain Works of National Tube Division.

operated turning device, to permit finishing the 2½-inch square billets in diamond passes on their diagonals.

Billets of 4½-inch square size enter the V-1 pass on the flat for alternate flat and edge reduction to lead-oval and finished rounds. No. 4 horizontal set delivers billets to the flying shear for cropping and cutting to length. A specially designed double skew table with disappearing stops receives the product from the flying shear. Here the product is gaged, then conveyed in groups to the roller line opposite the cooling beds. The roller line has disappearing stops that position these groups opposite either one of the three adjacent cooling beds, over which the product travels to the cradles and storage bays. This completes the cycle of operations beginning with the 32½-inch ingot on the 46-inch blooming mill, as described in Section 1 of this chapter. Figure 25-34 is a flow chart summarizing a typical series of operations possible with this modern mill.

Hot Scarfing Machines—The increased demand for conditioning of semi-finished products (see Chapter 26) has led to the installation of hot-scarfing machines in many primary mills. Such machines may be placed immediately after the bloom shears or, when multiple units are fed from the same blooming mill, they can be installed after the roughing or the first billet mill.

The scarfing head of the machine contains oxy-acetylene burner nozzles and is designed to be adjusted rapidly to accommodate several different sizes of billets. The head also can be moved laterally to permit the scarfing of blooms or billets from different passes in a set of rolls, or to remove it entirely from the line to permit the passage of steels not to be scarfed. The machine desurfacing process can remove defects within ⅓ inch of the surface, which is usually sufficient to remove such defects as rolled seams, light scabs, checks, etc. It is not always economically advisable to cut at depths necessary to remove the deepest defects. General practice in those mills using the process is to desurface each grade of steel to the depth which strikes the right economic balance between loss in yield due to removal of metal and processing costs on one hand, and savings in lessened rejection loss on the other hand. This depth will vary with different materials, but the metal loss is generally 2 to 3 per cent of the product.

Roll Adjustment—There are several different methods for adjusting rolls on two-high mills (in addition to the one described earlier for three-high mills). One is a simple method of using a rider bearing on the bottom roll neck. The top-roll carrier bearing rests on liners on the bottom rider bearing. A wedge is placed between these liners to vary the distance between the rolls. Another method of adjustment consists of supporting the top roll by springs from the housing cap. Turning of the housing screw compresses the springs, and thus the space between the rolls is varied. Still another method of adjustment in which the top roll remains stationary and the bottom roll is moved up or down is used in a good many mills. This is accomplished in the following manner: a cast-steel screw box in which the threads have been babbitted to prevent excessive wear is placed on the sill of each housing. A screw bolt is placed in each of these, the outside one containing a left-hand thread while the inside one has a right-hand thread. The two screws are joined together by a cast coupling. Above the screw bolts, and resting upon them and the screw boxes, cast-steel wedges are mounted containing the same number of babbitted threads as the screw box. The bottom chocks are wedge-shaped and rest on the screw wedge. Since the two screws are coupled together, turning of the screw on the outside of the mill causes both screw wedges to move in or out and, due

to the wedge shape of the bottom chock, the bottom roll is raised or lowered. This method of adjustment is used on many continuous mills. One of the newer methods of adjusting rolls on billet mills makes use of an electric screw-down. With this type of adjustment, the top roll is supported by two hydraulic cylinders through steel-yard rods in each housing, reaching up to the top-roll carrier bearings. The top roll is held down by screws reaching through the cap to the breaker blocks on the rider bearings. An electric motor mounted on the housing cap actuates the two housing screws.

Shears—The product from the blooming mill must be cropped to discard pipe before entering the billet mill and the finished product from the billet mill must be cut to length. The bloom-crop shears, however, usually are considered part of the blooming mill rather than the billet mill. When the primary mill set-up consists of several billet mills fed one from the other, and all or part by the same blooming mill, crop shears usually are placed before each unit. Crop shears assure a clean end entering the mill and also enable cutting of the stock to the right length to accommodate the various mill tables. These crop shears usually are stationary, and may be steam, hydraulically or electrically driven.

Billets of large cross-section generally are cut by stationary shears. Such billets are usually short enough to be handled on tables and transfers, and there are comparatively few cuts to the finished piece. These shears cut one or more pieces at the same time. The length of cut is determined by an adjustable stop on the shear table and the shears usually can cut accurately to within ¼ inch of the desired length.

Another form of shear is the gang shear in which several shears are placed in line in such a manner that any length of billet may be sheared by moving the position of individual shears within the limits of the first and last shear in line. They may be made to cut in unison, or separately, as desired.

The flying shear, as opposed to the stationary shear, cuts the piece as it travels in a continuous operation. These shears are used for the smaller sizes that would require excessively long tables and transfers and would, of course, consume too much time in handling, if cut on stationary shears. This is obvious when it is realized that an 8,000-pound ingot, rolled into a 1½-inch by 1½-inch billet, would be over 1000 feet long. By the use of flying shears, this piece can be cut effectively into shorter lengths as it leaves the finishing stand.

Billets also may be cut to length by saws or flame cutters to eliminate distorted ends produced by shears. Sawing is usually slower and more expensive than shearing, and saws are more costly to maintain.

Flame cutting, while entailing a comparatively small initial investment, is costly in that it is slower than shearing and also requires the use of relatively expensive gases.

Identification—It is of primary importance that every billet be identified properly. Every billet should be stamped with its heat number, and some orders require that top and bottom cuts from the ingot be identified. The steel must be followed closely through the mill, especially in those mills composed of several units, to make certain that the correct steel is coming for which the stampers already have received instructions. This tracing of the steel can become quite complicated at times, and must be adhered to rigidly in order to prevent costly errors in identification. Some mills identify all products by the use of special hand or pneumatic hammers having suitable heads for containing the stamps. Heat numbers can be machine stamped on billets after leaving the finishing stand by the use of a

wheel, suitably mounted and containing the proper marking devices or stamps, contacting the steel. These wheels can be held in a stationary housing, so arranged that the height above the table can be varied for different sized billets, or they may be moved by a manually controlled hydraulic cylinder to contact each piece as it passes over the table. Usually, heat numbers only are applied in this manner.

After leaving the shears, billets are delivered usually to cooling beds, or hot beds as they are sometimes called, where they are cooled before shipping. In many mills, the above mentioned hand stamping is done on billets on the hot bed. The hot beds are at right angles to the direction of delivery from the mill and are wide enough to handle the longest billet length regularly produced on the mill. These beds are composed of skids placed close enough together to support the billet, but not too close to permit air to circulate around them. The skids may be composed of rails or of a series of specially designed castings. The castings give much better results than rails

since they do not bend so readily with prolonged use. After cooling, the billets are pushed off the hot beds into cradles, from where they can be loaded easily into cars for shipment, or transferred to the conditioning area where they are handled as described in the next chapter.

Chapter 26

PREPARATION OF SEMI-FINISHED STEEL FOR FINISHING

SECTION 1

SURFACE DEFECTS ON SEMI-FINISHED STEEL

Semi-finished steel is previously hot-worked cold steel intended exclusively to be subjected subsequently to further hot deformation. When steel is rolled from ingot to semi-finished forms, such as blooms, billets and slabs, a variety of ingot defects and some defects arising during heating and rolling may be carried through to appear on the surface of the semi-finished product. It often is necessary to remove these defects before the steel is converted further into finished products by forging, rolling or other hot forming operations. The removal of these defects, which operation is known as **conditioning**, will be the subject of the first three sections of this chapter; a discussion of the principles and practice of controlled cooling of certain grades and sizes of semi-finished products from rolling temperatures will be presented in Section 4.

Surface defects on semi-finished products may be caused by defects on or in the ingot or by improper handling after pouring or by variations in heating and rolling practice.

The major surface defects which generally are attributed to defects on the ingot are:

1. **Ingot Cracks**—These defects occur as both transverse and longitudinal ruptures in the ingot wall, and normally are observed first while the ingot is being rolled on the primary mill, although some are apparent on the surface of the ingot itself, especially if it becomes cold. Ingot cracking has been the subject of numerous investigations, and some of the causes have been brought to light although many still remain obscure. Excessively high pouring temperature (a temperature considerably above the solidification temperature) has been established as one definite cause of ingot cracking. During solidification a dendritic crystalline structure is developed in the ingot and interdendritic zones of weakness are formed which extend from the ingot surface toward the center. The larger the dendrites, the more pronounced are these zones. Lower pouring temperatures will help eliminate cracking from this origin by limiting the size while increasing the total number of individual dendrites. Folds due to surging of the molten metal in the mold form discontinuities in the ingot wall that lead to transverse ingot cracking. This type of defect has been minimized by use of mold coatings and improved mold design. Steels of the 0.15 to 0.25 per cent carbon grades, especially the fine-grained killed types, have the greatest tendency toward transverse cracking. Generally, the higher carbon steels have the least tendency toward this transverse rupturing. **Hanging** of hot-topped ingots by fins forming over the edge of the mold wall usually produces a transverse crack approximately 6 inches below

the hot-top junction, easily recognizable and termed a **hanger crack**. Hanger cracks from this source can be prevented by use of properly designed hot-tops. Plain-sided molds are more prone to produce or at least accentuate transverse cracking than the fluted type. Longitudinal cracks generally are related to the flute or corner design of the mold.

Other and more obscure causes and corrective measures for ingot cracking are a constant subject for study by practically all steel-mill personnel.

2. **Scabs**—This type of defect is caused by splash of metal against the mold wall when an ingot is being teemed. Rapid solidification and oxidation of the metal on the mold wall causes it to stick to the ingot surface and finally appear as a scab on the surface of the rolled product. A picture of a scabby surface on a bloom is shown in Figure 26—1. This defect can be minimized by bottom pouring, use of mold coatings, and proper mold design, as well as by proper attention to pouring speed and technique, as discussed in Chapter 20. A “cold” heat usually causes difficulties in pouring, such as inability to obtain a tight closure of the ladle nozzle; the resulting leakage of molten metal when the ladle is positioned over the mold generally results in an ingot surface covered with scabs. Properly prepared mold coatings not only will minimize scabs but also will improve the surface condition generally. Many types of coatings have been employed with varying success, such as graphite, tar, aluminum paint, oil, and others. However, it might be noted that a poor coating is often worse than no coating at all, becoming a better adherent for splashes than the original mold wall itself.

3. **Seams**—This term is used to denote the straight-line longitudinal cracks or openings that may appear on the surface of semi-finished steel. Generally, they may be divided into two classes:

(a) A long deep seam usually is the result of ingot cracks, either longitudinal or transverse. A transverse crack in the ingot is elongated during rolling, and the seam so produced often has a “steeple” at the head, drawing out into a long straight line or a pair of parallel lines on the product. A deep seam on the semi-finished product surface such as originates in an ingot crack, is shown in Figure 26—2. The basic causes of these defects in the rolled steel are obviously the same as those outlined above for ingot cracks.

(b) Short seams, usually light and in clusters, may be due to a number of causes. Surface pits on the ingot, or subsurface blowholes which become exposed and oxidized during heating, will produce this defect. Some other causes include poor heating practice, and rolling

FIG. 26—1. Scabby surface on a bloom, showing the effects of roll collars on the pre-existing scabby surface on the ingot from which it was rolled.

FIG. 26—2. Deep seam on the surface of a semi-finished rolled product, originating with an ingot crack.

FIG. 26—3. Clustered seams on the surface of a semi-finished rolled product, pickled after rolling to facilitate detection of defects.

outside the proper temperature range. Clustered seams are illustrated in Figure 26—3.

Those surface defects which originate at the soaking pits and on the primary mill and other mills rolling semi-finished products are:

1. **Cinder Patch**—This defect is the result of pick-up of material from soaking-pit bottoms, and generally has the appearance of a very scabby bottom. Cinder patch can be overcome to a great extent by proper attention to bottom making. Some plants charge hot-top ingots of the big-end-up type upside down in the pits, thus

causing the cinder patch to be confined to the hot-top or discard portion of the ingot.

2. **Burned Steel**—This defect is very often the result of flame impingement on the surface of ingots, usually on their corners, as they are heated in the soaking pits, causing penetrating oxidation at the grain boundaries with a resultant tearing or rupturing of the ingot on the primary mill. A burned bloom is shown in Figure 26—4. Burned steel seldom can be salvaged and normally must be scrapped. Some steels are more sensitive to burning than others.

CONDITIONING

FIG. 26-4. Surface of a "burned" steel bloom.

FIG. 26-5. A lap on the surface of a rolled steel billet.

3. **Laps**—Laps are the result of overfilling in the mill passes that causes fins or projections which turn down as the material rolls through succeeding stands in the mill train.

A lapped billet is shown in Figure 26-5. Laps usually are deep and the product often cannot be salvaged economically.

The foregoing list of defects is not all-inclusive, but presents merely the more important causes of surface defects that require removal in conditioning. There are numerous other defects, such as: twist, guide marks, collar cut, diamond, bent, crop ends, and so on, the names of which are self-explanatory. Most of these will receive attention at various points in the text.

SECTION 2

INSPECTION

Conditioning is that function of steel manufacture which, by removal of defects, renders steel more suitable for subsequent hot- and/or cold-forming operations. Of primary importance is the detection and proper removal of the defects where required. It is neither economical nor always necessary (and, strictly speaking, probably not possible) to remove all of the imperfections.

What, if anything, is removed is determined by the prospective subsequent operations and final end use of the product. The following paragraph is an example of the method for determining the conditioning practice in a plant producing semi-finished steel for bar products.

Using an arbitrary classification, product end uses can be grouped to include under one class semi-finished products which require the removal of all surface defects visible after pickling or skinning. As an example of this class of material, if the steel is intended for alloy-steel bars of high hardenability and the bars are further quenched in oil after reheating, it is obvious that any light seams may result in quench cracks, so that all

defects should be removed from the semi-finished steel. In a second example, where the material is to be rolled or forged to some finished form, but not heat-treated, oxidation during the reheating for rolling or forging will eliminate, in many cases, slight surface imperfections, and semi-finished products for this use could be placed in another class for which removal of only those defects visually detectable without pickling would be required. If material is to receive considerable work in further hot rolling or cold machining, even medium-sized seams can be acceptable, offering another classification which might be defined as a class of material requiring the removal of only major defects such as scabs, ingot cracks, laps, and deep seams. Finally, the remainder of the product can be placed in a class from which only those defects need be removed such as large scabs or ingot cracks, deep laps, and burned steel which might be damaging to either or both the final product or the operation (such as subsequent hot rolling where large scabs might cause cobbles on the mill, tear out the

guides or cause other damage). Thus, it can be seen that the basis for inspection is predicated both on the end use of the product as well as upon the operations employed to shape the steel into its final form.

Pickling for Inspection—Pickling, as applied to surface inspection and conditioning, consists of immersing the steel in a chemical solution for the purpose of removing the scale on the outside surface so that defects will be exposed. The usual solution for ordinary steels is composed of 5 to 8 per cent sulphuric acid in water, used at temperatures between 150 and 180° F. A good, clean surface is desired for optimum results in inspection, and to attain this, relatively close control of temperature and acid concentration is necessary. A thorough rinse

after pickling is required, either by immersion in clean, hot water or washing with high pressure nozzles. The time required for pickling varies with the grade of steel; for example, a 10-ton lift of blooms of plain-carbon steel may require pickling for around 45 minutes, while the same quantity of constructional alloy steel may require treatment for from 1 to 2½ hours.

Pickling generally has been associated with hand chipping, as a dual operation. In those plants where hand scarfing has replaced hand chipping, the pickling practice has been abandoned, too. Modern practice for the same specifications is: for rectangular sections, to skin by scarfing and then spot scarf where needed; for round sections, to peel mechanically and then spot scarf.

SECTION 3

REMOVAL OF DEFECTS

Hand Chipping—Until a few years prior to the First World War, the practice of extensive conditioning of semi-finished steel was almost unknown except for seamless tubes and special forgings. For most purposes, the use of a cold chisel and hand hammer was about all the work that was done, and this only to knock off such things as large slivers or scabs that might tear out the guides in rolling on a secondary mill. For the most part, steel was either accepted or scrapped in the semi-finished form. It is not to be assumed from this that a good deal of unusable material was produced, for it must be borne in mind that, in those days, a great deal of stock-removal in machining was accepted as commonplace and the tolerances for finished work were much wider. This was the only method of steel preparation used to any great extent until the early 1930's.

Hand chipping, as it is known today, consists of using a pneumatic hammer with a cold chisel placed in the barrel, so that the reciprocating action of the piston on the chisel causes the chisel to cut into the steel and remove the surface to the desired extent. Figure 26-6 shows a close-up view of a chipper at work.

Machine Chipping—There are available several large machines built specifically for the purpose of removing

imperfections from the surface of steel blooms and billets. These machines fall into two general types: the planer and the milling machine.

The planer type, illustrated in Figure 26-7, is constructed with a large table which can be moved longitudinally and a tool holder which can be moved to any position in a plane vertical to the table motion. The steel is clamped onto the table by mechanical or hydraulic vise-type jaws. The table then is operated to move in a horizontal direction, back and forth in a reversing motion, so that the steel passes under the tool. The tool can be adjusted while the machine is in operation. The distance of travel and the depth of cut are governed by the operator. Speeds are varied in accordance with the hardness of the steel and the depth of cut desired. In this manner, any length of cut or repeated cuts in depth can be made, so that either complete skinning or partial surface removal can be accomplished.

The milling machine, typified in Figure 26-8, is constructed with a multiple set of tools in a revolving head. The steel is clamped in a stationary position, and the tool head can be moved in a horizontal as well as a vertical direction so that surface removal can be restricted to selected spots or the piece being conditioned

FIG. 26-6. Chipper using a pneumatic hammer equipped with a cold chisel for removing selected portions of steel billet surface.

CONDITIONING

FIG. 26-9. A scarfing torch in use removing surface imperfections from a rolled steel slab.

can be skinned completely. The entire frame of the machine carrying the tool is capable of traveling the entire length of the pieces processed.

Scarfing—Scarfing in the steel mill consists of surface removal by the use of oxygen torches (Figures 26—9, 26—11 and 26—14). The oxygen rapidly oxidizes the steel surface, generating elevated temperatures that cause the oxidized product to become liquid. The process can be carried out on hot steel between stages of rolling, when hot scarfing machines are used, or on cold steel in the conditioning area by the use of the hand torch. In principle, the tip of the scarfing torch is similar to the regular oxygen-gas torches used for the burning of steel. As early as 1919, surface-defect removal on semi-finished steel was attempted by hand scarfing, but because of lack of knowledge of proper torch design and the difficulties encountered with the fuel gas, the results obtained were unsatisfactory. During the 1920's, some attempts at specialized uses of torches met with success, but it was not until 1929 that a determined effort was made to procure fuels and equipment to perform satisfactorily the function of defect removal from the surface of semi-finished steels. Promotion of the chemical reaction that forms the melted iron oxide is not the only function of the oxygen; its kinetic energy must also force the liquid, oxidized metal from the path of the torch.

Hand Scarfing of Cold Steel—As might be expected, the first hand torches, though successful, were cumbersome and slow, but since 1929 many outstanding improvements have been effected so that the bulk of semi-finished steel now is conditioned by the scarfing method. So far, only oxygen has been mentioned, but fuel gas, too, is necessary to the functioning of the scarfing torch. The gas acts as a preheating agent to elevate a spot on the steel surface to such a temperature that the oxygen and the steel will begin to combine chemically. Once this preheating has been accomplished, the heat of reaction between oxygen and iron produces sufficient heat in front of the torch tip to maintain the reaction and fuel gas is no longer a necessary part of the operation. An interesting development with respect to this spot pre-heating is the so-called **starting rod**, which is a small rod of steel that extends into the flame and is heated until a small drop of melted rod falls onto the steel surface, thus instantly kindling the reaction. The melting of this steel rod is a matter of a fraction of a second as opposed to the 6 or 8 seconds required to heat sufficiently a spot on the steel surface with the flame alone. Many different types of torches and many different kinds of fuel gases are employed currently.

Perhaps the largest tonnage of all conditioned steel is processed by hand scarfing. Scarfing can be used for both small and large sizes down to about 2 inches by 2 inches, below which a bowing effect is produced.

A factor present in scarfing cold steel which is not present in other types of conditioning previously de-

scribed might be termed the metallurgy of scarfing. When a relatively small portion of a large piece of steel, such as the area adjacent to a cut made by the scarfing torch, is heated to a high temperature and the source of heat is suddenly removed, a **quenching effect** is produced by the rapid extraction of heat from the hot area by conduction of heat into the surrounding relatively cold areas. This rapid cooling of a heated portion of steel from a temperature above its critical temperature range causes it to harden, to a degree proportionate to its carbon content and to some extent also to the hardenability of the particular steel being scarfed. In plain low-carbon steel, this effect is not noticeable, but as the content of carbon or alloying elements increases, the effect becomes more and more severe, producing, in the extreme case, a hard, martensitic layer on the surface where scarfing has been performed.

This hardened surface will crack upon cooling if no preventive measures are taken. Scarfing cracks on a billet are shown in Figure 26—10. To prevent scarfing cracks, preheating before scarfing to temperatures between 300 and 500° F normally will suffice, although in highly critical grades, such as SAE 52100 (1.0 per cent carbon, 1.3-1.6 per cent chromium), postheating for stress relief after scarfing also should be employed. To eliminate completely the hardened surface, a normalizing or annealing heat treatment is necessary. Ordinary brick pits, gas fired, can be used for routine preheating before scarfing, where a sufficient tonnage of sensitive steels is involved. Conventional car-bottom or continuous heat-treating furnaces are employed for complete softening of the steel by heat treatment. The necessity for proper preheating of some steels cannot be over-emphasized, since scarfing cracks cannot be tolerated in finished products.

Mechanical Scarfing of Hot Steel—The mechanical hot scarfer (Figure 26—11) originated about 1930. It is installed directly in the mill line, and is composed of a number of scarfing torches so designed that they form a pass on the mill. The torches are used in exactly the same manner as the hand torch. A starting rod is not used because the high temperature of the product being rolled is enough to obtain quick starting action. The working speed of the machine must be coordinated with the mill so that no delay in rolling production is encountered. Only a moderate amount of metal can be removed but very satisfactory results can be obtained in conditioning some products. This equipment is not confined to four-side removal, but has been employed for two-side removal (of slab edges and the like). Such machines can be designed to meet the needs of individual mills.

Grinding—Conditioning by grinding also is in general use. For semi-finished steels, the **stationary** or **swing-frame grinder** is employed. This machine consists of a large grinding stone, up to 24 inches in diameter, electrically driven. The machine is suspended so that it can

FIG. 26—10. Surface cracks resulting from scarfing to remove surface imperfections from a rolled steel billet.

FIG. 26—14. Overall view of a bloom-turning machine showing a bloom on the supporting arms being scarfed.

be raised or lowered readily to suit the product being ground. When the material is positioned properly and held firmly, the operator grasps the handle bars and, by body pressure, forces the revolving stone against that portion of the surface to be removed, moving the stone with a slight back and forth horizontal movement until the defect is gone (Figure 26—12). The grinding wheel can be considered as a revolving cylinder carrying many sharp tools, which are the abrasive grains. When revolving at a proper speed, the grains cut very small chips from the material being ground. It is, therefore, the cumulative effect of the action of a very large number of cutting points which produces the result. Grinding cracks can result from the heat generated by grinding unless the proper wheels are used; this occurrence is related to the quenching effect discussed under "Hand Scarfing of Cold Steel."

Grinding is a more or less specialized process, being particularly adaptable to stainless steel and other products which cannot be scarfed or chipped.

Material Handling—New developments in the material handling field are being employed in increasing numbers to simplify the handling and stocking of material for conditioning. The use of **straddle carriers** (Figure 26—13), in some plants which have large conveniently located vacant areas, has revolutionized the transporting of semi-finished material, permitting flexibility and simplification of stocking areas, improved scheduling and better control of inventory. **Bloom-turning machines** (Figure 26—14) safely and efficiently position material automatically for hand scarfing, permitting increased tonnage to be conditioned. These machines are designed to be loaded and unloaded by fork lift trucks, eliminating the need for cranes.

SECTION 4

CONTROLLED COOLING OF SEMI-FINISHED PRODUCTS

Blooms, billets and slabs are rolled at temperatures well above the critical temperature range of the steel and thus, in cooling to atmospheric temperature after rolling, must pass through its transformation range. Depending upon the chemical composition of the steel and the size of product rolled from it, it may be necessary to retard the rate of cooling by artificial means for two reasons:

- (1) To prevent the formation of small internal ruptures, called flakes.
- (2) To minimize development of internal stresses.

Some steels are relatively very sensitive to rapid changes in temperature, and this thermal sensitivity requires that great care be exercised during both heating and cooling to avoid physical damage to the steel due to high internal stresses.

Nature and Prevention of Flakes—Flakes are small internal ruptures that usually occur some distance away from the end of a piece and often midway from the surface to the center of a section. Although there is not complete accord as to the relative importance of the

various factors contributing to flaking, it generally is considered that hydrogen dissolved in the molten steel makes it more susceptible to flakes and that proper retardation of cooling from forging or rolling temperatures effectively will prevent their formation.

Development of Controlled-Cooling Practices—The earliest method employed for retarding the rate of cooling after forging or rolling was to bury the steel, as it came from the press or mill, in ashes or some other insulating material such as sand or slag. The purpose of this was not to prevent flakes, but to retard the cooling sufficiently to lessen the hardness developed by the steel on cooling and to minimize the development of internal stresses. Rates of cooling varied greatly, depending upon the type of insulating material used and the depth to which the steel was covered. No positive control of cooling rates was possible with such crude methods, and the time required before the steel safely could be removed usually was two to ten days. Another method of slow cooling involved the use of unfired pits, lined with brick to provide insulation. After the steel was placed in these

FIG. 26—15. Cooling curves superimposed on isothermal transformation diagrams of two steels, showing cooling cycles employed to effect transformation in a minimum of time while still avoiding flake formation.

pits, they were covered with insulated lids, and the charge cooled at a rate dependent upon the mass of the charge and the rate at which heat was lost by radiation. In another method, steel boxes were inverted over piles or bundles of hot steel as it was delivered from the mill. Because of the space and long time required, and the difficulties involved in handling, the burying processes proved entirely inadequate as increased ton-nages of alloy steel came to be produced. Consequently, it became imperative to develop more suitable means for slow cooling.

In recent times, use has been made of automatically controlled furnaces, insulated and heated railway gondola cars with covers, and heavy pits equipped to control temperatures during slow cooling. With such equipment, it has been possible to take advantage of cooling cycles of considerably shorter duration with better control of results. When using equipment that makes possible close control of rate of cooling, the temperature of the steel can be lowered rapidly and arrested at the desired temperature which improved knowledge of heat-treating procedures has established as effective for each particular type of steel. After a suitable holding time, measured in hours instead of days (as was the case when the steel was simply buried in ashes), the steel can be removed and air cooled in the open, permitting prompt placement of the next charge in the furnace or pit.

Much experimental work has been done to determine the proper holding temperature for the different grades of steel. Figure 26-15 shows the cooling curves for AISI 4340 and 52100 steels superimposed on the isothermal transformation curves for these steels. The latter curves, formerly called "S" curves, show the time required to complete transformation at various temperature levels, and a more detailed description of their derivation and use will be found in a later chapter. The objective in selecting the holding time for each of these grades was to determine what temperature would require the minimum holding time to obtain transformation and still give a product free from flakes. In the case of the 52100 steel, 1200° F was selected as the temperature from which the billets could be air cooled. For the 4340 steel, holding at 1200° F was not feasible, as excessive time would be required for transformation. Since 600° F corresponded to the minimum time of holding, this was the temperature selected. Transformation in this

range would result in an appreciable amount of internal stress which might result in flakes on cooling in air to atmospheric temperature. Hence, instead of air cooling immediately after the end of the holding period, this particular steel should be heated instead to a temperature just below the critical range to relieve these stresses, after which it may be cooled.

These two types of cycles are applicable to a large number of different grades of steel, and the holding temperature for a particular grade can be determined from the proper isothermal transformation diagram. In general, the higher holding temperatures followed by air cooling can be used for the carbon and lower alloy grades of steel; the use of lower holding temperatures, followed by immediate reheating to just below the critical temperature range, is applicable to the more highly alloyed deep-hardening steels.

Chapter 27

ROLLING OF CARBON-STEEL PLATES

SECTION 1

PLATE-MILL OPERATIONS AND PRODUCTS

Plates are classified, by definition, according to certain size limitations, in order to distinguish them from sheet and strip. In accordance with this classification, carbon-steel plates are considered to be those flat, hot-rolled, finished, carbon-steel products that come within the following dimensional and weight limitations:

- 0.180 in. or thicker, over 48 in. wide
- 0.230 in. or thicker, over 6 in. wide
- 7.53 lb. per sq. ft. or heavier, over 48 in. wide
- 9.62 lb. per sq. ft. or heavier, over 6 in. wide

There are a few exceptions to the above classification. Flat hot-rolled semi-finished carbon-steel products such as slabs, sheet bar and skelp are not classed as plates, although their dimensions and weights may be included within the foregoing limits.

Plates are used in plate girders, chord sections, gussets, and other parts of bridges, in freight and tank cars, in ships, line pipe, storage tanks, penstocks, pressure vessels, machine-tool frames, weldments, galvanizing pots and many special applications.

Plates are produced by hot rolling, either from reheated slabs or directly from ingots. The terms applied to plates to differentiate between the several kinds are based upon the types of mills used in their production, e.g., sheared plate, or sheared mill plates when rolled between straight horizontal rolls and later trimmed on all edges. They are called universal plates, or universal mill plates (abbreviated U. M. plates) when rolled simultaneously between both plain horizontal and vertical rolls and trimmed on the ends only. Grooved rolls are sometimes substituted for the plain horizontal rolls used for universal plates.

Carbon-steel rolled floor plates are also flat, hot-rolled, finished steel products which come under the plate classification. Floor plates are hot-finished in the final pass or passes between one or more pairs of rolls. One roll of each pair has a pattern cut into it so that one surface of the plate passing between the rolls is forced into the depressions on the pattern roll to form a raised figure at regular intervals on the surface of the plate. Individual floor-plate patterns are produced exclusively by each manufacturer, the patterns differing in both dimensions and appearance.

In addition to carbon steels, the complete range of steel-plate production includes high-strength, alloy and stainless steels, which are discussed in later chapters relating to these individual subjects.

Carbon steels constitute the major plate-steel production, but a discussion of the rolling mills and auxiliaries is common to all plate-steel production. There are, however, even with carbon plate steel, special manufacturing and quality requirements which have been adopted by the industry. These are not dis-

cussed here, but are given in full in "Steel Products Manual, No. 6," issued by the American Iron and Steel Institute.

The several types of plate mills, their design features and operation are discussed in the following paragraphs, and descriptions are given of individual mills, including sheared plate, universal plate, continuous and semi-continuous types.

Mill Operations—The sequence of operations for plate mills is covered by the following general subdivisions:

1. Heating the slabs for rolling
2. Descaling
3. Rolling plates
4. Leveling or flattening
5. Cooling
6. Shearing

Heating (General)—The era of the predominance of three-high plate mills was coincident with the development of open-hearth furnaces in which furnace capacities were relatively small, ranging from 40 to 100 tons. Ingots, with the exception of those poured for armor plates, were also relatively small and 40-inch maximum width dimensions were about the largest produced. The three-high mills, however, were not as restricted in the production of plate-size ranges as might be inferred from the restricted ingot sizes. Slabs were conveyed to the mill in a broadside position and after the requisite number of passes were taken to attain plate widths, turning hooks attached to rigid masts were employed to turn the stock 90 degrees by utilizing table traction. The stock was then reduced to final thickness in successive passes. Batch-type heating furnaces provided the additional flexibility of permitting slabs to be provided either for single units of the ordered plate size or for a range of multiples that would best conform to physical equipment limitations and operating economies.

Plate-producing plants were laid out so that slabs from the primary mills could be conveyed or transported to the batch furnaces as hot charges. Such layouts were motivated by the considerations: (1) that small ingots were not so susceptible as large ingots to being the source of major surface defects that carried through to the finished product; (2) that economical, intermediate-conditioning processes had not yet been developed; and (3) that the economies of increased production rates from hot charges would more than offset the surface rejections which might be incurred.

Heating in a fuel-fired batch furnace is essentially a process of transmitting heat by radiation and convection from the combustibles to the top slab surface and by conduction through the thickness of the slab to the bottom surface and the hearth. Even where the tem-

peratures of both the hearth and the charge are high in relation to the drawing temperature at the beginning of a cycle of charges and draws, the heating rates per square foot of furnace area are low in contrast with continuous slab-heating furnaces. When the cycle involves cold charges, the initial abstraction of heat from the hearth, which must be restored later in the cycle, slows the process to the point where continuous operation is impracticable, if the heating capacity was installed initially for hot charges. The process of heating from top to bottom through the thickness, in itself, suggests the existence of a temperature differential which can be minimized only by soaking. Changes which have occurred in the industry in the past thirty-five years have created a trend in the direction of cold charges and have confronted many plants with the necessity of determining whether to operate mills on an intermittent basis, add heating capacity, or build new mills.

Furnace-control equipment is intended not only to effect fuel economies, but also to improve the quality of heating. Slab heating is improved if slabs are brought to the plastic state most satisfactory for rolling, with a minimum of temperature variation in each slab without any part ever attaining an excessive temperature, and with the production of a scale coating conducive to the best surface finish. The thickness and the type of scale formation is dependent on temperature, time at temperature, and availability of oxygen. The temperature that must be used is dependent upon the required plastic state of the heated steel; time of heating is controlled by the heating capacity of the furnace; therefore, control of the fuel-air ratio is the only flexible practical determinant of the types of scale that may be formed, which may vary from extremely adherent to loose. Automatic furnace-control equipment was not available when the bulk of existing batch furnaces was designed. Some were modified later to permit installation of controls. Several furnaces, such as at Homestead District Works, built during World War II, were designed for and equipped with automatic furnace controls. The preponderant number of batch furnaces still in operation are dependent on manual control.

Most of the existing continuous slab-heating furnaces were designed for and are operated on cold charges. The slabs are charged into the low-temperature end of the furnace and progress toward the high-temperature end by being pushed progressively forward on water-cooled skids. Burners located above and below

the skid level furnish heat by radiation and convection to both the top and the bottom surfaces of the slabs until they reach the high-temperature zone, which is, in effect, a soaking zone. Only top burners are provided for the high-temperature zone. The slabs are at approximate rolling temperature when they arrive in this zone, and elimination of skid marks (visibly colder "stripes" on slabs caused by contact with the water-cooled skids) and other temperature non-uniformities, plus making up radiation losses to maintain the desired furnace temperature, are the principal heat requirements to be met. Slab-heating furnaces of this type either had furnace controls included in the original design or they were added later, inasmuch as such furnaces are very adaptable to automatically controlled operation. Scale formation, consequently, can be controlled closely with respect to both thickness and type.

Descaling Methods and Equipment—Prior to the introduction of the modern hydraulic pressure sprays, various expedients were resorted to for primary scale removal. Moistened burlap thrown on the slab at the entry side of the rolling mill embodied the same scale-removing principle as the more common use of salt. In both instances the materials were used to get moisture between the work rolls and the stock, where it vaporized instantaneously with explosive effects and removed the scale. Of all flat, hot-rolled products, hot-rolled sheet and strip must meet the most stringent surface finish requirements, and it was natural that scale-removal methods and equipment would first reach their maximum development in connection with those product classifications which were rolled on continuous mills. The trend of development moved in the direction of the use of a leading roll stand in which light drafts were taken for the initial breaking of the scale. Hydraulic sprays, impinging on both top and bottom surfaces, were placed on the delivery side of the scale breaker and on the entry side of the roughing stands and the first finishing stand. Hydraulic pressures were increased with various installations from the 600 to 800 pounds per square inch which prevailed for general plant hydraulic equipment, up to 1,500 pounds per square inch. It was found, however, that with proper heating, spray pressures of 1,000 pounds per square inch were adequate for the production of surface finishes to meet consistently the most stringent requirements. The continuous hot-strip mill method of scale removal was, therefore, adopted for new plate-mill installations.

SECTION 2

GENERAL TYPES AND OPERATING CHARACTERISTICS OF PLATE MILLS

In this section, general design and operating features of plate mills of several types will be compared. Detailed descriptions of existing plate mills will be given in Section 3.

Plate-rolling mills are generally considered in two very broad design classifications. One type includes the universal mills, which are characterized by vertical rolls preceding and following the horizontal rolls. The horizontal and the vertical rolls are integrated into a single mill unit and work the stock simultaneously. The purpose of the vertical rolls is not only to work the edges of the stock in the process of reduction, but also to produce a rolled width in conformance with specified standard tolerances.

The second type includes the sheared-plate mills,

some of which may include edge-working equipment. While some installations use the edging equipment for both edge working and approximate width sizing, final widths are attained by edge shearing. Sheared-plate mills, in turn, may be subdivided into the following mill types: (1) the single-stand two-high pull-over mill, (2) the single-stand two-high reversing mill, (3) the conventional three-high mill, (4) the four-high reversing mill, (5) the tandem mill, (6) the semi-continuous mill, and (7) the continuous mill. In addition to the distinct types mentioned, a variety of tandem combinations are in operation. If the characteristics of the five distinct types are understood, the working characteristics of a variety of possible tandem arrangements readily can be inferred.

TWO-HIGH PULL-OVER MILLS

The two-high pull-over plate mills were essentially an adaptation of the then existing sheet mills to plate rolling. Prior to the development of mechanical passers, single-stand hot sheet mills were drafted in one direction only, and the sheet packs were returned for successive passes by being lifted manually on to the top roll and pulled over by hand to the starting or entry side with the aid of the tractive friction of the top roll. Roll settings were altered after each pass by hand operation of levers, which rotated the head screws. Plates rolled on these mills were limited in size and weight by the ability to handle manually. This restricted their utility and soon rendered these mills obsolete for producing finished plate. Two-high non-reversing mills still are in operation, however, in the form of single-pass units, such as scale breakers and roughers, in tandem arrangements in which the finishing-mill unit is either a three- or a four-high mill.

TWO-HIGH SINGLE-STAND REVERSING MILLS

Hot-rolled sheet production by the pack method antedated volume tonnage production, and recognition of the impracticability of handling similarly the heavier plate weights prompted the introduction of reversing engines for two-high mills. These mills, likewise, soon reached their practical limit of application, particularly with respect to the production of the wide, lighter-gage plate. The fact that all passes from slab to finished plate were made on the same set of rolls accelerated roll wear, which is always greatest in the central portion of the roll body and in itself imposes a restriction on the gage that can be finished satisfactorily. Roll deflection is an important factor and, for the same roll diameter, increases with the body length for like reductions. An increase in the roll diameter to provide more strength and stiffness increases the separating force between the rolls for the same draft, because of the greater area of contact between the stock and the rolls. The lessening of roll deflection, therefore, progresses at a diminishing ratio with increasing roll diameters.

The art of casting massive rolls developed gradually. Increased roll separating forces for like reductions meant greater power requirements for rolling, as well as to overcome greater resistance to acceleration and deceleration. The design of reversing engines of increasing power also was a gradual development. Neither of these developments progressed sufficiently to meet expanding plate requirements prior to the invention of the three-high mill which overcame, at least to a degree, some of the principal drawbacks of the two-high reversing mill.

Operation of two-high single-stand reversing plate mills continued in England after they were largely displaced on the Continent and entirely displaced in this country. As they are obsolete in this country, a detailed description of any installation would have historical value only.

THREE-HIGH MILLS

The invention of the three-high mill provided design features which, to a degree, overcame some of the principal limitations of the two-high reversing type. In the three-high mill, the top and the bottom rolls are of large diameter, whereas the middle roll is friction-driven and usually about two-thirds of the diameter of the top and bottom rolls. The top roll can be raised and lowered in the housing by power-operated screws, and the middle roll can be brought into contact alternately with the top and the bottom rolls. In making the bottom pass, the stock passes between the middle and the bottom roll

while the top roll serves as a backup roll. The stock is raised on the delivery side by a tilting table for a return pass between the middle and the top roll, while the bottom roll serves as a backup roll. The sequence of alternate passes is continued until the stock is reduced to the desired finished plate thickness.

The middle roll is changed when combined roll wear produces a crowned plate which approaches the permissible tolerance limits. The replacement roll is itself crowned to compensate for the wear which already has taken place on the top and the bottom rolls. Successive replacements in the course of a week's rolling schedule are turned with progressively increased crowns to compensate for the continued wear of the top and the bottom rolls. During the weekly mill-repair shutdown, the top and the bottom rolls are either turned in place to their original contours or are replaced with newly dressed rolls. The cycle of replacement of middle rolls with progressively increased crowns is repeated in the following week.

The fact that one of the rolls in contact with the stock on each pass is of smaller diameter than is required for strength (the requisite strength being provided by the roll serving as a backup) reduces the total roll separating force for like drafts in contrast with a two-high mill. This principle, when applied to wide plate production, served to solve the problem of providing rolls of the required strength without being too massive. The fact that only one smaller-diameter roll needed to be replaced in the course of a rolling schedule for wear compensation, eased the roll-changing problem. The three-high roll arrangement, with tilting tables on entry and delivery sides, eliminated the necessity for using reversing engines. The tilting tables and the unidirectional main drives permitted a shortening of the rolling-time cycle and provided a temperature advantage in the finishing of light-gage plates. Continued trade demands for improved finishes, lighter gages, and closer and more uniform rolling to desired dimensions (width and thickness) for many applications, which the three-high mill could not meet consistently, hastened the development of the other plate-mill types.

FOUR-HIGH REVERSING MILLS

The development of the four-high reversing plate mill further increased the advantages which the three-high mill possessed when compared with the two-high reversing mill. The backup-roll to work-roll diameter ratios were increased to over two-to-one as compared with the three-to-two ratios prevailing in three-high mills. For like reductions, therefore, not only is the total roll separating force less, but also strength is provided for each pass by the backup rolls on both top and bottom sides. A four-high reversing plate mill was in operation in 1917 at the Coatesville, Pennsylvania, plant of the Lukens Steel Company; but the general adoption of the type for plate rolling was retarded until antifriction bearings for the rolls became available. Such bearings were developed for the hot-strip mills and the cold-reduction mills and their use was extended to four-high reversing plate mills. A concurrent development was the designing of multi-armature reversing motors for primary mills. The development of the latter motor types reduced the inertia effects of massive mill parts and their relation to acceleration and deceleration on reversals. The multi-armature motors replaced the reversing steam engines as prime movers.

TANDEM MILLS

Many of the original single-stand plate mills have been supplemented by an additional stand to form a

tandem plate mill. The various tandem-mill arrangements represent a wide variety of mill unit combinations, which achieve two principal objectives. When the total work of reducing slab to plate is divided between two mill stands, satisfactory surface finish and shape of rolls can be maintained for longer periods between roll changes. Secondly, since the work is divided between two units operating simultaneously, the required time interval for the reduction of a slab to a plate is reduced and the overall capacity of the unit is increased correspondingly.

A wide variety of tandem arrangements exists because they represent modifications of original rather than new installations, and because they were accomplished by the maximum utilization of existing equipment, the minimum expenditure for new equipment and a minimum of alteration to auxiliary facilities. The tandem arrangements, consequently, may include a two-high reversing rougher with a three-high finisher; a two-high reversing rougher with a four-high finisher; a three-high rougher with a three-high finisher; or a three-high rougher with a four-high finisher.

The two principal advantages of the tandem mills over the corresponding single-stand mills have been stated. No specific installation has mill or auxiliary equipment of engineering interest which is not covered in descriptions of more standardized arrangements.

SEMI-CONTINUOUS AND CONTINUOUS MILLS

These plate mills constitute the plate-mill groupings which include multipass, reversing, roughing units for the semi-continuous mills, and non-reversing roughing units for the continuous mills, coupled with two or more single-pass continuous units in which the plate is reduced simultaneously. Two-, three- and four-high stands with or without scale breakers, broadside stands, squeezers, and edgers are used as roughing units, while four-high stands are used as finishing units. The semi-continuous mill arrangement, although requiring a larger capital investment, has a number of operating advantages over both the single-stand and the tandem-mill types. The total reduction work is divided between individual stands to an even greater extent than in the case of the tandem mills. The roll wear of individual stands is, therefore, less than that of the prior mill types. The total time increment for reduction from slab to plate also is less, and the tonnage capacity per unit of time correspondingly is greater. The decreased time element permits sheets as well as plates to be rolled on these units.

UNIVERSAL MILLS

Universal plate mills are single-stand units which roll plates to width within standard tolerances. Although universal plate mills producing widths up to 60 inches have been in operation, the bulk of the installations has been of 48-inch width and under. The number of installations and the capacity has decreased rather than increased in the past several decades. This may be attributed to the development of the narrow as well as the wide continuous hot-strip mills, and to the development of the wide-flanged beam mills. The former mill types, particularly in the narrower widths, have displaced directly considerable universal-mill tonnage, owing to the improved surface finishes that can be obtained with the continuous hot-strip mills. The production of deep wide-flange beams displaced a large tonnage of fabricated beams and columns that formerly had utilized universal plates for the web portions. Consequently, the universal plate mills which are in operation today date back several decades to their installation

dates; and the unit which will be described in detail is typical in spite of its early construction date.

PLATE-ROLLING VARIABLES

The rolling of plates is subject to a number of variables. Control of temperature, if not properly effected, may cause variations in mechanical properties in steel from the same melt or lot of material. Inherent characteristics of equipment permit one mill to roll plates to closer limits for thickness, weight, width, length, camber (the greatest deviation from a straight line along a longitudinal edge), and flatness of plate after mill finishing-pass delivery and ordinary roller-leveler treatment.

Other variables affecting rolling are the **mill spring** (the total looseness under load of all mechanical parts) between the roll necks and the housings, which makes it necessary to increase spring allowances for light mill construction as compared with heavier or more rigid mill construction for the same loading.

Bending of rolls and resultant **crown** in the plates are also variables which affect the accuracy of rolling. When the rolls are subjected to the separating force of a plate being rolled between them, they are equivalent to beams supported at the bearing centers and subjected to a uniformly distributed load over the length. Uniformly loaded beams have maximum deflection in the center and a similar condition exists in the rolls. For the same drafts, small-diameter rolls are subject to less separating force than large-diameter rolls but the latter have greater resistance to deflection. The minimum roll deflection and plate crown are found in a mill with small-diameter work rolls backed up by large-diameter rolls. Crown (increase in thickness of the rolled center of the plate over its edges) is related to the amount of bending or deflection in the rolls. A minimum crown and uniform thickness of plates are desirable for many applications, especially forming operations.

Roll wear is an important factor in rolling plates. There is only one point in the arc of contact of the rolls with the stock at which the linear speed of the rolls and the stock is identical. As mentioned in Chapter 19, this is called the neutral point. There is backward slippage of the stock on the entry side and forward slippage on the delivery side of the neutral point. Slippage contributes to roll wear, and as the central portion of the roll face comes in contact with the stock on all widths, it is subject to the most wear and gradually develops a hollow contour across the roll face, accompanied by a surface roughness.

The effect of roll wear on plate crown and surface finish can be visualized readily. An additional effect relates to plate flatness and becomes more pronounced with the thinner plate gages. Roller levelers operate on the principle of imposing a slight extension, through the bending-roll action, on each increment of constricted plate surface as it goes through each bending action in the leveler. The extensions which can be imposed by the bending action are relatively slight and, even for these to be accomplished in one pass, a minimum state of plasticity (corresponding to that which obtains at the lower transformation temperature) generally is required.

Because edges of rolled plate cool faster than the center, the desired shape for entry into the leveler, particularly for light gages, is one with a slight edge wave. A mill which is too full will deliver light-gage plates with center buckles that require excessive edge extensions in the leveler to secure flat delivery. Conversely, a hollow mill will deliver light-gage plates with more

edge wave than can be compensated for by the limited extension of the central portions of the plate which can be accomplished in the leveler.

Temperature variation in the plate from the front end to the back is also a problem in rolling plates. Every roll pass involves a time interval for its accomplishment. In initial passes, when the stock is relatively thick and short, the time interval has no practical effect in creating a temperature differential from front to back. If the stock is being reduced to wide, light gage, and is elongated to long, thin lengths in the last several passes, the time interval will cause temperature differentials of such magnitude that the consequent gage differential must be anticipated in mill settings in order to retain the gage within tolerances. Differentials are minimized by shortening the time required for rolling.

Leveling (Flattening)—The amount of flattening required by the plate after leaving the rolls generally increases with decreasing thickness of the plate. The effectiveness with which flattening can be accomplished by a leveler increases with decreasing roll diameters and spacings and with increasing temperatures. For light-gage plates, therefore, a roller leveler with small-diameter rolls and with close roll spacings should be located near the mill finishing stand.

Heavier-gage plates, at corresponding temperatures, require greater strength and rigidity of rolls than lighter-gage plates. The heavier gages usually are delivered from the rolls at higher finishing temperatures and require accelerated cooling prior to leveler entry or the leveler must be located at a greater distance from the finishing stand to permit proper cooling before leveler entry. A compromise in roll diameters and leveler location may be satisfactory if the range of gages produced does not include extremes.

Levelers with small-diameter bending rolls backed up by short, rigidly supported backing-up rolls are used for cold releveling. They provide the requisite combination of severe bending and roll rigidity.

Cooling—Plates delivered from the roller leveler must

be cooled uniformly to avoid localized stresses that again would set up permanent localized distortions. As more heat is given up by the plate on contact with another metallic surface than by exposure to the atmosphere, it is necessary that cooling conveyors be so constructed that only momentary, staggered contacts are made with the bottom surface of the plate and cooling of the bottom side is effected primarily by radiation, similarly to the top surface. This cooling condition should be maintained until temperatures are reached at which the plates are no longer susceptible to distortion as a result of non-uniform cooling.

Shearing—All plates are sheared above atmospheric temperature in normal production. The most important factor in shearing plates to the desired size is the proper allowance for shrinkage. The cooling rate of plates decreases as they approach atmospheric temperature, consequently, extremely long cooling lines would be required to permit plates to cool sufficiently for accurate shearing to be done without the necessity for making allowance for shrinkage.

Manual layout of plates for shearing introduces some degree of deviation from theoretical accuracy. Mechanical layout machines and calibrated dials integral with the shearing equipment reduce the frequency and extent of deviations. The fundamental characteristics of the shearing equipment itself influence the degree of accuracy that can be attained consistently.

Identification, Inspection and Loading—Except for material in the lighter gages or narrower widths, each plate is marked by hand-stamping, painting or writing with chalk to show the heat number and any other necessary identification marks. It also is inspected for possible defects. If the order calls for special treatment such as annealing or other forms of heat-treatment, the plates are sent to the heat-treating department. Samples cut from the plates are usually subjected to the specified mechanical tests. If the plates meet the requirements, they then are loaded in railroad cars in accordance with standard loading practice.

SECTION 3

DESCRIPTIONS OF TYPICAL EXISTING PLATE MILLS

This section will describe several existing installations of plate mills of different types, beginning with a description of a three-high plate mill and its auxiliaries. The principle of the three-high mill and its advantages over earlier types has already been discussed in Section 2.

THREE-HIGH PLATE MILL

The 160-Inch Mill at Gary Works—The 160-inch plate mill at Gary Works, Figures 27—1 and 27—2, is typical of the single-stand three-high plate mills currently producing plates in a wide range of sizes. The furnace building parallels a conditioning yard which also is the delivery end of the primary mills supplying slabs to the plate mill. Slabs vary from 2½ to 24 inches in thickness, 50 to 66 inches in width and 57 to 130 inches in length with the weight ranging up to 44,000 pounds. Plates produced vary from ¼ to 14 inches in thickness, 48 to 148 inches in width and up to a maximum length of 720 inches. The maximum width of 148 inches is confined to the ¾- to 2-inch thickness range and is decreased progressively with lighter as well as heavier thicknesses. The maximum length of 720 inches is confined to the ½- to 3-inch thickness range and also progressively decreases with thicknesses outside of that range.

A minimum gage of ¼ inch rolled to a maximum width of 132 inches and a maximum length of 300 inches can be rolled satisfactorily for only a short time when roll conditions are ideal. A thickness of ⅝ inch is considered the minimum gage with rolls in the average condition.

The reheating furnaces are serviced by four 15-ton-capacity charging and drawing cranes with revolving mast, cage, and peel. The mill is serviced by ten in-and-out batch-type furnaces. Five of the furnaces are of the regenerative type, fired alternately from each end. These furnaces are controlled manually and, under continuous mill-operating conditions, develop a maximum heating capacity of 10 tons an hour per furnace at a fuel rate of 3,440,000 Btu per ton. One furnace, with a capacity of 8 tons per hour, is a continuous, recuperative furnace with a division wall dividing the hearth and the furnace into two sections, operating independently. The remaining four furnaces are of the recuperative design with full automatic control. These furnaces are divided and operate as two independent sections, similar to the furnace previously described. Capacities of 12 tons an hour per furnace were developed under the same conditions as previously stated, with a fuel consumption of 2,190,000 Btu per ton. All furnaces are

FIG. 27—1. The single-stand, three-high, 160-inch plate mill at Gary Works, showing the tilting tables at the entry and delivery sides.

fired with coke-oven gas as the primary fuel, with oil available as an alternate fuel.

Slabs are drawn from the furnaces and placed on a transfer car, which operates on trackage running the full length of the furnace building, and delivers the slabs to the mill approach table. This table extends toward the mill at 90 degrees to the furnace building. Thirty table rollers with 24-inch spacings convey the slab to the entry tilting table. Twenty-two table rollers with 21-inch spacings constitute the entry mill table which conveys the slab to the mill, and alternately receives the stock at the elevation of the top pass and re-enters the stock into the mill at the elevation of the bottom pass. The delivery mill table is of identical design and performs an identical function in addition to conveying the plate away from the mill after the final pass.

The top and bottom rolls, made from either grain or chill iron, are 44 inches in body diameter, 164 inches in body length, 30 inches in neck diameter, and 29 inches in neck length, and are turned with a $\frac{1}{64}$ -inch crown. Middle rolls made from chill iron are of 28-inch body diameter, 164-inch body length, 18-inch neck diameter, 29-inch neck length, and are turned with variable crown from $\frac{1}{64}$ to a maximum of $\frac{3}{32}$ inches.

The main roll necks are journalled in babbitt bearings with bronze inserts, and the middle roll necks are journalled in brass bearings. All roll-neck bearings are lubricated by an automatic forced-feed lubrication sys-

tem. The top roll is positioned through motor-driven screws and is balanced hydraulically. The middle roll is actuated through a leverage system and is balanced by counterweights. The middle roll is changed with the overhead crane and requires one hour for the operation. Main rolls are changed with a buggy-type roll-changing device, and a complete roll change requires an eight-hour period.

The main drive is a 7000-horsepower, 82-r.p.m. motor. Power is transmitted through a spindle to the middle pinion of a conventional three-pinion stand with pinion pitch diameters of 38 and 48 inches. Connecting spindles from the top and the bottom pinions transmit the power to the top and the bottom rolls.

Ninety-degree turning of the slab for width extension and turning again for resumption of length extension is accomplished by the manual operation of a large hook hinged on the entry side of the mill housing. Salt spread by hand on the slab surfaces in the initial passes, followed by high-pressure spray impingement in later passes, is the method of scale removal employed. Hydraulic pressure is supplied by motor-driven centrifugal pumps. Spray nozzles are directed at the bottom plate surface on the entry side, and on the top surface on the delivery side.

A 40-roll table conveys the plate from the delivery tilting table to the roller leveler. The leveler is a 9-roll machine with 5 bottom and 4 top rolls of 18-inch diameter and 13-foot 10-inch body length. The rolls are

Fig. 27—2. Schematic layout (not to scale) of the units comprising the 160-inch plate mill at Gary Steel Works.

spaced on 18¼-inch centers, and the top rolls may be adjusted individually in a vertical position through a selective screw-down assembly mounted on the housing. The unit is driven by a 250-horsepower, 750-r.p.m. motor reduced through gearing to drive the rolls at 40 r.p.m., equivalent to a surface speed of 200 feet per minute. Hydraulic sprays operating at a pressure of 500 pounds per square inch on the entry side serve to remove secondary scale as well as to increase the cooling rates of heavy plates which are passed back and forth through them.

The plates are delivered from the leveler over a table of rollers to a continuing roller table. At a distance of approximately 425 feet from the mill center line is the beginning of a plate-marking machine which operates parallel with the adjacent conveying table. The sheared width is inscribed as two parallel lines on the plate. The plate lengths are measured off manually, but also inscribed on the plate by a transverse motion of the machine.

From the marking machine, the plate is moved to a hydraulically operated, down-cut guillotine end shear which has a 166-inch opening between the housings. The plates are then conveyed to side shears on opposite sides of the table. The side shears are similar in construction and thickness capacity to the end shear, with the exception that these shears can make a cut of 184-inch length per stroke. All three shears are equipped with magnetic holddowns and auxiliary guillotine

shears for side- and end-scrap disposal. The side-shear tables also are equipped with positioning magnets for properly positioning the inscribed lines on the plates along the knife edges. Unloading tables and beds on the delivery side of the second side shear facilitate the removal of plates which require further processing in the stock building. Plates for direct shipment continue on to a transfer which carries them to a table line, which in turn conveys them into a shipping building parallel with and adjacent to the mill building. The end 125 feet of this table consists of four unloading-table sections, which have tilting arms that raise and permit the plate to slide on skids. A gravity-feed bed is located at the end of this building area which permits returning plates from the storage area to the shear roller line for further processing. Completely processed plates are moved either into designated floor locations for accumulation of carload lots or directly into railroad cars.

Auxiliary processing facilities are located in a stock building, at right angles to and adjoining the mill and the shipping buildings. A rotary-type, motor-driven circle shear is provided for cutting circles ranging from 24 to 150 inches in diameter in a ½-inch maximum thickness. A brick-lined, gas-fired, slow-cooling pit is provided for retarded cooling of plates when the grade and dimensions make this necessary. A gas-fired, car-type furnace also is provided for annealing, normalizing, stress-relieving, and preheating for flame cutting. This furnace has four heating zones, with individual temperature controls. Two cars of 120-ton load capacity are provided in order that one car may be in the process of loading or unloading while the other car is in the furnace. A total of eight burning beds, three of which are equipped with two gantry cranes each, auxiliary equipment for flame cutting, and high-frequency electric hand-grinders constitute some of the additional available auxiliary processing equipment.

FOUR-HIGH REVERSING PLATE MILL

Homestead District Works 160-Inch Four-High Mill—The 160-inch mill at Homestead District Works, Figure 27—3, has a cold-slab storage yard parallel and adjacent to the slab-conditioning yards of the 45-inch slabbing mill. The gross area of 51,700 square feet provides ample storage area for stocking approximately 15,000 tons of slabs in accordance with a predetermined rolling sequence. Six gas-fired preheating pits are located in this yard; each has a capacity of approximately 10 slabs (50 tons) and is capable of heating cold steel to a temperature of 1200° F in 24 hours. Three gas-fired pre-heating hoods, each with a capacity of approximately 120 tons, can heat cold steel to a temperature of 1600° F in 24 hours. Slabs are transferred to the reheating-furnace areas by two standard-gage shuttle-car transfers, powered by 25-ton, Diesel-electric locomotives.

The slab-heating equipment consists of two continuous-type furnaces and two batch or in-and-out type furnaces. The batch-type furnaces are designed to heat slabs of a maximum size of 144 inches long by 20½ inches thick. They are two-zone-controlled, end-fired, recuperative-type furnaces with an effective hearth area of 12 feet by 46 feet. They are designed to operate on a mixture of coke-oven and natural gas and have a rated heating capacity of 15 tons per hour from cold to 2250° F. Each furnace is provided with two doors composed of three sections without jambs, and each section may be operated independently. Either half of the furnace front may be opened with no obstruction other than the center jamb. These furnaces are served by a 20-ton, stiff-legged, 3-swivel charging crane which charges the cold slabs from the transfer car into the

FIG. 27—3. Diagram (not to scale) of the physical layout of equipment comprising the 160-inch plate mill at Homestead District Works.

furnace and draws the heated slabs and delivers them on to the furnace delivery table.

The continuous-type furnaces are designed to heat slabs from 3 to 12 inches thick, 44 to 60 inches wide and 70 to 120 inches long. They are conventional two-zone-controlled, triple-fired, end-charged-and-discharged, recuperative-type furnaces and have an effective heating length of 80 feet and width of 23 feet. The top and the bottom burners of the primary heating zone are designed to burn a mixture of coke-oven and natural gas as a primary fuel and also can burn fuel oil as an alternate fuel. Only the gas mixture is burned in the holding zone. The heating capacity of each furnace is approximately 70 tons per hour from cold to 2250° F with full hearth coverage.

The continuous furnaces are served by a 30-ton electric overhead traveling crane which takes the slabs from the transfer cars by magnet or slab-handling tongs, and

places them on the furnace charging table. The slabs are fed through the furnaces by double rack-type pushers arranged to feed two rows of slabs through each furnace (Figure 27—4). Slabs are discharged from the delivery end, and slide down the furnace dropout skids to the furnace delivery table against spring-backed bumpers.

Heated slabs are conveyed on a roller table from the furnaces to a scalebreaker stand (Figure 27—5) which is a two-high mill with fluted alloy-steel rolls of 36-inch body diameter, 70-inch length, operating in water-lubricated composition bearings. Additional lubrication is provided by shots of water-soluble oil at 20-minute intervals timed by an automatic timing device.

The top roll is balanced by carrier bars supported from a yoke which is actuated by hydraulic jacks and accumulator to hold the top roll against the housing screw. The screws are operated by 50-horsepower motors through worm reduction gearing at a lineal vertical speed of 11 inches per minute. The rolls are changed at approximately one-month intervals under normal operating conditions. Approximately four hours are required to make the roll change with the use of a "C" hook and an overhead crane.

The mill is driven by a 1600-horsepower, 375-r.p.m. motor. Power is transmitted through a 15.68-to-1 double-reduction flywheel gear drive, a universal leading spindle, mill pinions and universal mill spindles, resulting in a lineal roll speed of 295.6 feet per minute. A meter in the pulpit gives the operator a reading of the opening between rolls at all times. Drafts of ½ inch may be taken on this stand, and the passage of the slab is guided to and from the mill by twin adjustable side-guides. Primary descaling is completed on the delivery side of the mill as the slab is passed through top and bottom hydraulic sprays operating at a pressure of 1,500 pounds per square inch.

The 160-inch reversing-mill stand (Figure 27—6) is separated from the scale breaker by a distance of 160 feet, spanned by 40 feet of 72-inch-wide table and 120 feet of 168-inch-wide table. All table rollers in this mill are journaled in antifriction bearings. A lift-and-turn table device is located on the reversing-mill side of the junction between the narrow and the wide table sections. The turntable is elevated and lowered by oil-hydraulic pressure and turned by a motor-operated rack and pinion. This permits either straightaway or broadside slab entry into the reversing mill. When spreading is required in the first pass, the slab may be entered following the preceding plate without a turning delay.

The crowned (0.024-inch maximum) alloy-iron work rolls of the four-high reversing stand have a body diameter of 38 inches, a body length of 160 inches, a neck diameter of 26.991 inches, and a neck length of 39 inches. The necks are fitted into the inner races of four-row tapered roller bearings. The alloy-steel backup rolls have a 59-inch body diameter, a 154-inch body length, a 33-inch neck diameter, and a 52-inch neck length. The roll necks operate in oil-film bearings at 17-pounds-per-square-inch oil pressure, through which the roll-separating force is transmitted. Thrust is taken by two-row steep-angle tapered thrust bearings. The top rolls are balanced by hydraulic jacks mounted in the bottom backup chucks, with the hydraulic system operating at 3700 pounds per square inch. An automatic forced-feed lubricating system is connected with all wearing surfaces on the mill other than the oil-film bearings.

Three sets of work rolls are used in the course of a normal weekly rolling schedule. Approximately one

FIG. 27-4. General view of the charging end of continuous-type reheating furnaces supplying hot slabs to the 160-inch plate mill at Homestead District Works.

FIG. 27-5. Close-up view of the scalebreaker stand of the 160-inch plate mill at Homestead District Works.

FIG. 27-6. The 160-inch reversing mill stand of the 160-inch plate mill at Homestead District Works, showing powered side guards for squaring and centering slabs and holding plates during the rolling operation.

hour is required for a work-roll change, which is accomplished by an overhead crane-suspended "C" hook, equipped with a motor-driven shifting device that positions the hook suspension over the center of gravity of the unloaded or loaded hook. The average time between complete roll changes, including the backup rolls, is three weeks. The complete roll change requires approximately ten hours, with the backup rolls being moved in and out of the mill on a motor-driven slide.

The main mill drive consists of two 5000-horsepower, DC, reversing motors, each directly connected to a work roll through universal spindles 36 feet long. The motor speed range is from 40 to 80 r.p.m., which provides a roll surface speed of 400 to 800 feet per minute. The mill screws are operated by two 150-horsepower mill-type motors, supplied by a variable-voltage motor-generator set. A 13-pass, 2-schedule, pre-set, automatic screw-down control, with optional manual control, is provided for this mill. Provision is made to set up one schedule while another is being run. The control is operated by the screw-down operator, who also reverses the mill drive and who can make manual adjustments to the screw settings by interrupting any automatic setting without affecting the accuracy of the following automatic stop. The mill is capable of producing the minimum gage of $\frac{3}{16}$ inch to sheared widths of 120 inches. Auxiliary facility limitations restrict the sheared-plate gages to a $\frac{3}{16}$ to $1\frac{1}{2}$ -inch range, widths to a $38\frac{1}{2}$ to 144-inch range and lengths to a 720-inch maximum. Flame-cut plates range from $1\frac{1}{2}$ to 15-inch thickness and a maximum of 144 and 480 inches in width and length, respectively.

The front and the rear mill tables are 33 feet long and have tapered table rollers with a taper of 1 inch in 14 feet. Even-numbered rollers all are tapered in the same direction and driven as a unit. Odd-numbered rollers are tapered in the opposite direction and also are driven as a unit. By rotating the alternate roller units in opposite directions, it is possible to turn a slab 90 degrees as desired. Heavy, powered side-guards are on each side of the mill for squaring and centering the slabs and holding the plates during the rolling opera-

tion. Hydraulic sprays on both sides of the mill, operating at a pressure of 1400 pounds per square inch, are utilized for top and bottom secondary scale removal.

The remainder of the 216-foot distance between the center line of the four-high mill and the leveler is occupied by a conveying table. Top and bottom water sprays span 180 feet of this distance to facilitate the cooling of heavier-gaged plates prior to leveler entry and to retard secondary scale formation. A section of the table on each side of the leveler is designed to permit plate removal by a "C" hook suspended from an overhead crane. The plates may be transferred to either one of two motor-driven transfer cars and subsequently transferred to the cooling area of the adjacent flame-cutting building or to the controlled-cooling facilities located in the shipping yard.

The leveler has two 16-inch diameter by 160-inch long entry pinch rolls and 6 top and 5 bottom 13-inch diameter by 160-inch long bending rolls. The machine is driven by a 250-horsepower, 400 r.p.m. motor, and positioning is accomplished through a selective screw-down assembly which is equipped with drum indicators located at all four corners of the leveler housing. The leveler can level structural-grade plates of $1\frac{1}{2}$ -inch thickness and can be raised to a maximum passage opening of 6 inches.

One hundred forty feet of the 275-foot distance from the leveler to a transfer stop is part of a chain-transfer cooling bed. This grid-type bed spans a distance of 120 feet and delivers the plates from the mill building onto a 292-foot disc-roller marking table located in the shear building. A motor-propelled automatic measuring and marking machine traverses a 140-foot distance parallel with this table. Indexed longitudinal and transverse movements enable the operator to measure and mark off mechanically any desired size and shape of a rectangular plate, and scribe a reference line which is used by the side-shear operator in the trimming of the side scrap. Beyond the marking machine, all required identification stamping and painting of the plates and test coupons are performed manually prior to entry in the crop shear.

The down-cut guillotine crop shear with knife blades 160 inches long and a knife rake of $\frac{1}{2}$ inch per foot is capable, in common with the main line shear units, of cutting 1½-inch gage to the maximum width produced. Powered mechanical manipulators are available for the square positioning of the plate. Oil hydraulic hold-down gags operating at 1700 pounds per square inch furnish positive clamping for the shearing stroke. The shear operates on the oil-hydraulic principle at pressures of 7000 to 9000 pounds per square inch, and has a self-contained pump with motor drive. The crop shear is used for dividing plates that are too long to pass over a second transfer, and for front-end shearing of heavy, wide plates, which must be free of shear bow.

Plates from the crop shear are delivered either to another chain transfer or to a 40-foot table section beyond the transfer, which is equipped with roll-off lifting arms and a side piling bed. This run-off and piling bed is utilized to divert flame-cut plates of such size and composition that will permit their conveyance to this point without the necessity of slow-cooling cycles. Plates to be finish-sheared are moved across the transfer to the transfer run-out tables, which double back through the shear building and are parallel to the marking line.

The main shear line consists of two side shears and one end shear. These shears are similar in design and construction to the crop shear, with the exception that the side shears have knives 180 inches in length. The side shears are staggered on either side of the table and are 78 feet apart. The side crop is sheared at the first side shear by positioning the plates to the reference line. A series of electromagnets with hydraulic vertical motion and screw drive transverse motion are utilized to position the plate so that the reference line is matched with a positioning line on the shear block. A mechanical width-gage guide is provided at the second side shear, which facilitates the positioning of the plate by working against the finished sheared edge; and its position in relation to the shear knife is recorded on a dial located on the shear housing. The end shear, located 84 feet from the second side shear, is a duplicate of the crop shear and is equipped with squaring pushers located on the entry side, and two motorized gage stops on the delivery side, which gage plates mechanically to predetermined lengths. One stop is used for short and the other for long lengths in the 60- to 720-inch sheared-length range.

The crop and end shear equipment consists of 150-horsepower motor-driven guillotine-type scrap shears capable of cutting a 33-square-inch cross-sectional area. A butterfly chute arrangement diverts test coupons, "block sheared," to a test box in which they are periodically delivered to a test-cutting shear for final handling. The test-cutting shear is also a motor-driven guillotine-type shear with a capacity of 27 square inches of cross-sectional area. The side shears are provided with 75-horsepower motor-driven alligator-type scrap shears with a capacity of 30 square inches of cross-sectional area. Side scrap is fed to the scrap shears by conveyors located below the table level, and the cut scrap is guided to removal buckets through gravity chutes.

Plates are delivered from the end shear to a 720-inch scale table, where they are weighed individually. They then proceed to a table section spanned by two transverse, selective, electromagnetic-type piling cranes. One crane can handle a 360-inch plate length, and the two cranes working together can handle a 720-inch plate length. Lifting force of the magnets can be regulated at will to provide a wide range in the lift combi-

nations. The cranes transfer the plates into the shipping building and deposit and pile them on gravity conveyor tables. The piles are moved by a conveyor-chain dog into positions from which they can be picked up by the overhead shipping cranes.

The shipping building is 110 feet wide by 1,100 feet long and is equipped with a shipping track extending its entire length. A connecting spur track of an 8-car capacity is located in an adjoining lean-to section of the building. This track is not serviced by overhead cranes and is used for preparing cars which require special blocking, either prior to or after loading. The shipping building is serviced by four 30-ton electric overhead traveling cranes of the double-hoist type. This building also is equipped with controlled-cooling hoods. Two additional inlets into this yard, other than the piling cranes just mentioned, are provided in the form of motor-driven transfer cars located at the extreme ends of the building. One car delivers directly from the mill building, and the other car delivers from the flame-cutting unit located in the end of the shear building.

The flame-cutting unit, located at the end of the shear building, is equipped with a flame planer, three pantographs, and sketch-cutting machines. The flame planer is designed primarily for side and end trimming as well as splitting rectangular-shaped plates. The pantograph machines are designed primarily for intricate shape cutting, although they can be used efficiently for cutting rectangular shapes. Magnetic tracing mechanisms, traveling over templates or operated manually over sketch drawings, guide the torch through the course desired.

Another flame-cutting unit is located in a building parallel and adjacent to the mill building. A continuation of this building merges with the end of the continuous-furnace building, and the two 30-ton cranes servicing this unit operate on a common runway with the crane servicing the continuous furnaces. This unit is equipped with three pantograph sketch-cutting machines, two large heat-treating ovens, and a heat-treating pit. The heat-treating facilities are used extensively in preheating, stress-relieving, normalizing and the controlled cooling of flame-cut products requiring these treatments. The heat-treating ovens also can be used for preheating slabs prior to charging in the slab-heating furnaces when such practice is necessary. Cooling skids are provided in this area for heavy-gage plates which are transferred hot from the mill by a 200-ton transfer car previously mentioned.

The greasing system for all table bearings, spindles, spindle carriers, jacks, slide joints, etc., is of the automatic "single-line" reversing type and contains eleven major pumping units.

Oil lubrication for the majority of the equipment, such as table line shafts, gears and bearings, leveler drives, screw-down drives, reduction gears, pinions, backup-roll bearings, and motor-room equipment, is accomplished by circulating systems of the single- and double-tank types.

SEMI-CONTINUOUS PLATE MILL

The 100-Inch Semi-Continuous Plate Mill at Homestead District Works—The 100-inch semi-continuous plate mill at Homestead District Works (Figures 27-7 and 27-8) has a slab-storage yard with an area of 66,000 square feet, having a slab-storage capacity of 18,000 tons stocked in rolling sequence. It adjoins two buildings of corresponding dimensions and area in which slabs produced by the 45-inch slabbing mill are cooled and conditioned. Two gas-fired, insulated, fabricated-steel preheaters, each having a capacity of 70

FIG. 27-7. General view of the 100-inch semi-continuous plate mill at the Homestead District Works.

tons, are located in this yard. Slabs are placed in lifts on a yard table which delivers them to a magazine feeder located in the slab-storage yard which serves as an intermediate unit between the yard and the furnace tables. These tables, as well as all others in this mill, are equipped with anti-friction bearings.

The feeder raises each pile of slabs to the level of the furnace charging table and discharges them one at a time onto the furnace table by an endless chain pusher. The slabs then are positioned in front of the furnace doors for charging by two pushers which can be operated independently or in unison for each furnace. The mill is served by four conventional, continuous, triple-zoned furnaces with non-metallic recuperators. The furnaces have an effective heating length of 76 feet, 10 inches. A mixture of natural and coke-oven gas is the primary fuel, although fuel oil can be burned as an alternate. The furnaces are equipped with combustion and temperature controls. They have heated, on a continuous basis, 68 tons an hour per furnace from cold to 2250° F. Slabs charged vary from 24 inches to 60 inches in width, 3¼ inches to 12 inches in thickness, and 65 inches to 92 inches in length.

The slabs slide down the furnace dropout against inclined spring-loaded bumpers or an improved shockless bumper onto the furnace tables. A skew table with movable side guards permits straightaway entry or may be used as a turnaround for broadside entry to the scale breaker. This is a two-high stand with smooth rolls, each having a 36-inch diameter body, 100 inches in length, with 23⅞-inch neck diameter by 26¾-inch neck length, operating in bronze-insert babbitt bearings. The mill is driven by a 1000-horsepower, 500-r.p.m. motor, transmitting power through a 24.4-to-1 ratio reduction gear and conventional pinion stand. Top and bottom descaling sprays operating at 1000 pounds per square inch are located at the delivery side of the scale breaker and at the entry sides of the reversing rougher and the first finisher.

The distance between scale-breaker and broadside stand is spanned by a conventional roller table into which is incorporated an electrically-operated lift-and-turn platen at the broadside entry. The broadside mill is a four-high nonreversing stand. Work rolls are of 42-inch body diameter, 120-inch body length, 30-inch

FIG. 27-8. Schematic arrangement (not to scale) of the production units comprising the 100-inch semi-continuous plate mill at Homestead District Works.

neck diameter, and 34-inch neck length. Backup rolls have a 52-inch body diameter, 120-inch body length, 36-inch neck diameter, and 44 $\frac{1}{2}$ -inch neck length. Both work and backup rolls operate in bronze-insert babbit bearings. The mill is driven by a 4500-horsepower, 370-r.p.m., AC motor, transmitting power through a 22-to-1 gear ratio and conventional pinions to give a lineal speed of 185 feet per minute at the work-roll face. Movable side guards on the entry side permit centering of the slab. Pushers on entry and delivery sides facilitate entry and return for another spreading pass if required.

A duplicate of the turn-around on the entry side is located on the delivery side in the table leading to the slab squeezer. The squeezer is a two-ram width-sizing machine located 30 feet from the broadside stand. The rams are supported above the mill table rollers and are positioned for the squeezing stroke in conformance with the plate widths being rolled. Forging power is supplied by a 500-horsepower, 500-r.p.m. motor, transmitted through gearing and mechanical linkage to actuate the forging rams. A hydraulic hold-down prevents bowing of the slab as the edges are subjected to the squeezing action.

The four-high reversing roughing mill is located 154 feet, 9 inches from the squeezer. On the entry side of this mill are movable side guards which guide the slab into a vertical edging mill. The vertical rolls have a 40-inch diameter and an 11-inch face with a 5-degree downward taper. They are driven by a 600-horsepower, 125 to 406-r.p.m., variable-speed motor. The work rolls of the reversing rougher are of 36-inch body diameter, 120-inch body length, 0.008-inch crown, 24-inch neck diameter, and 21 $\frac{1}{2}$ -inch neck length. The backup rolls are of 54-inch body diameter, 120-inch body length, 31-inch neck diameter, and 32 $\frac{1}{16}$ -inch neck length. The mill is connected directly through mill pinions to a 7000-horsepower, 40 to 80-r.p.m., variable-speed motor which provides a lineal speed range at the work-roll face of 376-752 feet per minute. Both work and backup rolls operate in anti-friction roller bearings. Heavy ram-type guides on entry and delivery sides and a turn-around on the delivery side permit the finish rolling of plates wider than could be finished through the continuous stands.

The first of four, four-high, continuous finishing stands is located 172 feet from the reversing rougher. The four finishing-mill stands are exact duplicates of each other. The work rolls are of 27-inch body diameter, 100-inch body length with crowns varying from 0.004 inch to 0.008 inch, 20-inch neck diameter and 15-inch neck length. Backup rolls are of 54-inch diameter, 100-inch body length, 31-inch neck diameter and 32 $\frac{1}{16}$ -inch neck length. Both work and backup rolls operate in anti-friction roller bearings. The finishing stands designated as No. 4 to No. 7 are each driven by a 5000-horsepower motor. No. 4 to No. 6 stands have a speed range of 110-250 r.p.m. and No. 7 has a speed range of 125-265 r.p.m. Reducing-gear ratios for No. 4 to No. 7 are, respectively, 2.32, 1.77, 1.46 and 1.35. Corresponding lineal speed ranges at the work-roll faces are: 333-760, 440-1000, 530-1200 and 655-1386 feet per minute. Pull-back chutes with a variable opening up to a 100-inch maximum guide the rolled plate through the individual stands. Steam top-side blow-offs are provided between stands in addition to the hydraulic sprays at No. 4-stand entry.

The scale-breaker top roll and the top work and backup roll of all the other stands are balanced by hydraulic jacks and accumulators. Overhead cranes and counter-balances are used to change scale-breaker rolls and the work rolls of the broadside and the finish-

ing stands. A roll-changing rig is used to change the reversing-rougher work rolls, and the broadside, the reversing-rougher, and the finishing-stand backup rolls.

The first 60 feet of the 280-foot run-out table is equipped with a series of cooling sprays. The far portion of the table is a part of a transfer, over the cooling grids of which the plates are moved laterally by a rope-and-carriage transfer 162 feet long and 18 feet wide. Located immediately beyond the transfer is the light leveler with 17 bending rolls of 8-inch diameter and 108-inch length. A cooling table with individually-driven disk rollers spans the 310-foot distance between the light and the heavy levelers. The heavy leveler is an 11-bending-roll machine with 12-inch-diameter rolls 108 inches long. After leveling, the plates may progress through either one of two alternate routes, to the No. 3 shear unit or toward the rotary-shear line.

Shear Units—The No. 3 shear unit consists of two similar shear lines, each one of which is a continuation of the dual transfer table. Each line consists of a shear approach table, a $\frac{3}{4}$ -inch by 100-inch motor-driven guillotine shear, a powered gage and gage table, and a "kick-off" table with a 60-foot stacking bed. A guillotine scrap shear of 16-square-inch capacity serves both end shears.

As all the kick-off tables and the stacking beds in this mill are of similar design, a brief description of one will suffice for all. The kick-off mechanism consists of a series of arms which, during a plate delivery from the shear, are positioned between and below the table rollers. The arms are of a double-bar design with small idler rollers free to rotate in the space between the bars. The stacking-bed ends of the arms are keyed to a pivot shaft which, on being rotated through a partial arc, will lift the arms correspondingly through a partial arc and permit the plates to slide down along the idler rollers.

The stacking beds consist essentially of a series of double beams between which movable stops may be shifted and secured in a position to correspond with the widths of plates to be received. A series of beams spanning about 20 feet is fastened to a bed frame and constitutes a stacking-bed section. The sections can be raised individually or in unison to receive the first plate of a stack and are then lowered in consecutive increments as the stack is built up. The stacks are removed from the beds by overhead cranes equipped with sheet carriers or spreaders.

The No. 3 shear unit is utilized for cutting sheet and light plate gages up to $\frac{3}{8}$ inch. The mill is capable of rolling material to thicknesses of approximately 0.10-inch minimum, 72 inches wide. The sheets and the plates sheared on the No. 3 unit generally are cut into multiples of the ordered lengths in order to keep ahead of the mill rolling rates. The mill has rolled a maximum of 2,137 tons in an 8-hour period. The multiple-length, side-untrimmed sheets and plates are transferred to the No. 4 shear unit by a 70-ton transfer car or by placing them on a gravity-feed table, which moves them under a magnetic depiler.

The No. 4 shear unit is housed in a building adjacent to and parallel with the mill building on the motor-room side. Two gravity conveyor tables, one located in the shear building and one in the mill building, move the stacks under a magnetic depiler. The stacks are depiled, and the plates are placed singly on the approach table of a backed-up roller leveler. The leveler has two 12-inch-diameter by 108-inch pinch rolls, nine 8-inch-diameter by 108-inch bending rolls and eleven 8 $\frac{1}{4}$ -inch diameter by 30-inch backup rolls. A marking

mechanism attached to the delivery side of the leveler scribes the ordered width on the plates.

The plates progress from the leveler to a $\frac{3}{4}$ -inch by 125-inch end shear equipped with a powered gage which can be set in the range of 48 inches to 510 inches. Delivery from the shear gage table is made to the caster bed of a left-hand $\frac{3}{4}$ -inch by 144-inch side-trimming shear and from there to the caster bed of a right-hand shear of otherwise identical design. A scale table and a kick-off table with a 60-foot stacking bed complete the main shear line.

Beyond the main shear line are located one $\frac{1}{2}$ -inch by 144-inch squaring shears and a circle shear serviced by gravity conveyors and a jib hoist. The circle shear has a 9-inch diameter by $2\frac{1}{2}$ -inch upper cutter and a $4\frac{1}{2}$ -inch diameter by $2\frac{3}{8}$ -inch, 45 degree-bevel lower cutter. It can cut 8-inch to 96-inch diameter circles from $\frac{3}{32}$ -inch to $\frac{3}{8}$ -inch, 0.30-carbon steel at a cutting speed of 50 to 100 feet per minute. A $\frac{3}{4}$ -inch by 30-inch guillotine scrap shear serves both the resquaring and the circle shears, and a similar shear serves each of the side shears.

Rotary Shear Line—No. 1 Shear Unit—Heavier-gage plates, after moving across the dual transfer, continue their travel in a reverse direction to the mill rolling direction, over spool-type marking and inspection tables toward a $\frac{3}{4}$ -inch by 100-inch crop shear. The distance traveled by a plate from the finishing stand to this crop shear is approximately 1,200 feet. The plates are cropped and are divided into multiples of the ordered lengths at this point and progress to a 123-foot by 41-foot roller-chain lift transfer located immediately beyond the shear. Required painting and stamping identifications are applied as the plates travel over this transfer.

Sketch plates and other plates which are beyond the capacity of the rotary shear are diverted from the delivery side of the transfer by a table extension and stacking beds. They are moved by overhead crane and transfer car to the No. 2 shear unit for cutting. Plates within the capacity of the rotary shear resume travel in the rolling direction toward that unit.

The rotary-shear approach table is equipped with magnetic manipulators to position the plates for the shear entry. The shear is a double-rotary, side-trimming shear driven by a 300-horsepower motor. The top knives are 15-inches in diameter by 2 inches thick, the bottom knives are 60-inches in diameter by $2\frac{1}{2}$ inches thick, and the scrap cutters are 12 inches by $3\frac{3}{4}$ inches by $1\frac{1}{2}$ inches. Scrap from each side is guided from the main cutters through chutes to the scrap cutters located below the large knives. The scrap is cut by a rotary, eccentric motion and is dropped through chutes into disposal buckets. The shear has a capacity for cutting 20-inch to 90-inch widths, $\frac{3}{32}$ -inch to $\frac{3}{4}$ -inch gage, of 0.30-carbon material at a cutting speed of 79 to 237 feet per minute. The cutters may be set to $\frac{1}{16}$ -inch increments within the width range.

The trimmed plate may be sent to either one of two end shears for final cutting to ordered length. The near or No. 2 end shear, located in the shipping building, is reached by traversing a 127-foot by 27-foot rope-and-carriage transfer located immediately beyond the rotary-shear delivery table. The far or No. 3 end shear approach table is immediately beyond the transfer referred to, and is reached by direct, continuous travel from the rotary shear. Both shears can handle material $\frac{3}{4}$ -inch thick by 100 inches wide, and each is driven by a 150-horsepower motor. They are followed by gage tables equipped with motor-operated, tilting, and traveling plate stop-gages with a 48-inch to 720-inch travel

range from the knife edge. The gage carriage travel speed is 50 feet per minute. Each end shear is serviced by a $\frac{3}{4}$ -inch by 20-inch guillotine scrap shear with a 15-square-inch cutting capacity.

The sheared plates from the No. 3 end shear are transferred into the shipping building by a 74-foot by 27-foot roller chain lift transfer. Travel direction is reversed to move over a scale table with an automatic weight-recording device and continue on to a 110-foot kick-off table and stacking bed. Plates from No. 2 end shear travel over a similar scale table and on to a 150-foot kick-off table and stacking bed. The kick-off table connects with the conveyor feed table of the continuous normalizing furnace. The shipping building in which the stacking beds are located is a 90-foot by 1,540-foot structure with a net shipping space of 60,000 square feet.

Continuous Normalizing Furnace—Plates to be heat treated in the normalizing furnace are placed in stacks on a gravity feed table which moves them under an unpiler. The unpiler is a motor-driven traverse bridge and hoist with five selective magnetic lifters having a total capacity of ten tons. It operates on a structural framework runway, 35 feet long with a 40-foot span. The runway extends over a 75-foot, pipe-roller, roller-bearing, gravity conveying table which also connects the No. 1 shear line kick-off table with the normalizing furnace.

The furnace is of the straight conveyor type, divided into five zones. All zones, with the exception of the entrance or heating zone, are equipped for recirculation to improve temperature uniformity. There is an alloy baffle between the heating and the recirculating zones. The furnace is 130 feet long, 9 feet wide, and the roof is 2 feet 10 inches above the conveyor. The conveyor consists of 5 sprocket-driven chains with vertical flights. A variable speed range with a maximum of 75 feet per minute is provided. Pressure burners for all zones, burning a mixture of coke-oven and natural gas, with temperature and fuel-air ratio controls, provide the heat input. A stack at each end of the furnace provides natural draft.

Plates emerging from the furnace may be quenched in a 20-foot quenching hood prior to leveler entry. The backed-up leveler is a duplicate of the one described in the No. 4 shear unit. Plates from the leveler traverse an 80-foot by 28-foot cooling bed and are stacked in conventional stacking beds at the far side of the traverse.

No. 2 Shear Unit—The No. 2 shear unit has two main shear lines, consisting of a rotary shear line housed entirely in the 80-foot by 860-foot shear building, and the sketch shear line, which has the feeding table and two shears in the shear building and one shear, scale table, and stacking beds in the No. 2 shipping building. The No. 2 shipping building, adjacent to and parallel with the No. 1 shipping building, is an 80-foot by 1,136-foot structure with a net shipping space of 55,000 square feet.

The sketch shear line, as its designation implies, is used to shear irregularly shaped plates. It also is utilized to shear structural-grade, rectangular plates heavier than $\frac{3}{4}$ -inch gage, and alloy plates of thinner gage which, because of composition, are beyond the cutting capacity of the No. 1 shear line. Such plates are diverted from the No. 1 shear line beyond the No. 2 transfer and moved to the No. 2 shear unit by transfer car, as previously described.

Plate stacks for the sketch shear line are placed on a 90-foot gravity feed table by an overhead crane. An overhead, selective, magnetic unpiler puts the plates singly on a marking and layout, five-chain conveyor

table, 140 feet long. Both sketch and rectangular plates are laid out manually on this table. The first shearing unit in the line, a 1½-inch by 110-inch end shear, cuts the plates to length. The plates may be turned 180 degrees on the caster beds immediately beyond and returned, if necessary, to have both ends front-end cut for the elimination of shear bow. A continued, manually propelled movement of 55 feet over caster beds brings the plate to a 1¼-inch by 144-inch side shear for edge trimming. A lateral movement of 44 feet into the shipping building brings the plate to an opposite hand but otherwise identical shear for the trimming of the opposite edge. Further manual propulsion opposite to the original travel direction moves the plate back to powered traction on a 35-foot scale table and a 60-foot kick-off table and stacking beds. Two scrap shears serve the three major shearing units in this line.

When the mill rolling rate on ¾-inch to ¾-inch gage plates exceeds the capacity of the No. 1 shear line, the excess multiple-length plates are diverted at the same point and are transferred to the No. 2 shear unit in the same manner as sketch plates. The plates are spread on a 160-foot chain-conveyor marking table and move over an approach table to a double-rotary side-trimming shear. In general design features, the shear is similar to the one in the No. 1 shear line. Shear-knife diameters are 14 inches and 58 inches for top and bottom, respectively. The capacity ranges from 30 inches to 96 inches in width and ⅜ inch to ¾ inch in gage at a cutting speed of 50 feet per minute. The scrap cutters are of the revolving-drum type. A duplicate of the end shear in the sketch shear line is located 71 feet from the rotary shear. It is followed by a 60-foot back shear table, a 30-foot scale table and a 60-foot kick-off table with stacking beds. A guillotine scrap shear of 32½-square-inch capacity serves the end shear.

Auxiliary shearing equipment in No. 2 shear unit consists of a resquaring shear, a circle shear, and a test-cutting shear. The squaring shear is a ⅜-inch by 144-inch, motor-driven unit. The circle shear, driven by a 110-horsepower motor, has a capacity ranging from 20-inch to 150-inch diameter, ⅜-inch to 1¼-inch gage, in structural grades at a cutting speed of 56 feet per minute. Both top and bottom knives are 16½ inches in diameter and 2 inches thick. The guillotine-type test-cutting shear has a capacity of 16 square inches, equivalent to cutting 20-inch by 1¼-inch thick plates.

An individual plate inspection unit is made available by feeding from the shear building and repiling in the shipping building. It includes two parallel sections of gravity table for plate entry and two parallel sections for plate delivery. Each section is 90 feet long with pipe rollers operating in roller bearings. Located between the gravity table lines is a motor-driven roller table over which individual plates are moved and are tilted for inspection by eight lifting arms to an angle of 75 degrees. The unit is served by one unloading unit and one piling unit. Each traverse and hoist, with five selective magnetic lifters, operates on a structural framework 40 feet long with a 40-foot span.

CONTINUOUS PLATE MILL

The 96-Inch Four-High Continuous Plate Mill at South Works—The four-high continuous plate mill which will be described in detail was placed in operation in the early part of 1931 and, therefore, represents an early stage in the development of the wide four-high continuous mills. The wide, four-high, continuous hot-strip mills, which have been placed in operation in the intervening period and which are described in another section of this book, are more representative of the

Fig. 27-9. Diagram (not to scale) of the layout of the mills and auxiliary equipment comprising the 96-inch four-high continuous plate mill at South Works.

potential productive capacities, the surface finish, and the width and gage uniformity which can be achieved with a modern mill of this type designed primarily for plate production.

The 96-inch continuous plate mill at South Works, Figures 27-9, 27-10 and 27-11, receives the bulk of its charge in the form of cold slabs from a multi-purpose slab-yard building running at 90 degrees to the mill center line and serviced by four 20-ton, single-trolley, single-hoist, overhead cranes. The 96-inch plate mill and its supplying unit, the 44-inch slab mill, have a common and continuous center line. The slab mill shear delivery and piler tables form a continuous table line with the 96-inch mill furnace and mill approach tables so that hot slabs may be table-conveyed directly from the slab-mill shears into the 96-inch mill. A pusher and chain transfer adjacent to No. 1 reheating furnace permits the diversion of hot slabs from the mill table and their transfer to the charging ends of the reheating furnaces. It also is utilized for the recharging of furnace kick-outs.

The slab mill has a rated capacity of 140,000 product tons per month. It supplies all of the slab requirements

FIG. 27-10. General view of the 96-inch continuous plate mill at South Works.

of the 96-inch mill, with the bulk of its excess productive capacity allocated to the slab requirements of the 80-inch hot-strip mills at Gary Sheet and Tin Mill, and a smaller percentage allocated to the 30-inch universal plate-mill slab requirements and semifinished trade-slab requirements. Virtually all the slab-mill production is removed from the run-out tables by three sectional pushers and pilers located in the slab yard. Slabs in ingot stacks are removed from the pilers by overhead cranes. Slabs for the hot-strip mills are placed in a cooling area west of the run-out table in conformance with the principle of utilizing fully the conditioning capacity of the western extremity of the slab

yard for this product. After cooling, the slabs are loaded into standard-gauge cars placed on tracks running transversely through the extremity of the building, for shipment to the conditioning yard of the 80-inch hot-strip mill at Gary.

All 96-inch plate mill slabs are placed in the central portion of the slab yard, adjacent to the pilers, for cooling. After cooling, they are conditioned, and piled in rolling sequence in an area approximately 70 feet by 100 feet located near the pilers. This area has a storage capacity of 5,000 tons. A portion of the slab tonnage produced for other applications and cooled in the central area also is conditioned here and is loaded

FIG. 27-11. General view of inspection and marking operations on plates at the delivery end of the 96-inch continuous plate mill at South Works.

out on standard-gauge tracks. Cool slabs in excess of the yard conditioning capacity are sent to other yards for conditioning.

The plate-mill furnace-charging tables extend into the slab yard. The slab charger is a side unpiler consisting of a skidded deck with a vertical screw motion and a pusher operating transversely to the table travel direction and at the table-top elevation. Slab stacks are placed on the unpiler deck in its down position, and the slabs are pushed singly on the charging table as the unpiler is moved upward in slab-thickness increments. The slabs are positioned at the furnace charging doors and are charged into the furnaces by double-row pushers which can be operated singly or in unison.

The heating equipment for this mill consists of four continuous-type, two-zone, triple-fired furnaces equipped to burn natural gas or fuel oil through all burners. One of the originally installed furnaces of 13 by 59 foot inside dimensions is manually controlled, is not equipped with either recuperators or regenerators and is only used for standby service. When this furnace is used, it is single-row charged with slabs of 83-inch maximum length. Three furnaces installed in 1950 are 16 by 60 foot 6-inch inside dimensions, are equipped with automatic heating controls and metallic recuperators. Slabs charged into these furnaces vary from 3½ to 6½ inches in thickness, from 28 to 60 inches in width, from 50 to 83 inches in length for a double-row charge and up to a maximum of 178 inches for a single-row charge. Each of these furnaces has a rated heating capacity of 50 slab tons per hour.

The two-high scale-breaker stand is located 156 feet, 3 inches from the center line of the near furnace. It is driven by a 600-horsepower, 488-r.p.m. motor, driving through a gear reducer and conventional pinions of 34-inch pitch diameter. The steel rolls of 20-inch neck diameter, 18¾-inch neck length, 30-inch body diameter, and 66-inch body length, operate in bronze-insert, babbit bearings. The top roll is counter-weight balanced. Drafts on this stand are limited to ⅜-inch maximum. Top and bottom hydraulic sprays operating at 1000 pounds per square inch are located on the delivery side of the mill.

The roughing train consists of three duplicate two-high stands with spacings of 35 feet between the scale breaker and No. 1 stand, 41 feet, 5.3 inches between No. 1 and No. 2 stands, and 32 feet, 2 inches between No. 2 and No. 3 stands. All three stands are driven by a 6000-horsepower, 370-r.p.m. motor, driving through a special gear-reduction set with two flywheels on the high-speed shaft and through conventional pinion stands. No. 1, No. 2, and No. 3 stands operate, respectively, at 8.5, 10.1 and 15.15 r.p.m., corresponding to lineal surface speeds of 116, 138 and 206 feet per minute. Only one slab can be undergoing reduction in the roughing train at any time. The cast-steel rolls for these stands have a 35-inch neck diameter, 36½-inch neck length, 53-inch body diameter, and 100-inch body length. The rolls operate in bronze-insert, babbit bearings. The top roll is balanced hydraulically. The screw-downs are operated by two motors tied in with a magnetic clutch so that they may be operated in unison for draft settings or individually for roll alignment. High-pressure hydraulic sprays are located at No. 1 and No. 3 delivery and at No. 4 entry.

Motor-driven sectional side guards on the skew roller table between the scale breaker and No. 1 stand may be positioned to permit either a straightaway entry to No. 1 stand or to form a turning pivot for a 90-degree turn and a broadside entry to No. 1 stand. Therefore, No. 1 stand may be utilized as either a straightaway or

a broadside mill. A rack-type carriage pusher operating on a structural framework above the table provides for a square entry for the broadside pass. Powered side guides at the entry of each roughing stand, as well as the first finishing stand, permit centered entry.

A similar arrangement of side guards and skew table on the delivery side of No. 1 stand makes possible either continued straightaway progress of the slab or a 90-degree turn after a broadside pass.

The finishing train consists of six duplicate four-high stands spaced on 21-foot centers, with the first or No. 4 stand spaced 72 feet from the center line of the No. 3 roughing stand. Each mill is driven by a 3500-horsepower, 165-330-r.p.m. motor through a gear-reduction unit, conventional pinion stand and wobbler-type spindles. The speeds of the work rolls of the various stands in r.p.m. and f.p.m. are listed below:

Stand No.	Speed Range	
	Rev. per min.	Ft. per min.
4 Finishing	20 to 49	128 to 315
5 Finishing	30 to 72	193 to 463
6 Finishing	39 to 94	250 to 600
7 Finishing	49 to 118	315 to 760
8 Finishing	54.5 to 132	350 to 850
9 Finishing	60 to 146	385 to 940

Grain-iron work rolls in No. 4 and No. 5 stands, and chilled-iron work rolls in the remainder of the stands, have 16⅞-inch neck diameter, 41½-inch neck length, 24½-inch body diameter, and 100-inch body length. The steel backup rolls have 27-inch neck diameter, 44¼-inch neck length, 52-inch body diameter, and 96-inch body length. Both work and backup rolls operate in anti-friction roller bearings. The top backup and work roll are balanced hydraulically as an assembly, with the work roll being held against the backup roll by two spring suspension take-up rods positioned through yoke extensions. Draft settings are made by 100-horsepower motors driving the screwdowns through worm reduction gearing. The two motors for each stand are connected by magnetic clutches and are operated in unison for draft settings and singly, when the stock is in the mill, for camber correction.

The spacings between the mill stands are each occupied by a two-sectional retractable table which in a normal operating position presents a continuous, smooth iron liner surface to plate travel. Adjustable, powered side guides center the plates for admission at the point of entry, and top and bottom stripper-guide assemblies are attached to the delivery section. A looping roll normally is positioned below the table surface and is raised in an arc by pneumatic cylinders when it is necessary to take up stock slack while speed adjustments are being made. Prior to a roll change, the two table sections are retracted so that the liners and the supports of one section overlap the other in the center of the spacing. In this position both the entry- and the delivery-guide assemblies are free of the rolls.

An overhead-crane-suspended sleeve, into which a work roll is fitted as a counterweight, is used for work-roll changes. The frequency of work-roll changes is extremely variable and is dependent on the particular roll stand as well as on the preponderance of product gages rolled. In the rolling of sheet gages, the leader and the finisher may require changing at four-hour intervals. When the schedule includes only plate rolling and the preponderance of the tonnage is in the heavier plate gages, the work rolls in No. 4 and No. 5 stands may last out the weekly schedule or require changing only once to meet wide-plate rolling requirements in

the latter part of the week. Work-roll changes are made in 25 minutes.

A cast counterweight secured on an integral arm and sleeve which fits over the roll-neck extension, is used for the changing of the backup rolls, whereas a sleeve and another roll as a balancer are used for changing the roughing rolls. The frequency of backup-roll changes is also variable and dependent on the roll-stand position and gages rolled. Since one roll is changed per week, the average time interval amounts to 12 weeks. No. 3 roughing rolls are changed each week, No. 2 at weekly or bi-weekly intervals dependent on schedules, and No. 1 at 3 to 4-week intervals. Backup-roll changes require an average of $2\frac{1}{2}$ hours per roll, and roughing rolls require $3\frac{1}{2}$ hours a set.

Product is delivered from the finishing stand onto a central runout table, 132 feet long, consisting of individually-driven disk rollers which protrude through openings in cast alloy-iron aprons. Plates are stopped on the runout table by raising the lifting aprons above the table rollers. The plates are moved 18 feet, 4 inches laterally over iron gridwork by a cable-carriage dog transfer to either one of two duplicate, parallel finishing lines.

The 126-foot leveler-approach tables convey the plates to the light levelers, the first processing units in each line. They are located immediately beyond the hot transfer and have seventeen bending rolls, 8 inches in diameter by 100 inches long. Delivery from the leveler is made to the first of five 125-foot sections of sprocket-driven chain spool conveyors. These conveyors span the distance to the heavy levelers and also serve as cooling and top surface inspection tables. The heavy leveler is a 13-roll machine with seven top and six bottom, 14-inch diameter by 100-inch long, rolls. From the leveler the plates are discharged on a 132-foot combination table and turnover device. The turnover consists of two series of arms keyed to pivot shafts located between two parallel roller tables. In an idle position both sets of arms are below the roller-top levels of the two tables. When the plate is delivered from the leveler, the arms are moved toward each other in an arc, with the sending arms passing through a greater arc. This results in a transfer of the plate to the receiving arms as they approach a vertical position. The lowering of the arms transfers the plate to the adjacent parallel table which reverses travel direction toward the multiple shear.

Five 70-foot approach table sections serve as a bottom surface inspection and marking table. The first identification is made by chalking on the plate surface. Multiple lengths to be sheared are also marked on the plate with allowances for necessary tests. The multiple shear is a $\frac{3}{4}$ -inch by 100-inch, motor-driven, open-throat, downcut shear. A chain scrap conveyor is common to the multiple and the adjacent end shear and carries the scrap from both to an alligator scrap shear.

Continued table travel of 178 feet brings the multiple plates to a 64-foot cold transfer. This is a chain lift transfer with a 32-foot span from the center line of entry and delivery, tables. During the crosswise travel, physical identification of product and test pieces is completed by manual painting and stamping. Routing information for placement in the shipping area or direct car loading also is indicated on the plates.

Travel in the rolling direction is resumed on the 60-foot approach table to the rotary shear. The finish-shear lines are located in the shipping buildings which are adjacent and parallel to the mill building. Three magnetic manipulators traveling in a direction trans-

verse to that of the table are available for positioning the plates for the rotary-shear entry. An electromagnet, traveling with the table direction, holds the plate in a fixed lateral position. The double rotary shear has 15-inch diameter top and 60-inch diameter bottom knives. Cutting capacity ranges from $\frac{1}{8}$ -inch to $\frac{3}{4}$ -inch gage and 20 inches to 96 inches in width at a cutting speed of 79 to 158 feet per minute. Width settings may be made in $\frac{1}{16}$ -inch increments. Side trimmings are guided to rotary scrap cutters, cut into short lengths and dropped into a hold for removal by magnet.

Two 46-foot table sections that serve as delivery and entry tables for the rotary and the end shears respectively have powered side guards to guide the delivery from the rotary shear and facilitate square entry into the end shear. The end shear is a duplicate of the $\frac{3}{4}$ -inch by 100-inch multiple shear. A motor-operated lift plate gage with a travel speed of 50 feet per minute can be set from a 6-foot to a 60-foot distance from the shear knife. The 60-foot delivery table is followed by a 68-foot scale table and two sections of 64-foot push-off tables and side pilers. The side pushers travel in transverse ways across the tables to stack the plates in the pivoted side pilers, the table ends of which are lowered in conformance with the height of the plate stack.

Plates heavier than $\frac{3}{4}$ -inch and up to $1\frac{1}{4}$ -inch gage are laid out manually on the push-off tables and continue over a short approach table to a $1\frac{1}{4}$ -inch by 100-inch end shear. The shear is a conventional motor-driven downcut type followed by a short depressing table and a delivery table with an overall length of 26 feet. The plates then are moved manually over caster beds to a $1\frac{1}{4}$ -inch by 180-inch side shear located 58 feet from the end shear. The plates are turned 180 degrees on the caster beds and moved back to the side shear to trim the opposite edge. Side-trim scrap is moved manually to an alligator scrap shear for cutting into short lengths.

A circle shear is located beyond the side shear of the west shear line. The shear has a cutting capacity of $\frac{1}{8}$ -inch to $\frac{3}{4}$ -inch gage and 16-inch to 84-inch diameter at a cutting speed of 20 to 60 feet per minute. A transfer car at the extreme end of the building permits the transfer of circles and plates between the various buildings.

UNIVERSAL PLATE MILL

The 30-Inch Universal Plate Mill at South Works—The 30-inch universal plate mill at South Works, Figure 27-12, was erected in 1907 to produce rolled-edge plates ranging from $\frac{3}{16}$ inch to 6 inches in thickness and 6 inches to 30 inches in width. Slab sizes utilized to produce this range vary from $2\frac{1}{2}$ inches to $11\frac{1}{2}$ inches in thickness, 5 inches to 31 inches in width and 55 inches to 120 inches in length.

The conditioning and slab-storage yard serving this mill is under an open crane runway of 83-foot span and 280-foot length, serviced by two single-trolley, single-hoist, 10-ton cranes. The yard consists of four sections, for slab receipt, conditioning by hand scarfing, stock storage, and current charge storage. Charge slabs are piled in upright racks in the proper sequence. Forty-five hundred tons can be stored in the charge and stock racks.

Reheating Furnaces—Two single-zone, end-fired, hydraulic-pusher-charged, continuous reheating furnaces service the mill. The burners located above the discharge doors are designed for changing quickly to natural gas or oil for combustion. Neither gas nor air is preheated, inasmuch as neither checkers nor recupera-

Fig. 27—12. Layout (not to scale) of the 30-inch universal plate mill at South Works.

tors are incorporated into the furnace design. Air for combustion is provided under pressure by a fan which draws directly from the atmosphere. Fuel-air ratio and furnace pressure controls are operative for natural-gas combustion. The furnaces are rated at 20 tons an hour per furnace for full hearth coverage and a cold charge. Heated slabs and billets slide down the dropout skids onto the mill approach table.

30-Inch Universal Plate Mill Stand—The single-stand two-high reversing mill, with vertical edgers front and rear, is located 68 feet from the center line of the near furnace. The chilled alloy-iron horizontal rolls are $24\frac{1}{2}$ inches in diameter and 67 inches in body length; the chilled-iron vertical rolls are $14\frac{1}{2}$ inches in diameter and 19 inches in body length. The top roll is balanced by counterweights, and is positioned for draft settings by a 50-horsepower motor driving both vertical screw-downs through worm reduction gearing. The maximum available horizontal roll opening is 10 inches. Initial roll

alignment is provided by placing liners as required under the fabric bearing chucks of the bottom-roll.

Additional roll-alignment adjustment required in rolling is obtained by the manual operation, during pass intervals, of a device which varies the distance between one screw and bearing chuck.

The vertical-roll assemblies at each side of the mill are positioned by a 30-horsepower motor. A drive shaft extends across both main housings and has pinions meshing with a spur-gear train on the outer vertical face of each housing. Bronze nuts, driven by the gearing, move upper and lower screws transversely, which in turn move the vertical-roll housings. A yoke connects the outer square ends of the screws to prevent their turning. It also has an adjustable rod attached with a nut to the yoke center that extends through an opening in the housing and is pinned to the vertical-roll yoke. The yoke and the rod serve as a pull-back when the roll spacing is widened. Available roll opening varies from a 5-inch minimum to a $31\frac{1}{2}$ -inch maximum. The weight of the vertical-roll assemblies is supported on an inverted V slide at the base of the main housings.

The mill is driven by a 4000-horsepower, 150-r.p.m. reversing motor, the first reversing-mill motor to be built and placed into successful operation. Power is transmitted through a leading spindle to the bottom pinion of a five-pinion, three-high, cast-herringbone pinion stand. The bottom and the second pinions, of sixteen teeth each, are connected directly through spindles to drive the top and the bottom horizontal rolls. The top pinion of fifteen teeth meshes with the middle pinion below it and with one fifteen-tooth pinion at each side of it with a common center-line elevation. All five pinions are journaled in babbitt bearings in the pinion housing. The side pinions drive the vertical-roll square shafts on which the square bores of the bevel driving gears for the vertical rolls slide for roll positioning, and which transmit power to the mating gears keyed to the vertical rolls.

Rolling—Slabs intended for plates in the 6-inch to 8-inch width range are provided 1 inch narrower than the finished plate width. A slab 6 inches thick and 8 inches wide rolled down to 1-inch gage will finish $9\frac{3}{4}$ inches wide on this mill if it is allowed to spread freely. Therefore, on the basis of slab provision for a 1-inch-gage, 8-inch wide plate, a 1-inch spread is allowed; and the edges actually are worked down $\frac{3}{4}$ inch. Slabs provided for over 8-inch to 12-inch widths are $\frac{1}{2}$ inch narrower than the finished size; slab and finished widths are equivalent in the over 12-inch to 17-inch range; and slabs $\frac{1}{2}$ inch over finished size are provided for the over 17-inch to 30-inch range. Edging drafts are taken alternately with the vertical rolls on the delivery side of the horizontal-roll drafting passes. As the horizontal-roll drafts are variable, vertical and horizontal-roll diameters must be kept matched so that the peripheral speed of the vertical rolls exceeds that of the horizontal rolls. Main-roll changes average three per week for a normal schedule and require 55 minutes to complete. Vertical rolls are changed at three-week intervals and require $3\frac{1}{2}$ hours to change both sets. Spray nozzles operate at 650 pounds per square inch pressure for descaling on both sides of the mill.

Hot Bed—The finished plate is delivered by a 69-foot delivery table to a two-section lift chain hot bed, each section being 77 feet long by 59 feet wide, with transfer chains spaced on 5-foot 6-inch centers. When delivered to the hot bed, the plate is moved off the hot-bed entry table by the transfer chains and positioned against fixed raised castings or anvils which are

parts of a straightener-press used to remove delivered camber, and to prevent camber resulting from the initial cooling stages. The straightener-press contains 30 individual blocks, each of which consists of a 3½-inch diameter worm screw, a bronze nut, a head casting attached to the worm screw, and the fixed table casting that serves as the anvil. The blocks are on 5-foot, 6-inch centers and are located between the transfer chains and adjacent to the hot-bed entry table. Two worm line shafts, each 5 inches in diameter and 89 feet, 7 inches long, drive the individual worm screws. Each line shaft, in turn, is driven by a 50-horsepower motor through reduction gearing. The castings which serve as anvils are integral parts of troughs through which cooling water circulates. When the worm screws are operated, the movable heads push against the edge of the plate and press it straight against the anvil castings.

Plates are delivered to the two hot-bed sections alternately. When the plates are released by the straightener-press, they again are picked up by the lift transfer chains and moved across the bed in plate-width space increments. In the course of their traverse progress the plates are identified by painting and stamping and laid out for the lengths that are ordered.

Required tests also are laid out and identified. The final chain movement places the plates on the combination bed-delivery and shear-approach table.

Finishing—The end shear, located immediately adjacent to the hot bed, is a 42-inch by 2-inch guillotine downcut shear with a counterweighted upper-knife holder, and is operated by an 11-horsepower, 800-r.p.m. motor. A chain conveyor moves crop scrap to a chute which guides it into a scrap box for disposal. The sheared plates go over a table to a roller leveler which has 6 top and 5 bottom bending rolls, 8 inches in diameter and 44 inches in body length. Plates up to 2-inch thickness are pulled off the table line on the delivery side of the leveler. They are pulled off manually with the use of hooks into stacking cradles. Heavier plates are pushed manually on an idler table to a horizontal gag in which they are straightened and pulled off in a similar manner on the delivery side.

Auxiliary equipment includes flame-cutting equipment for heavy plates, hand-grinding tools and powered hack saws. Storage racks are provided for carload-accumulation storage in the combination shearing and shipping building. Additional storage and shipping facilities are available in an adjacent building.

Chapter 28

RAILROAD RAILS AND JOINT BARS

SECTION 1

ROLLING OF RAILROAD RAILS

Dating from the invention of the steam locomotive, the railroad rail represents one of the first sections to be rolled. The railroad rail is a most vital part in railroad operations and represents a difficult section for the roll designer and roller. With the advancement in speed of travel and weight of loads carried, more and more has been required of the rail, until today no product is subject to more severe service conditions. Exposed to the weather at all times, it is subjected, under constantly varying conditions, to high compression and bending stresses, impact, vibration, friction and wear.

The railroad rail should be designed to have the greatest possible transverse strength, to provide an abundance of metal for wear, to present a wide base for fastening to the cross tie, and, for the sake of economy, it should be of the lightest section possible. The American Tee Rail best meets all of these requirements and represents the accepted design.

Historical Development of Rail Sections—The history of rail development is indicated in the sketches of Figure 28—1. The first running surfaces for the early railroad rolling stock consisted of strap rails comprised of cast-iron plates approximately 4 inches by 1¼ inches by 5 feet long, which were attached to a wooden base. The first strap rails were used around 1767. Various types of cast and malleable iron rails were used until about 1820 when the first iron rails were rolled. These were supported by cast-iron holders, called chairs, attached to stone supports. In an effort to eliminate use of the expensive chair required for this type of iron rail, a rail with a wide and relatively heavy flange on the bottom was rolled in 1831. The difficulty of rolling the flange led to the better balanced Locke rail of 1837, the bull head and U-shape rails of 1844, and the pear head rail of 1845. Then came the compound rail of 1856 (not shown in Figure 28—1) and another form in 1858, which was the U-shape of 1844 with the lower parts closed in and welded to form a web. As neither of these forms proved serviceable, a demand for more metal in the head for wear forced a final return in 1858–1868 to the tee shape with wide thin flange. Subsequent to 1858–1868 the quality of the steel, the design of the rails and rolls, and the equipment of the mills have improved continuously. Present standard railroad rails are being rolled in various sizes ranging in weight from 65 lb. up to and including 155 lb. per yard. Rails 60 lb. per yard and lighter are classed as light rails. Representative chemical compositions for rails are shown in the American Railway Engineering Association (A.R.E.A.) tabulation given in Table 28—I.

Mills for Rolling Rails—There does not seem to be much accurate information available about the first mills which rolled rails. It is probable that existing mills designed to roll bars were utilized with such alterations

and additions as were necessary. Credit for rolling the first steel rail in 1857 is given to the Dowlais Plant, Wales, while the credit for rolling the first steel rail in this country is given to Captain Ward's North Chicago Rolling Mills, where the first Bessemer steel rails were rolled experimentally in 1865 from blooms made of hammered ingots produced at Wyandotte, Michigan.

Rails were originally rolled on the pullover mill, and later on the reversing mill. In this country rails have been rolled for many years on the three-high mill, which was usually made up of a single train of three stands driven by one engine. Sixty-nine mills were reported to be rolling rails of various weights in 1874. During this great railroad-expansion period, rails were in such demand that even this large number of mills could not supply the demand. These mills were scattered around the country with one as far west as Laramie, Wyoming. The tonnages produced on the old mills were small in comparison to present-day tonnages. Since about 1900, rail mills have been forced to undergo many changes because of the ever increasing requirements of the railroads with respect to quality of the steel, size of the rail section, length of rail, freedom from internal and surface defects, exactness as to dimensions, and a variable demand as to quantity. At the end of 1954, there were nine mills in the United States and Canada which were producing railroad rails. Additional rail mills on the North and South American continents are at Monterey, Mexico and Volta Redonda, Brazil. These mills are far from being standardized in layout. Some have a large number of stands, others only a few, some are two-high throughout, while others are three-high. No one rail mill may be cited as an example typical of all, but a brief general description of a mill which requires reheating of the blooms and another mill which rolls direct will illustrate operating conditions of representative mills.

In the first example, that of a large rail mill in which the blooms are reheated, the ingot first passes through a 48-inch, two-stand, two-high, tandem bloomer with two passes in each stand. After the ingot has passed through once, it is returned to the first stand by a run-

Table 28—I. Representative Chemical Compositions for Rails

Constituents	Nominal Weight in Lb. per Yard

THE MAKING, SHAPING AND TREATING OF STEEL

FIG. 28-1. Sketches of cross-sections of rails from the earliest periods of railroading until the present, showing the evolution of the modern railroad-rail design. Certain special rail sections are shown at the lower left.

around turn table for the second pass. After passing through the stands twice, the piece goes on to a three-high 40-inch blooming mill, where it is given seven passes. After being sheared into bloom lengths and reheated, the blooms go on to a four-stand rail finishing mill, the first part of which consists of two engine-driven three-high stands. The bar is given five passes in the first set of rolls and four passes in the second set and then moves straight forward to a three-high stand driven by its own engine, where it is given three additional passes. From this stand, the rail moves on to the two-high finishing mill for the final pass. There are thirteen passes from the bloom to the finished rail.

The second example, a mill in which rails are rolled directly from ingots, is represented by the largest rail

mill in this country, the layout of which is somewhat similar to the cross-country type. This mill starts with four tandem stands of 40-inch, two-high rolls. In these stands, the ingot is given one pass per stand, and is turned after each pass. The passes are of diamond, diamond-square, and box-pass design. After the initial passes, there is a 40-inch three-high mill with five box passes, the final pass being slightly shaped to give the hitherto rectangular bloom a form more suitable for subsequent rolling. Following this three-high blooming stand is the bloom shear and then the cross-country arrangement of seven stands of rolls arranged in two groups of three stands each and one separate stand. The leader stand has a vertical roll working on the head of the rail; the finishing stand one for the rail base.

FIG. 28—2. Sketch of rolls used in second roughing stand of a rail mill rolling by the tongue-and-groove, flat, or slab-and-edging method, showing shape produced in each of the four passes.

Rails are formed by two general methods of rolling, known as the tongue-and-groove, flat or slab-and-edging, and the diagonal or angular method. Several of the rail mills combine these two methods, some of the passes being designed to form by the first method and the remaining passes to roll the section by the second

method. In the tongue-and-groove, flat or slab-and-edging method, illustrated by the second roughing stand in Figure 28—2, the axis of symmetry of the rail coincides with the pitch line and is parallel to the train line of the rolls.

The diagonal or angular method of rolling is repre-

FIG. 28—3. Sketch of rolls used in the roughing stand of a rail mill rolling by the diagonal or angular method.

sented by the roughing stand shown in Figure 28—3. It differs from the slabbing method in that the shaping of the rail is begun with the first pass in the roughers and instead of first compressing the bloom to a smaller size and then forming the section partly through compression and partly by spreading, the process is one of compression from beginning to end.

DESIGNING THE ROLLS FOR RAILS

The first consideration in designing the rolls for rails is to produce a finished piece of the correct size and form. This objective can be accomplished only by directing and controlling the flowing, spreading and bending of the steel. The ease with which this forming is done depends on the plasticity of the metal, which in turn is affected by the temperature. With the speed of the rolls fixed, the temperature confined to a narrow range, and the grade of steel given, the only means of control remaining to the roll designer is the size and shape of the passes, and in part of these, at least, the size will be governed by the size of the bloom. In designing the passes, a good designer will endeavor to work the steel in such a manner that the quality of the product will be benefited, and no defects will be developed. The defects that should be carefully avoided are fins, laps, overfills, and underfills. Laps may result from fins or a collaring of the piece in the rolls; overfills, from worn rolls, poor or improper design; and underfills either from poor design or incorrect adjustment of the rolls.

Stages of Reduction—The formation of the rail from the bloom may be considered as taking place in three steps or stages. The first stage, called the **roughing**, is merely one of preparation; in it a large amount of work is done, but this work is expended mainly in reducing the size of the section and elongating the piece. The intermediate stage proceeds with the forming of the rail and involves a combination of **slabber**, **dummy**, **former**, **edger** and **leader** passes, dependent on the mill layout. The finishing pass completes the formation of the rail.

The Section—No original designing of section is done by the roll designer. The first requirement in the rolling of a new section is that the roll designer be supplied with a drawing or print of the section, which must be accompanied with all the dimensions, preferably indicated on the print. The weight of rail desired or expected should also be given. Here the matter of dimensions is

of extreme importance, for the designing of the templets cannot be started until each and every dimension required is given. These dimensions not only include linear measurements, such as height of rail, width and thickness of parts, but also the radius of all curves, and amount of slope on inclined surfaces expressed in degrees or percentages.

Roll Preparation—With all the necessary information available, the first step taken by the roll designer is to prepare a drawing for the cold templet. This drawing is constructed on the axis of symmetry of the rail, which is the vertical line drawn through the center of the head, of the web, and of the flange. On this line the section of rail is symmetrically constructed to the dimensions given on the drawing, all the dimensions being made with extreme care and accuracy. Upon completion of this very accurate drawing, the area of the section is measured with a planimeter in order to check the weight of the section. Any discrepancies between dimensions or weight are clarified with the customer after which the cold templet is prepared from either brass or steel.

The next step, which is really the first step in designing the roll passes, is the making of the hot templet. This templet is similar to the cold templet, but larger in size, as it represents the section of the rail at the finishing temperature of rolling.

From the hot templet the various passes are designed successively as the experience and judgment of the designer dictates. Roll designers may prepare the various pass templets by several methods. Usually the pass templets from a similar section are used as a guide, since many of the sections currently being rolled have been perfected through many modifications from initial designs for the passes. Frequently, the designer constructs each pass outline in a drawing showing the different passes superimposed upon each other. As a preliminary step toward designing passes back to the bloom from the finished templet, a table is usually prepared. This table will consist of various passes, cross-sectional area of the head, web, and base, per cent reduction, and spread in inches. The designer must constantly keep in mind the danger of forming fins. In order to avoid these defects, the designer may arrange the passes so that each side of the piece alternately enters an open and a closed side of the groove when rolling by the tongue-and-groove, flat or slab-and-edging method. Even with

FIG. 28—4. Differences in peripheral speeds at various points in the roll pass contacting, respectively, the flange, head and web of a rail during rolling.

this arrangement, fins would still be formed if the passes were not properly designed. To avoid the possibility of forming fins, two modifications of design may be used. In the leader pass, the corner of the head, which is to come opposite the openings between the rolls in the finishing pass, is well rounded off, so that the spread or flow of the metal will be taken up in filling out this rounded corner and none will remain to be forced into the clearance. For the same reason, that half of the flange on the same side of the rail is left much shorter. This provision is made in many of the passes. Great care is necessary in distributing the reduction of each part to prevent the metal flowing away from parts where it is needed. For example, if a too great reduction in the web takes place in one pass, it will produce a flow of metal away from the head, causing the latter to be underfilled. The cause for much of the trouble of this kind lies in the different diameters of the pass, which cause a different roll-surface speed for head, web, and flange, and hence different rates of elongation. If the elongation produced through compression is at the point of less speed, the section will be imperfectly formed, or cracks will result. The accompanying illustration (Figure 28—4) will help in understanding this point.

The roll designer strives to keep the roughing passes of such shapes and sizes that the same set may be used for a large number of different rail sections. The pass contours for producing the 132-pound RE rail are illustrated in Figure 28—5.

FIG. 28—5. Roll-pass contours for producing a 132-pound RE rail.

Upon completion of the pass templets, including both male and female for the cold templet, they are sent to the tool shop where they are used as patterns in making a set of tools for turning the rolls for the section. As many as 24 different tools may be required for the last six passes of each size rail. After shaping these tools a little over-size, they are heat treated and then redressed to exact size before they are used to turn the rolls. When ready, templets and tools go to the roll shop, where the work of turning the rolls is done. Rail-mill rolls may be

sand iron, alloy iron, or alloy steel rolls. Frequently more than one grade of rolls will be used on the same mill.

ROLLING PRACTICE

After the rolls have been properly turned, they are placed in the housings in their proper position and carefully lined up. A trial rolling with one bloom will then be made with the roller checking the piece closely to see that it goes through the mill in a satisfactory manner. The trial rail thus produced is gaged by templets which permit checking of base over-all, head width and contour, flange length and thickness, head radius and fish. (Fishing is a mill term for the dimensions of the theoretical contour of the under side of the head, the side of the web, and the upper side of the base.) By comparison with a master or cold templet the height and web thickness can be checked. If this section is found to be correct, the mill is then ready to begin the rolling. At frequent intervals, the rails are gaged and examined for defects such as collar marks, underfills, roll marks, overfills, guide marks, cracks, seams or pickups. One of the things that cannot be avoided in the rolling is the wear of the rolls which is aggravated by the slippage associated with the irregular section. The grooves tend to wear down rapidly, which will produce a "loose fish." "Rocking base" rails may result from worn rolls.

Standard specifications for rails require that the cold templet shall conform to the specified section as shown in detail on the drawing of the purchaser and shall at all times be maintained perfect. The rail section shall conform as accurately as possible to the templet or drawings furnished by the purchaser. A variation of $\frac{1}{64}$ -inch less or $\frac{1}{32}$ -inch greater than the specified height is permitted. A variation of $\frac{1}{16}$ -inch in the width of either flange is permitted, but the variation in total width of base shall not exceed $\frac{1}{16}$ -inch. No variation is permitted in dimensions affecting the fit of the joint bars, except that the fishing templet approved by the purchaser may stand out not to exceed $\frac{1}{16}$ -inch laterally.

Girder Rails—Among the special types of rails rolled are the girder rails of the plain, guard and grooved type, used principally by electric surface railways. These rails represent some of the most difficult sections to roll and are usually produced on structural mills. Demand for these sections has diminished to the point that the rolling of many sections has been discontinued, with replacements being made with standard T-rails. Contours of typical girder, guard, and grooved rails are shown in Figure 28—1.

Crane Rails—Crane rails, in three sections of 104–105 pound, 135 pound, and 174–176 pound, are currently being produced. These rails in general have a heavier head and web than the railroad rail in order to withstand the heavy loads imposed in service. These rails ordinarily are rolled on rail mills and are made by the same manufacturing practices as railroad rails.

Light Rails—Light rails are rolled on several types of mills—bar mills, light structural, and, in some cases, mills built and operated exclusively for light rails. Light rails are produced from heavy rails or from billets. In the rerolling of light rails from standard rails, either passes of the edge and flat design or of the diagonal design may be used. The rolling of light rails from billets is accomplished in much the same manner as the rolling of standard rails. An average of nine passes is generally used, although in a few extreme cases as few as five passes have been used.

FINISHING OPERATIONS FOR STANDARD RAILS

Cutting and Cambering—Railroad rails are ordinarily cut to produce the standard 39-foot rail. Lengths of 30

and 33 feet, which represent the old standard lengths, are produced in small tonnages, and long rails of lengths from 45 feet to 78 feet are produced in limited quantities. Finishing equipment is designed for standard lengths and longer lengths are handled with inconvenience and at additional cost. The rails are cut to desired lengths by hot saws operated singly or in gang, mounted over the runout table beyond the finishing stand. In cutting the hot rails, proper allowance must be made for linear thermal contraction, which, for a 39-foot rail, is approximately 8 inches. The exact amount of the contraction depends upon the temperature at which the rail is sawed. It is necessary to set the saws very accurately as the first rail from an ingot as well as the last rail from the same ingot must be within the length tolerance of plus or minus $\frac{3}{16}$ -inch. Vertical alignment of the saws must also be accurate and the saws must be maintained in sharp condition in order to meet a $\frac{1}{32}$ -inch maximum off-square tolerance. Drop-test and the nick-and-break samples are obtained from the crop ends cut at the hot saws. After sawing, the rails pass under a stamping machine which marks the heat number, ingot number and position of the rail in the ingot. The latter is designated by letters beginning with A at the top of the ingot. Between the stamping machine and cooling beds is a cambering machine which consists of a set of horizontal rolls with a vertical roll on each side, all in one housing and set to bend the rail slightly so as to make the top surface of the rail convex from end to end. This bending is done to compensate for the camber produced in a straight rail as it cools on the cooling bed, this camber being caused by the different rates at which the head and the base cool. A scale located near the end of the delivery table is used for checking the weight of the rails as often as desired, before they are advanced to the cooling beds. Rail specifications state that a variation of 0.5 per cent from the calculated weight of section as applied to the entire order is permitted.

Marking and Branding—One of the mandatory requirements for standard railroad rails is that each rail shall be legibly marked for complete identification. So far as practicable, this branding is done by numbers, symbols and letters cut in the bottom finishing roll to give raised characters on one side of the web of the rail. Markings that cannot be thus rolled into the web are marked intaglio on the opposite side of the web by a hot stamping machine following the hot saws. The nature of the information required and the methods of marking are as follows:

Method of Marking	Kind of Mark	Nature of Information
Engraving on bottom finishing roll	{ Raised characters }	Weight or section number
		Type CC (for control cooled) Manufacturer's brand Year rolled Month rolled
Hot stamping	{ Intaglio }	{ Heat number Rail letter Ingot number }

Controlled Cooling—Controlled cooling of rails on a production basis was begun between 1935 and 1937. From the rather crude start with various types of containers and covers, refinements have been made and specifications prepared so that a uniform controlled-cooling practice now is obtained.

Present specifications for rails intended for railroad service require controlled cooling of the rails within the

temperature range between 725° and 300° F. This is a process especially developed to prevent the formation of shatter cracks, also called internal thermal ruptures, flakes or internal thermal cracks. In mill operations, the rails are allowed to cool to under 1000° F and then are placed in either stationary or movable insulated containers. The rails must be placed in the container within the temperature range between 1000° and 725° F, which is checked by a radiation pyrometer. One or more thermocouples of the chromel-alumel type are placed between tiers of rails in the slow-cool container in order to obtain temperature readings during cooling. The containers are insulated to meet the specified cooling cycle of not dropping below 300° F in 7 hours for rails 100 lb. per yard in weight or heavier, from the time that the bottom tier is placed in the container, and 5 hours for rails of less than 100 lb. per yard in weight. Rails must remain in the cooling container for a minimum of 10 hours. Complete records of the cooling cycle to 300° F are maintained on each container.

Testing of Standard Rails—Testing of standard railroad rails includes both chemical and mechanical tests. Two ladle test samples, representing the composition of one of the first three and one of the last three ingots applied, are obtained. The drop test or the nick-and-break test are relied upon to supply the only mechanical-test information required. Crop ends 4 to 6 feet long are cut from the top end of the "A" rail from the second, middle, and last full ingot of each heat. ("A" rails are those rolled from the upper portion of the ingot, "B," "C," "D," etc., rails being rolled from steel in successively lower parts of the ingot.) These specimens are placed upon supports and subjected to the impact of a tup weighing 2000 lb., falling from a height of 17 to 22 feet, depending upon the weight of the section. For rails 106 lb. per yard or less in weight, the supports are placed 3 feet apart and for rails over 106 lb. per yard this distance is increased to 4 feet, with the tup striking the rail midway between the supports. If a specimen breaks, all the "A" rails of the heat are rejected and the "B" rails must be similarly tested. Failure of a "B" rail specimen causes all "B" rails to be rejected in addition to the "A" rails and similar tests must be made in "C" rails. Failure of a "C" rail specimen is cause for rejection of the whole heat. One specimen from a heat is given a number of blows to determine the ductility.

In progressive nick-and-break testing, if an interior defect shows on the fracture, the top end of the top rail is nicked and broken back. If a fracture free from interior defects is reached at a point permitting the rail to be finished to an acceptable length, the rail and the following rails of the ingot are accepted. If not, the rail is rejected and a test piece cut from its bottom end to represent the second rail of the ingot. The second and succeeding rails are tested in the same manner when so required.

Finishing Operations—Finishing operations for standard rails include preliminary inspection upon unloading from slow-cool cars or containers, removal of saw burrs, straightening, drilling, grinding of ends, beveling of heads when specified, inspection, classification, and painting. The purpose of the preliminary inspection is to check identification and lengths and to locate harmful surface defects and thus save the expense of finishing a rail that would be rejected. The removal of burrs made by the saws on the ends of the rails usually occurs prior to the straightening, although in some instances burr removal occurs after the straightening operation. The burrs are cut off with chisels and subsequently smoothed with a file or a grinder.

The rails are straightened on gag presses, each of

which is provided with two bottom supports located in the table proper on which the rail rests, and a top block with die attachment which moves up and down with a fixed stroke between the supports. The stroke of the block is of such length as not to touch the rail by about two inches at its lowest point. On each side of the press at spaced intervals are located two or three stands, each with a roll, to allow bringing the rail to the press and manipulating the rail back and forth while it is being straightened. The die has a double face, each side of which slopes to the center line. The gag, a rectangular block of steel slightly beveled to fit the die, is inserted between the rail and the die. The die form, in combination with the different dimensions of the gag, makes it possible to control the amount of bend the rail receives and to adjust the press to the several rail dimensions. To straighten a rail, one man called a gagger is stationed in front of the machine and a second referred to as a straightener at the end. By sighting along the rail, the straightener at the end locates the areas of rail which require straightening and brings them under the blocks while the gagger before the machine, acting under directions from the straightener at the end, inserts the gag in such a way that the stroke of the machine will bend the rail enough to straighten it, which requires that the rail be bent beyond its elastic limit in order to give a permanent set.

The rails are next moved to the drilling machines, which are arranged in pairs and so spaced that when one machine has completed the drilling on one end of the rail, it is moved under the other machine which drills the holes in the opposite end. These machines are provided with three drilling spindles, the middle one of which is fixed, and the outside two adjustable, and may be made to drill from one to three holes at one time. After drilling, the rails are moved to inspection beds where they are walked, or inspected, ends checked, ends beveled when specified, classified, painted, and separated for loading. The finished rail inspection is made by mill and purchasers' inspectors to satisfy themselves that the rails are according to specifications. The rails are inspected twice, one time with the base up and the second time with the head up. The location of defects or rails not satisfactorily straightened are marked with chalk. If these defects are located near the end, that portion of the rail may be sawed off and the rail still applied on the order as a short of first grade; shorts are accepted in limited quantities. If the defects are many or are near the center, the rail is either classed as a number two, or scrapped. Number two rails may contain slight imperfections which do not make them unfit for service. Number one rails must be free of injurious defects and flaws of all kinds. Rails which are not straight are transferred to a restraighening press for restraighening whereas rails required to be sawed are transferred to a recut unit which is equipped with slow-speed saws. Off-square ends are corrected either by use

of end-milling machines or hand grinders. Rails are classified into the following groups and each group is loaded in separate cars.

Classification	Painting on Rail Ends*
No. 2 rails.....	White
"X-Rayls"	Brown
"A" rails	Yellow
No. 1 rails of less than standard lengths....	Green
No. 1 rails of a heat whose carbon content is in the upper five points of the carbon range specified	Blue
No. 1 rails of a heat whose carbon content is lower than the upper five points of the carbon range specified.....	None

* Individual rails shall be painted only one color, according to the order of precedence listed above.

End Hardening—End hardening is a heat treatment given to the top end surface of a rail head which makes it more wear-resistant. The heating of the rail end is accomplished by either gas hoods, gas burners, or induction heating coils. Compressed air is used for the accelerated cooling. Usually the hardened pattern, including the hardened and transition zones, is about $\frac{3}{4}$ -inch in depth at the rail end, tapering to zero depth at a distance approximately $3\frac{3}{4}$ inch back from the end of the rail.

Some type of production-control testing is generally performed on end-hardened rails, usually the standard Brinell test, using a 10 mm. ball, made on representative samples.

Finishing and Inspection of Crane Rails—Crane rails are subjected to the same testing and processing as standard railroad rails. In the lighter sections, crane rails have been heat treated by quenching in oil and tempering with very satisfactory service results where heavy loads are involved. Crane rails in the control-cooled and the heat-treated conditions, with welded joints, have been placed in service in numerous locations.

Finishing and Inspection of Girder and Light Rails—Girder rails are not subjected to slow cooling, and straightening is usually done on a machine straightener, supplemented by gag straightening. Standard specifications cover girder rails of the plain, grooved and guard types, and finishing operations are comparable to standard rails. The impression test to check hardness is used rather than drop testing.

The finishing and inspection of light rails are different from the same operations for heavy rails. Because of the relatively small tonnage of most orders, light rails cannot be handled as separate heats and many light rails are rolled from billets of lower carbon content than heavy rails. Light rails are supplied in a variety of lengths and are usually straightened on a machine straightener. Bolt holes may be punched or drilled.

SECTION 2

THE ROLLING OF RAIL-JOINT BARS

Types of Rail Joints—Paralleling the development of rails to present-day standards has been the development in rail-joint bars and new techniques, such as welding for joining rails. Through the years, rail-joint bars have been known by various names, such as splice bars, angle bars, and fish plates. A great number of rail-joint bar designs were in use around 1925, such as (1) the Duquesne rail joint; (2) the 100 per cent rail joint; (3) the Weber rail joint; (4) the Hatfield rail joint; (5) the

Wolhaupter rail joint; (6) the Barschall rail joint; (7) the Bonzano rail joint; (8) the Abbott rail joint; (9) the Williams reinforced rail joint; and (10) the reinforced angle bar. Only a few of these rail joint bars are in use at the present time. In recent years there has been a trend toward a standard design of joint bar.

Present Rail-Joint Bars—Even with one type of joint bar, there must be many different designs, for the joint bar must fit accurately between the head and the base

FIG. 28-6. Cross-sectional diagram of the head-free type of conventional rail-joint bar.

FIG. 28-7. Diagrammatic cross-sections of two types of rail-joint bars, with nomenclature of principal components.

of the rail, and each change in these dimensions of the rail requires a change in the joint bar. The most popular rail-joint bar type at the present time is the short-toe joint bar of either the head-free or head-contact design. A sketch of the conventional rail-joint bar of the head-free type (with short toe) is shown in Figure 28-6. The head contact type of conventional rail-joint bar is identical with the sketch shown in Figure 28-6, except there is contact of the under surface of the head of the rail with the head of the joint bar. The head-free design is considered to have some advantage with respect to a lower rate of bolt-tension loss and lower resistance to expansion movement of rail ends. The principal advantage of the head-free design, however, is the fact that its use permits the desired thickening of the upper web and lengthening of the fillet radius. Nomenclature for the present conventional rail joint (with long toe) and the older type of continuous rail joint is shown in Figure 28-7. The continuous joint bar shown is still in limited use. This section is rolled with the lower base flared, the flare being pressed into a size to fit the rail base when the bar is punched. Other types of joint bars, with or without reinforcements in the web, are in very limited use at the present time.

Problems in Rolling Rail-Joint Bars—Passes for rolling three typical joint bars are shown in Figure 28-8. Joint bars are usually rolled from billets or blooms within the carbon content range of 0.30 to 0.60 per cent, although a lower carbon range has application for the cold-worked joint bar. The conventional joint bar and the joint bar with long toe are subject to all of the drawbacks of the rail section and to many others in addition, because of their irregular section and lack of symmetry. In the conventional joint bar, the angles at which the section is rolled are limited by possibility of undercuts, and the shape of the passes in which the piece is necessarily reduced are favorable to the formation of laps and seams. If the joint has a depending flange, or long toe, these difficulties are multiplied, while the excessively protruding parts of a joint, such as in the continuous section (Figures 28-7 and 28-8), often prevent the piece from entering the pass properly, by striking the rolls first or being a trifle colder than the rest of the piece. For similar reasons, it is difficult to make guides that will properly handle such sections, and they are prone to become cobbled or caught in the rolls of the

FIG. 28-8. Successive roll passes for the production of three typical rail-joint bars: (left) joint bar with toe; (center) continuous rail joint, and (right) joint bar without toe.

tables. The rolled section of joint bar is cut into convenient long lengths for handling and sent to the joint bar shop for processing into finished joint bars.

FINISHING JOINT BARS

In general, rail-joint bars may be finished in one of three ways: First, all the operations of shearing to length, straightening, punching and slotting may be performed upon the cold pieces without heating in any way; the finished pieces then are referred to as **cold-worked joint bars**. Second, the bars may be heated, after shearing to length, and the work of punching and slotting be done while they are hot, after which they are allowed to cool in air. In this case they are called **hot-worked joint bars**. Third, instead of cooling the bars in the air after hot working they may be cooled by immersing them in oil, when they are designated as **hot-worked and oil-quenched bars**. It will be observed that in this latter method, as in the other two methods, the bars are sheared to length cold, hot shearing being impractical, and hot or cold sawing too expensive. The hot-worked and oil-quenched joint bars possess such superior mechanical properties that practically all joint bars used on trunk-line railroads are finished by this process.

Cold-Worked Joint Bars—The bars rolled in long lengths are first sheared to length, punched and slotted and then inspected for straightness and flaws. The dies of the shears are, in all cases, made to conform to the shape of the bars, so that a clean cut is made without in any way deforming the bar. For a similar reason, the bottom blocks, or dies, of the punching and slotting machine support the web while the punches descend from above, pushing the material through conforming openings in the blocks. All dies are made of the highest grade of special tool steels and are kept in the best possible condition. In this way, the hole is made as smooth as it is possible to make it by punching. Bars of low carbon content are not adversely affected by the cold working but cold punching can injure bars of higher carbon content. One of the direct results of cold working high-carbon steel by cold punching is to increase the hardness of the metal about the hole; the worst effect, which applies only to bars of high carbon content, is the formation of very small cracks which extend into the metal along lines perpendicular to the surface of the hole. The difficulties in punching, as well as the deleterious effects of cold working, increase as the carbon content of the steel increases. As a rule, cold punching is applied only to the smaller joint bars with carbon content under 0.25 per cent.

Hot-Worked Joint Bars—The order of procedure for the manufacture of hot-worked joint bars is: shearing to length, heating, punching, slotting, straightening, cooling and inspecting. The "continuous" bar requires the additional operation of bending the base, which is usually accomplished on a combination folding and straightening machine.

The furnaces employed for hot working are of the continuous type, operating temperatures of modern installations being automatically controlled. After being sheared to length, the cold bars are laid upon water-cooled skid pipes and pushed into the furnace from the rear by electrically-operated dogs. The length of the furnace and rate of charging is such that about two hours are consumed in pushing each bar through the furnace. This time is sufficient to bring the bar to a working temperature of about 1500 to 1550° F (810 to 840° C) for 0.40 to 0.45 per cent carbon joint bars. The skids end near the front of the furnace, and the bars descend to a hearth or grate, whence they are removed

with tongs or hooks through the doors of the furnace.

During hot punching of a bar, in order to avoid spreading of the metal and consequent distortion of the bar, it is necessary to employ a confining die; that is, the cutting die must be enclosed in a die block or frame, the upper surface of which, together with the die itself, conforms in shape to the inside surface of the bar. The straightening machines are presses provided with a set of dies for each size of each section. One die conforms to the size and shape of one side of the section and the second die to the other side, and both are set in the press so that at the end of the stroke the space between the dies is of the same shape as the bar and just equal to it in thickness.

The harmful effects of cold working are entirely avoided by hot working, and, in addition, the reheating to a point just above the critical, or transformation, range tends to refine the grain structure and make it more uniform.

Hot-Worked and Oil-Quenched Joint Bars—The hot-worked and oil-quenched joint bar, at the present writing, is the only heat-treated rail-joint bar in commercial use. Reheating of the bars after hot working is not required because the operations of punching, slotting, and straightening can, with proper equipment, be done in a very short period and the bars delivered to the oil bath at a temperature satisfactory for quenching.

A joint-bar shop is usually equipped to handle any type of rail-joint bar by any one of the approved methods. To expedite handling of the bars, the shop is provided with a cold shear for cutting the bars to length, a reheating furnace for heating prior to working, a punching machine for punching the bolt holes, a similar machine for slotting the bars, a press for straightening them, and an oil tank for quenching. All these appliances are arranged in series in the order given, so that each bar may be passed easily and quickly from one to the other. The punches and press are set close to the delivery end of the reheating furnace. An endless-conveyor chain running at a uniform speed is employed to carry the bars from the straightener to the oil tank. The tank is rectangular in shape and provided with a link-chain conveyor which slowly carries the bars through the oil, the speed of the conveyor and its direction of travel being so regulated that the bars, upon entering at one end of the tank, are carried down into the oil, across the tank, and up to the opposite end. Adequate cooling and circulating facilities for the quenching oil are included so that the oil may be maintained at an optimum quenching temperature.

Welded Rail Joints—The joining of rails by welding the joints is being used by many railroads. The thermit process, the electrical method and the butt pressure method have all been used with the butt pressure method being most generally accepted for railroad installations. One result of the application of welded rail joints has been to increase the demand for rails in long lengths of 60 feet or more, which are produced at the present time in limited quantities. A typical example of welding rail joints as practiced by one of the major railroads in this country is as follows: Rails to be welded are held together end to end and a saw cut made at the junction of the two rails in order to produce parallel, clean and smooth end faces. A heating head with multiple orifices brings the two rail ends to welding temperature and then pressure is applied through clamps placed on the rails. After the welding is completed, the upset metal at the weld is scarfed off using a frame to protect the rail surface adjacent to the weld. Subsequent to the removal of the welding flash, a normalizing treatment is applied to the weld area.

Chapter 29

STRUCTURAL AND OTHER SHAPES

SECTION 1

EQUIPMENT FOR PRODUCING SHAPES

In rolling-mill parlance, the word "shape" is used interchangeably with the word "section" in describing forms of rolled material (except for geometrical shapes, which are known as rounds, squares, hexagons, etc.). Shapes, or sections, are normally divided into two classes, structural and other sections. Structural sections include standard items, such as I-beams, channels, angles, and wide flange beams, and special sections such as zees, tees, bulb angles, and car-building center sills. Other sections include such miscellaneous shapes as sheet piling, tie plates, cross ties, and those for special purposes.

The production of shapes, as enumerated above, involves a number of processes which are generally common to all of them. These processes include heating of the bloom, rolling to proper contour and dimensions, cutting while hot to lengths that can be handled, cooling to atmospheric temperature, straightening, cutting to ordered lengths, inspecting, and shipping.

The heating of the bloom for large sections is done in either of two types of furnaces, the in-and-out, or the continuous, which are described in Chapter 21. The in-and-out furnace is the more common of the two and serves nearly all of the older structural mills. A typical mill uses three furnaces of this type, having hearth areas about 18 feet by 36 feet. The newer mills tend to use continuous furnaces because of the greater economy, one or two continuous furnaces being sufficient. Practical widths of this type furnace can accommodate blooms up to 30 feet long, and one furnace of proper length, designed according to the cross-section of blooms to be heated, can have sufficient capacity to supply a mill. To hold heat loss to a minimum, furnaces are usually located adjacent to a bloom-storage yard, or the delivery table from a blooming mill, or both, and at a minimum distance from the first stand of the mill on which shapes are to be rolled.

A typical mill for the production of structural sections is shown schematically in Figure 29-1. It has a two-high reversing breakdown stand in which the initial shaping is accomplished, followed by a group of three stands, arranged in train, where the rolling process is completed. The first of these three stands, known as the rougher, is three-high. The middle stand, which is known as the intermediate, is also three high, and continues the formation of the shapes to almost finished dimensions. The finishing stand, which is usually two-high, establishes the final shape of the rolled section. Under some conditions it is desirable to have a three-high stand for the finisher. The two-high breakdown stand is fitted with rolls of cast steel, either carbon or alloy, with pitch diameter typically 36 inches, and body length 80 inches. The roughing, intermediate, and finishing stands, which are sometimes referred to

collectively as the finishing mill, usually employ rolls with a pitch diameter between 28 inches and 33 inches, and a body length of 68 inches. Cast rolls are used on these three stands, usually of carbon or alloy steel, grain or sand iron (see Chapter 23), the selection being based on service requirements.

In modern mills all of these rolls are driven by electric motors, with direct-current variable-speed reversing motors being essential for the breakdown stands, and preferred for all stands. On breakdown mills, the motor drives through a flexible connection to a two-high set of pinions, and through spindles to the rolls. Most structural finishing mills drive the three stands from a single motor, through a single three-high set of pinions, the drive being carried by spindles from the pinions to the roughing rolls, and by other spindles from the roughing rolls to the intermediate rolls. Two more spindles, connected to the middle and bottom rolls of the intermediate stand, drive the finishing rolls. Horsepower requirements vary, with 5000 horsepower being typical for breakdown stands, and 6000 horsepower typical for the finishing mill.

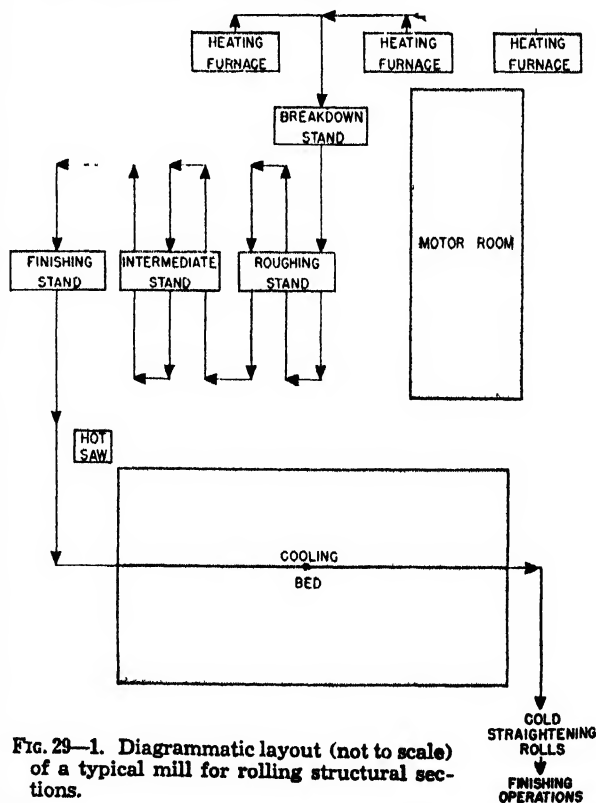

FIG. 29-1. Diagrammatic layout (not to scale) of a typical mill for rolling structural sections.

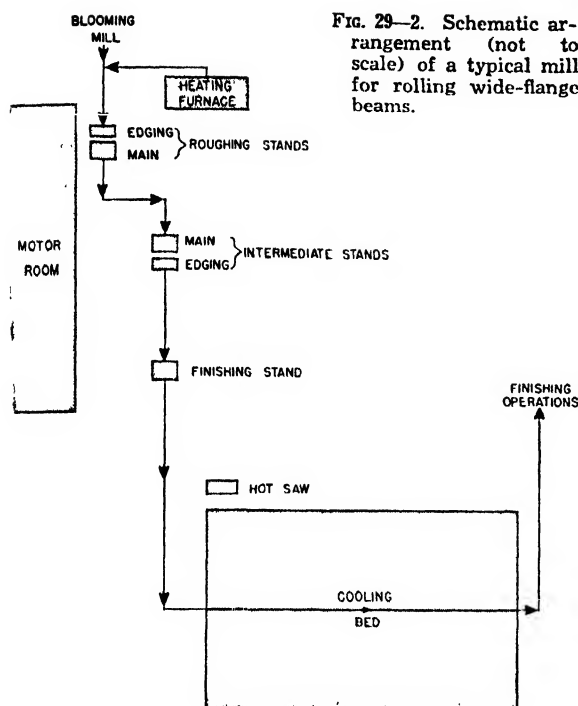

FIG. 29-2. Schematic arrangement (not to scale) of a typical mill for rolling wide-flange beams.

The breakdown stand is normally served by stationary roller tables equipped with mechanical manipulators. The shape is conveyed into, and received out of, the finishing mill passes by traveling, tilting roller tables.

The mill equipment for the production of wide-flange beams is substantially different from that used in the production of other shapes. Two or three groups of roll stands may be used, with each group containing more than one set of rolls. Figure 29-2 shows the schematic arrangement for a typical mill. This mill has a roughing group of stands which consist of a two-high roughing edging stand, closely associated with a roughing main stand, which has two horizontal main rolls and two friction-driven vertical rolls in a single vertical plane. The rolls in the roughing edging stand have a nominal diameter of 30 inches at the working zone and a body length of from 20 inches to 48 inches varying according to the depth of section rolled. The roughing main rolls have a nominal body diameter of 52 inches with a body length matching the edging rolls. Vertical rolls in the roughing stand, having a nominal diameter of 42 inches and a face width of 18 inches, are friction driven by the shape about a roller bearing in their bore. The intermediate group of stands is identical in all of the above particulars to the roughing group, with the exception of the edging stand being on the opposite end of the main stand. The finishing stand resembles the roughing and intermediate main stands in that it has main and vertical rolls of the same size in like arrangement, but does not have edging rolls. The general arrangement of the mill is such that the hot shape from the blooming mill or reheating furnace enters first into

the roughing edging stand and before clearing that stand enters the roughing main stand. The intermediate group of stands is placed a minimum distance to the side and one maximum shape length beyond the roughing group. The main intermediate stand is on the side toward the rougher and is closely followed by the intermediate edging stand, again arranged so that a single shape is in both stands of the group simultaneously ($12\frac{1}{2}$ foot centers). The finishing stand is in line with the intermediate group and 186 feet beyond the intermediate edging stand. Stationary roller tables are provided throughout with a short transfer mechanism to move the shape from the line of the roughing group of stands to the line of the intermediate group. All of these stands are driven by direct-current reversing motors, each individual stand having a separate motor, two-high pinions, and the necessary spindles. The roughing and intermediate main stands are driven by 7000-horsepower motors, and their respective edgers by 2000-horsepower motors. The finishing-stand motor is rated at 4000 horsepower.

Rolled shapes are further processed with equipment which is substantially the same for shapes produced on the standard type of structural mill as on the wide-flange-beam mill.

Removing ends not fitted to proper section, commonly called "crop ends," and cutting the hot shape into lengths which can be handled in further processing, is done with a hot saw. This equipment consists of a toothed circular saw blade mounted on a sliding frame and driven at high speed by an electric motor. Blades range up to 66 inches in diameter and copious water cooling helps maintain the cutting edges. The saw and its drive are moved on a sliding base at right angles to the hot shape so that the revolving blade cuts through the stationary shape.

Cooling of the rolled shapes is accomplished by placing them on a cooling bed which is a steel structure, arranged to support a continuous layer of shapes, while providing for a maximum circulation of air upward around them. A mechanism is provided to pull the shapes sideways into place and to slide them across the bed onto the discharge table.

Large shapes are straightened by roller-type straightening equipment, or a gag press. The former normally consists of seven or eight cast-iron or cast steel rolls assembled in a single housing with a single drive, driving either part or all of the rolls. The top rolls are placed midway between the bottom rolls and may be moved vertically by screws. All rolls are arranged for axial adjustment. The gag press consists of a horizontally-reciprocating ram midway between two support points on a platen which is so arranged that it can be moved closer to or further away from the ram, thereby varying the amount of bend made in the shape.

Cold cutting to final length is accomplished by shearing or cold sawing. The shears consist of a stationary bottom blade over which the shape is positioned, and a top blade which is forced down on the top of the shape to cut it through, either with a simple shearing action or by punching a slug, or short piece, out of the shape. The cold saw is similar in design and action to the hot saw, but is fed at a substantially slower rate.

SECTION 2

ROLLING METHODS AND PROCEDURES

The practice of heating blooms for rolling into shapes varies with the quality of the steel, the size of the bloom, and the temperature at which the blooms are

charged. A typical mill charges ordinary carbon-steel blooms received from the blooming mill at about 1800°F and heats them to 2250°F in approximately 45

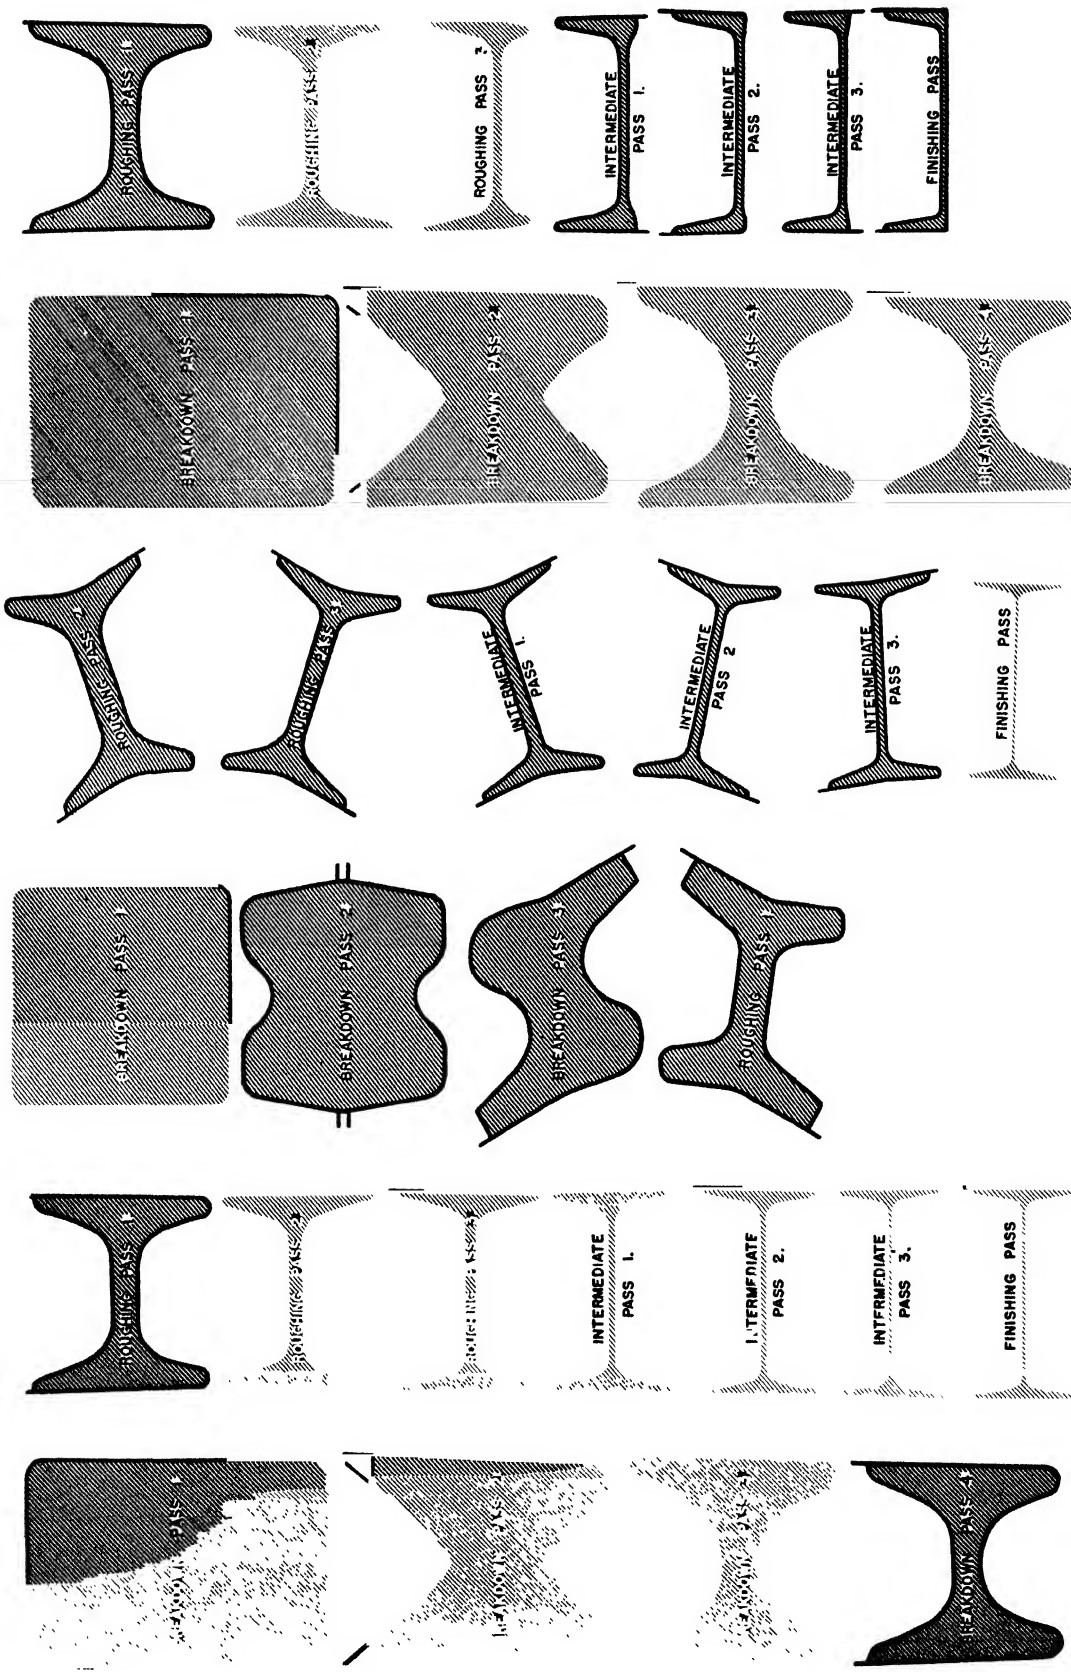

FIG. 23-5. Roll passes for producing a channel, using early passes shared for rolling beams.

FIG. 23-4. Roll passes for rolling beams by the diagonal method.

FIG. 23-3. Roll passes for rolling standard beams by straight-flanged method.

minutes. On a mill using three in-and-out type furnaces, normal operations find one furnace being charged, one heating, and the other being drawn, at a given time. Charging of the single layer of blooms in a furnace is begun as soon as the drawing has been completed. When steel at atmospheric temperature is charged, the heating to 2250° F requires about 2½ hours for the average size bloom. Handling the blooms into and out of the furnaces is accomplished by charging machines which grip the blooms on their sides. This necessitates a space between adjacent blooms of some six or eight inches as clearance for the charging-machine tongs.

Rolling—Heated blooms are deposited by the charging machine on the breakdown-stand approach table, which conveys them to the rolls. The manipulators, on the entry side of the mill, are brought into play to align the bloom with the first pass and to turn it about its longitudinal axis, if necessary. When properly aligned, the table rollers are revolved to feed the bloom into the first pass of the rolls. The rolls for the breakdown-stand generally have three or more pass grooves, some of which may be rectangular blooming passes. The number of different shaped grooves in the rolls, and the number of passes made in each groove, vary with the section being rolled. After making the required number of passes through the first groove, the bloom is re-aligned for subsequent passes by the manipulators.

Blooms processed through the breakdown-stand progress over the stationary rollers of the delivery table to the traveling tilting table which carries the bloom into line with the first pass of the roughing stand. Since the finishing-mill rolls are not reversed during operation, only a single pass is made through each groove. Similar tables on the opposite side of the finishing mill receive the shape from the first groove and enter it into succeeding grooves. Roughing- and intermediate-stand rolls usually contain from two to five pass grooves, while finishing-stand rolls are generally limited to a single pass on a shape. Finishers usually have duplicate grooves for the same section, or provide grooves for a variety of sections.

The type of section resulting from the rolling process is determined by the shape of the various pass grooves through which the material progresses, with optional groups of pass shapes frequently being available for the production of a given section. In the case of standard beams, at least three different systems of passes may be used.

The most common pass shapes used in rolling standard beams are those of the straight-flanged method which are shown in Figure 29-3. This method owes its popularity to the large range of web thicknesses which can be produced from a single set of rolls, the ability to use the early passes for the production of channels as well as beams, and the small thrust loads transmitted by the rolls to the bearings. The versatility of the weights produced results from the relatively small total taper in the live or open flanges which permit rolls to be separated to produce heavier webs with a minimum thickening of the live flange. The most undesirable feature of this method is the relatively slight taper in the pass sides which reduces the gain on dressing and results in passes getting progressively wider and flanges relatively heavier when dressed, thereby limiting the life of the rolls.

The butterfly method of rolling beams closely resembles the straight-flanged method. The outstanding difference is the fact that the live flanges are bent out to a much greater degree in all passes preceding the finishing pass. This results in greater ease of restoring

the open flanges by dressing, but imposes a serious limitation on the range of web thicknesses that can be produced in a given set of passes.

Figure 29-4 illustrates the passes used in the diagonal method of rolling beams. This method makes good provision for the restoring of both flange thickness and pass width by dressing, but involves serious restrictions in the web thicknesses that can be satisfactorily produced from a single set of rolls, and vastly increases the thrust loads that are imposed on the bearings which support the rolls. Since thrust-bearing wear permits longitudinal motion of the rolls with corresponding changes to the thickness of the open flanges, rolling difficulties result.

The method of rolling a channel using early passes shared with a standard beam is illustrated in Figure 29-5. This plan results in a smaller roll inventory, good flange control in the production of a large range of weights, narrower passes and stronger collars than can be had if the butterfly method is used. Figure 29-6 shows the butterfly design. It has the advantage of producing channels which are filled to proper section very close to the ends of the rolled bars. However, this method of production results in relatively thin weak collars on the rolls and almost precludes the rolling of multiple weights. This is caused by the extreme thickening of the flanges in the early passes when the rolls are separated to produce a thicker web.

Angles also offer the roll designer a choice between a number of proven rolling methods. Those most generally approved today may be referred to as the butterfly and the flat-and-edge methods. Typical passes for the butterfly angle are shown in Figure 29-7. The current popularity of this method is due to the relatively small crop loss on the shapes, the absence of vertical rolls or turning for edging, and the ease of controlling the bending, which is slight in any one pass. Undesirable features of the design are the lack of proportional thickening of the various parts of each leg when rolls are separated to make heavy weights, and somewhat poorer control of leg length.

The flat-and-edge type of design can be seen in Figure 29-8. This method is popular on those mills having vertical edging rolls and is sometimes used where the shape is turned 90° for edging in a pass in horizontal rolls. Leg lengths are readily controlled in the edging passes and thicknesses remain uniform when rolls are set to produce heavy weights. These advantages are frequently offset by the difficulty in maintaining proper entry alignment of the section in the later passes where bending is drastic. Turning long lengths of hot, flexible steel for edging, where that is necessary, is also difficult.

The special structural sections include shapes rolled rarely or for a single purpose. The passes used for the production of zee bars involve the same principles as the rolling of angles by the butterfly method, with each half of the pass resembling an angle pass, and with the two halves being fitted together reversed. The half center-sill section, used in making modern railroad cars, is a special type of zee bar, being irregular in both thickness of the members and flange lengths. Passes for its production are included here (Figure 29-9) because of the relatively great demand for the section.

Modern practice tends towards the production of tees by splitting a beam of proper size through its web to make two of the required sections. Some tees, however, are still rolled as such. The rolls are unduly complicated and the actual rolling is difficult. Where a choice is offered, the rolling of tees is usually avoided because of the necessity of turning the section between

FIG. 23-8. Roll passes for producing an angle by the flat-and-edging method.

FIG. 23-7. Roll passes for rolling an angle by the butterfly method.

FIG. 23-6. Roll passes for rolling a channel by the butterfly method.

FIG. 29-10. Roll passes for rolling an arch web section of sheet piling, showing how flange is bent to accurate configuration in the leader and finishing passes.

FIG. 29-9. Roll passes for the production of a half center-sill section, a special type of zee bar.

passes to permit each of the two tapered flanges and the parallel stem to be worked alternately so far as possible, in open and closed grooves.

One of the most interesting groups of sections produced upon standard structural mills is the sheet-piling group. Usually produced in three general types, known as straight web, arch web, and zee, these sections have been adapted as wall members in both permanent and temporary structures requiring strong vertical walls for lateral support, such as coffer dams, piers, dykes, breakwaters, etc. In the rolling of piling sections, the usual problems are complicated by the necessity of bending the flange which has been rolled straight to form the interlock. Precise control of the bend is necessary since proper clearance within the interlock must be maintained and the resulting opening between flange tip and thumb must be within close limits. The particular arch web section for which passes are shown in Figure 29—10 accomplishes this bending of the flange in two steps in the leader and finishing passes. Attention should be given to the fact that the shaping of the section starts in the blooming mill. This is typical of most piling sections and large beams, and is the result of the large size of the sections coupled with their intricate shape which precludes getting enough passes into the limited space of the breakdown and finishing mills to properly form the section.

While the rolling procedure for a section on the standard type of structural mill does not normally employ the same pass groove for more than one reduction in the shape, multiple passes being limited to the breakdown stand and seldom exceeding three passes in a groove, the opposite situation exists on the wide flange beam mill. Here as many as fifteen successive passes are taken through the main and edging stands of the roughing group. In a typical layout, the main and vertical rolls of the roughing main stand and the rolls of the roughing edging stand are moved to new settings with respect to each other by an automatic screwdown control. With this mechanism, the operator sets in advance of rolling the reduction to be taken on each pass. Then, pass by pass, he advances the lever of the master control switch a notch, with each of the three sets of rolls of the roughing group moving closer together simultaneously to the new settings. The control equipment is so designed that each of the three sets of rolls can be made to move different amounts, thus permitting proportional rather than like reductions on flange and web.

The equipment of the intermediate group of stands is practically the same as the roughing equipment. As in the rougher, fifteen passes are provided for in the control equipment. In practice, the passes are divided be-

tween the roughing and the intermediate stands in a proportion that gives equal duration of rolling cycle in each of the two stands. Since the shape at the roughing stand is relatively heavy and short, more passes are required there to balance the relatively few passes made on the elongated shape at the intermediate stands. Passes in actual use range from fifteen roughing and nine intermediate on sections requiring heavy overall work, to five roughing and three intermediate on the sections requiring a minimum of work; nine roughing and five intermediate passes represent the average condition. In all cases the intermediate passes are followed by a single finishing pass. In rolling wide-flange beams it is customary to roll a bloom which has, as nearly as possible, the same proportions as the finished beam. Each succeeding pass in the rolling cycle strives to maintain these proportions, resulting in reduction, pass by pass, being proportional. Since at no time after leaving the blooming mill are the flanges rolled in a closed groove, the loss in flange length is very small, and the rolling of beams with extremely high flanges is entirely possible.

Rolled material from either of the described structural mills is delivered by roller table to the hot saw. The blade of the saw is normally revolved in such a direction that the cutting edge is moving downward toward the shape. The action of the rapidly revolving toothed blade combines a mechanical sawing and melting of the steel, the chips when thrown clear frequently being molten. Cuts are usually made at the hot saw to remove the crop ends, to part the usable material into lengths that can be handled for further processing, and to provide short test pieces. Tests are cut for the guidance of the roller in correcting defects in the section and for various mechanical tests which are part of the inspection procedure.

Cooling is accomplished by the natural circulation of air about the shapes on the cooling bed. The rate of cooling can, to some extent, be controlled, and is of relative importance. Cooling can be accelerated by maintaining space between shapes on the bed, and by providing ample space below the bed for the passage of cool air. Retarding of the cooling cycle results from putting the hot shapes on the bed in a solid touching layer. If cooling is too drastically retarded, the size of the hot bed must be increased or rolling delays will result. On the other hand, too rapid cooling may result in mechanical properties outside the ordered range. Non-uniform cooling results in warpage of the shapes as they cool. This must be avoided in symmetrical shapes, if possible. Most non-uniform shapes warp during cooling, sometimes to the point that they are difficult to convey to the straightening machine.

SECTION 3

FINISHING AND INSPECTION

When the shapes have been properly cooled they are conveyed again by roller table to the straightening machine. For the products rolled on the standard type of structural mill and the smaller wide-flange beams, a roller straightener is normally used. The first shape to be straightened is stopped in the machine while the rolls are adjusted laterally to it. The top rolls are then moved downward to deform the shape with each successive top roll making less deformation than the preceding one. This shape is backed out of the machine and then run through for most of its length. If not straight to the eye of the experienced operator it is

again reversed in the machine. Further adjustment is made with this process being repeated until a straight shape is obtained. Subsequent shapes will require only slight alteration to the setting of the machine to compensate for wear and other variables. The larger wide-flange beams and some few standard mill products are straightened in the gag press. Here the process consists of advancing the stationary platen and the shape towards the reciprocating ram until a bend is accomplished in the shape. The operator has full control of the point on the shape at which the bend will be made, the amount of the bend, and by turning on the table,

the direction of the bend. Bending strives only to offset initial crookedness.

Cutting to final length is accomplished by one of several means. The most commonly used process is cold shearing. It is applicable to angles, channels, standard beams and the smaller sizes of wide-flange beams. It is relatively inexpensive and results in good uniformity of length with minimum distortion of the sheared end. Cold sawing is next in popularity, and is used on most of the wide-flange beams, the larger sizes of standard beams, and on sections, such as piling, where shear distortion of the ends would make the section unusable. Cold sawing is more expensive than shearing and results in a ragged burr which must be removed by chipping. Flame cutting is available for extremely heavy sections and unusual applications. Where overall length must be accurate, as in the case of columns, the ends may be milled. This results not only in close length tolerance, but in a reduction in the ends' out-of-square allowance as well.

Before the products rolled on the various mills may be shipped, they must be inspected for defects and tested for certain mechanical properties. This is accomplished by two general methods. First, the test cuts taken at the hot saw are sent to the laboratory where tests are made to determine the mechanical properties of the material, such as tensile strength and yield point. The other method of inspection is visual inspection of the material on an inspection bed where the shapes are inspected for metallurgical defects, such as pipe, blister

and scabby surface, and for dimensional variations such as length, straightness, and out-of-square condition. Dimensions such as web or flange thickness, flange height, weight per foot, etc., are checked on tests taken at the hot saw by the mill inspector, and the roller then adjusts the mill to correct improper conditions. Special sections may require additional inspection. An example is the slot and thumb on sheet piling. Chemical composition of all material is known, as a record is kept of all rolled products showing the number of the heat from which it was rolled.

The final steps are to separate and assemble for shipment. The material then is loaded in freight cars, river barge, or truck, and shipped to its destination.

Chapter 30

MERCHANT-BAR PRODUCTION

SECTION 1

MILLS AND THEIR PRODUCTS

The name "merchant mill" is said to have been given in the early days of rolling to those bar mills which carried a stock of their product from which merchants selected bars at their convenience. The name has been carried over from that time and is still applied in the designation of modern bar mills, particularly those on which some of the small shaped sections are rolled. In other plants, the mills are designated simply as bar mills.

Other designations sometimes used are "hand bar mills" and "guide mills."

In the early mills, rounds and sharp-cornered squares were rolled by hand, that is, the bars were prevented from turning over in the passes by a tongsman, who forcibly held the bars in the proper position in the grooves throughout their passage through the rolls. As a general rule, the finishing stand of rolls was two-high

FIG. 30-1. (Above) Schematic arrangement of a three-high and a two-high stand in train, set up for guide rolling of rounds. Note that the bottom roll of the three-high stand serves only as a spindle to drive the bottom roll of the two-high stand. (Below) Illustrating the use of tongs for preventing turning of the piece in a pass during hand rolling of rounds.

in these mills, though in rare instances a three-high stand was used. In the two-high mill, the bar delivering from a given pass was returned over the top roll for entering into the next pass, and so on until the section was finished. This type of rolling was arduous and the length of bar that could be rolled under these circumstances was limited to about 16 to 20 feet.

This limited length that could be rolled, in combination with the heavy labor involved, led to the adoption of the so-called guide mills, in which rounds and sharp-cornered squares were held in the passes by close-fitting entering guides. To do this for rounds, it was necessary to devise a new pass design in which a square (or gothic square) was entered into an oval pass and the resulting oval was then entered on edge into a round finishing groove. By using an oval, closely fitting entering guides could be used that would hold the oval section in its proper position as it passed through the round groove.

In the older hand-round method, bars entering the finishing groove were so nearly round that no enter-

ing guide could be devised which would prevent the bars from turning over in the grooves. Thus the guide-round design permitted the rolling of long lengths and this method has practically superseded the hand method, although, for various reasons, there are mills in which rounds still are rolled by hand. Figure 30-1 illustrates both the hand and guide method of rolling rounds.

The mills in which rounds and squares were rolled by hand were referred to by the early operators as "bar mills," whereas the mills using guides to hold up the bars were referred to as "guide mills." What can be called the first bar mill was the two-high mill designed by Henry Cort in the latter part of the 18th century. Many of the early mills were driven by water wheels, and it is known that two water wheels were used in some cases, one for each roll. Later, steam-engine drives became common.

Crude as these early mills were, they were vastly superior to those in use prior to Henry Cort's time. With these early mills as a start, the bar mill gradually be-

FIG. 30-2. Diagrammatic layout of the stands and auxiliaries for an arrangement known as a Belgian mill, featuring a roughing stand driven separately from the finishing train.

referred to as a **Belgian mill**, as it was said to have originated in Belgium. The mill could roll longer lengths and finish them at a higher rate of speed and, consequently, could produce greater tonnage than earlier mills.

As the next innovation, the Belgians and Germans introduced the looping of bars. In this practice, the bars in the finishing train, when they reached a stage in their reduction at which they were relatively flexible, were caught by the tongsmen on the front end as they emerged from the rolls and pulled around in a half circle and entered into the next pass. As a result of this practice, rolling time for a bar was appreciably reduced and more bars could be rolled per hour, producing greater tonnages. Some of the more improved mills of this kind had two or three roughing stands in train, on the same housing shoes, which permitted still greater production because the roughing passes could be divided among the two or three stands.

After the looping of bars became common practice, means were sought to eliminate, so far as possible, the manual looping of bars. A trough called a repeater was devised to conduct bars from one stand to another. The first successful repeater was put into use by W. McCallip, superintendent of a small bar mill in Columbus, Ohio, in 1877. For the most part, repeaters are used to direct the bar out of a square pass into the succeeding oval pass, while the tongsmen direct the ovals into square passes. Some mills also use repeaters for oval into square, in which case the oval must be twisted so that its longer axis is in a vertical position as it goes around the repeater; otherwise it will jump out of the trough.

In Europe, the production of the Belgian-type bar mills was further increased when two Austrians perfected a repeater for three-high roughing stands. This repeater was a trough which conducted the bars, as they emerged from the passes, around a half circle and back into the next groove in the same roll stand, obviating the use of a tongman who could not, in any case, work in such close quarters as would be necessary on these roughing stands. The repeaters were used on the last two or three passes in the roughing operation, when the bars were small and long enough to provide the necessary flexibility. Figure 30-3 shows a three-high mill repeater in use on the roughing stand of a mill in which the finishing stands have been divided into two groups, the second group being run faster than the first for increased production. The finishing stands employ two-high repeaters for looping square into oval. Some mills in the United States use three-high repeaters of this type.

Further improvement of the bar mills became possible with the introduction of the continuous roughing principle in 1882. Mills employing this principle consisted of an eight-stand tandem* continuous roughing mill and four finishing stands in line. Although such mills were first built for the rolling of rods, about 1900 several were built to roll bars from a 4-inch by 4-inch billet. Figure 30-4 shows an improved type of this mill with two additional stands added for the rolling of smaller bars.

The early mills of the type shown in Figure 30-4 had some serious disadvantages. As discussed in Chapter 19, since the cross-sectional area of a piece is reduced during rolling, the piece leaving the rolls has a higher velocity than that at which it entered, due to its being elongated. The continuous roughing stands of the early mills had fixed speeds, with each successive stand running faster than the preceding one by an amount cal-

culated to compensate for bar elongation. The fixed speeds made it imperative to have perfect balance between speed and elongation among the several stands, otherwise either the bars would be stretched or a loop would form between stands, either of which was undesirable. At the same time, the distances between stands were relatively short, causing heavy pressure on the delivery guides used to twist the bars 90 degrees for entrance into each succeeding stand. This heavy pressure often resulted in injurious scratching of the bars by the guides and these scratches, when rolled in, gave the bars a seamy appearance.

In the finishing mill the four roll stands, being in one line (in train), are driven at the same speed. As there is a reduction in cross-sectional area of the bar in each succeeding pass through the mill, and consequently a corresponding elongation of the bar, a successively longer loop forms between each stand. As a result, the back end of the bar becomes colder than the front end because of more contact with the floor and longer exposure to the air, a condition which introduces a variation in size of the ends of the bar as compared with the middle.

A number of mills were designed to overcome these disadvantages. Some had the roughing line split into

FIG. 30-5. Arrangement of a bar mill employing a 6-stand tandem continuous roughing mill, followed by a double finishing train. All stands are two-high.

* Rolling mills are said to be "in tandem" when they are arranged so that the rolled piece can progress from one stand to the next in a continuous straight path, as in the continuous roughing stands in Figures 30-4 and 30-5.

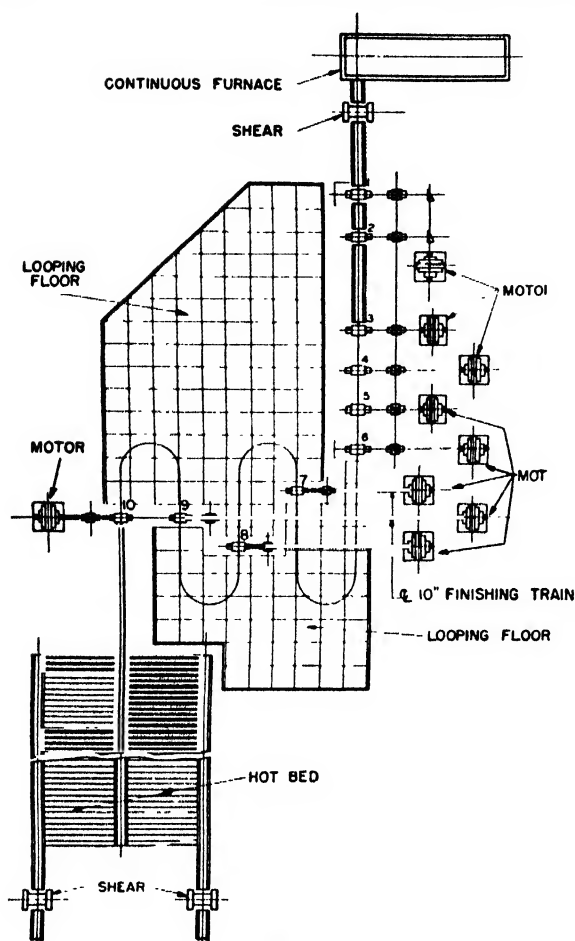

FIG. 30-6. Bar mill designed with a semi-continuous roughing arrangement followed by a four-stand continuous roughing mill, supplying roughed-down billets to the four stands of the finishing mill. All stands are two-high, and each is separately driven except for the two stands of the semi-continuous roughing set-up.

two or three groups so that the bar would run out to its full length between the groups. The finishing stands were also separated into groups of two or more roll stands, each group being separately driven and at a higher speed than the preceding one. Thus, between each group of rolls, the loop could be kept at a minimum, though they still formed between the stands which were in train. Space does not permit showing all of the arrangements devised to eliminate long loops.

A mill designed to overcome some of the disadvantages of these older mills is shown in Figure 30-5. In this mill, which has a double finishing train, the finishing stands have been divided into groups, with no more than two roll stands driven at the same speed. In each of these groups of two stands driven at the same speed, the second stand has rolls of larger diameter than the first in order to keep the loop between stands at a minimum. In a mill of this type the continuous roughing mill has sufficient capacity to supply both finishing trains, thus increasing production. Two billets can be sent through the roughing train, one for each finishing train.

Figure 30-6 shows a mill with a semi-continuous roughing arrangement in which the first two stands are driven by one motor and the bar runs free after each

stand. These two stands are followed by four continuous stands driven by individual variable-speed motors. The finishing unit is comprised of four stands, each one driven by an individual variable-speed motor at a successively increased speed. This mill, through the use of separate motors, permits excellent control over push and pull in the roughing stands, except in the first two, and, as the stands are a good distance apart, the heavy pressure on the guides experienced in the older close-coupled mill is relieved. In the finishing stands, the speed control provided by the separate motors permits close control of the length of the loop between any two passes. This mill was a considerable improvement over the older types.

Figure 30-7 shows a bar mill of the cross-country type which rolls a wide range of products. The mill has two hot-beds and finishes the large sizes out of stand No. 10. The smaller sizes are finished in stand No. 14 or No. 16. The mill is further distinguished by having a vertical roll stand immediately following stand No. 14 and continuous with it. The vertical stand provides the means for rolling off all over-sizes or shoulders formed in the horizontal stand, giving a more perfect round. So-called precision rounds, which are rounds rolled to approximately one-half standard tolerances, are finished through these two stands. The vertical stand is removed when finishing in stand No. 16 or when rolling to standard tolerances.

Figure 30-8 shows another cross-country design. This layout does not have any continuous stands and the bars run out free after each pass. The sections rolled on this mill range from $\frac{1}{2}$ -inch to $5\frac{1}{8}$ -inch rounds, squares

FIG. 30-7. Schematic layout of the stands and auxiliaries for a bar mill of the cross-country type, employing the continuous principle in the latter roughing stands.

FIG. 30-8. Bar mill of the cross-country type differing from that of the preceding illustration in that no continuous stands are used and the bars run out free after each pass.

in corresponding sizes, flats from 1 inch to 9 inches in width and other products of comparable dimensions. The larger size products are finished from stand No. 9-A, which has 16-inch rolls, and the smaller sizes are finished from stand No. 12, which has 12-inch rolls. The distinguishing feature of the mill is that each stand has a variable-speed motor.

The most modern of all the bar mill designs is the continuous mill with alternate horizontal and vertical rolls, an arrangement which, curiously enough, was embodied in the first continuous mill built by Bessemer in 1862. The use of alternate horizontal and vertical stands obviates the necessity for twisting the bars, and the twist guides, with their tendency to scratch bars, are eliminated. The stands of the mill are spaced far enough apart so that a slight loop can be formed between stands. Individual variable-speed drives for practically every stand permit regulation of speed relationships to take care of bar elongation between stands, and the slight loop eliminates all push and pull between stands. The general principle of employing alternate horizontal and vertical stands was discussed in the description of the continuous billet mill at Lorain Works of National Tube Division in Chapter 25.

Mills for Rolling Light, Narrow, Flat Material—Flat thin material of narrow width is produced on various types of bar mills. This material is known as narrow strip, band iron, hoop, and cotton tie. When first produced, this type of product was rolled on mills similar to the one shown in Figure 30-2, but as mills of this

type could not roll any large tonnage of such light weight material, better mills were soon developed for the purpose.

Figure 30-9 shows a modern mill designed to roll this thin material. This continuous mill produces comparatively large tonnages of hoop, cotton tie, and narrow strip. In mills of this kind, the very narrow widths of the thin gauge materials are obtained by rolling a multiple width of the material and then slitting the rolled piece (after it is cold) into the desired widths. This permits the mill to maintain a rate of production that could not be realized if very narrow widths were to be rolled.

Rail-Slitting Mills—Rail-slitting mills were first developed when Bessemer rails were being rolled in large quantities and before open-hearth furnaces were common. Bessemer rail scrap was a drug on the market, as it could not be used in any quantity in the Bessemer vessel. The rail-slitting mills, a number of which are still in use, solved the problem of utilizing this scrap by rerolling it into other and useful sections.

Figure 30-10 illustrates a rail-slitting mill. These mills take a heated rail, usually 10 to 16½ feet long, and run it through a two-high stand of rolls with sharp collars which cut through and separate head, web, and base. Each one of these parts is then rolled into a bar of some kind directly after it is slit. The products include rounds, squares, fence posts, angles, concrete-reinforcing bars, flats, and a variety of other small sections. The continuous stands shown on the drawing are used to bend and form a flat, rolled from the base of the rail, into a cylinder which is then welded at the joint to make a tube or pipe.

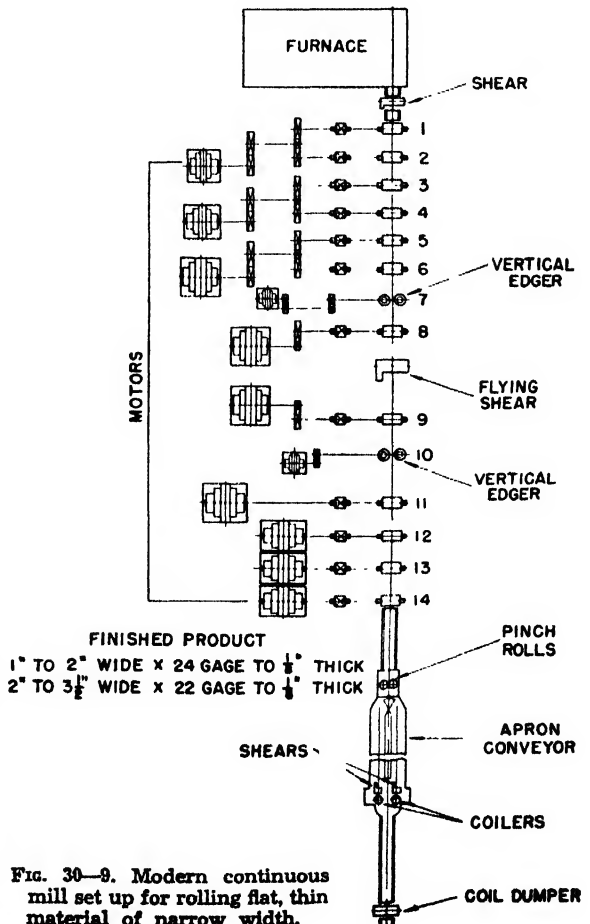

FIG. 30-9. Modern continuous mill set up for rolling flat, thin material of narrow width.

FIG. 30-10. Schematic arrangement of the slitting mill and roll stands of a rail-slitting mill. Inset at upper left shows how the head, web and base of the heated rail are separated in the slitting mill prior to rolling each, without reheating, into a bar. This particular mill has three continuous stands (marked "tube rolls") for forming a tube as described in the text.

ROLL DESIGN FOR BAR MILLS

The first roll designs for bar mills were very simple. They consisted of box passes, gothic passes, tongue-and-groove passes for flats, and so-called hand-round grooves for rolling rounds.

FIG. 30-11. Rolls and passes for rolling a hand round, using gothic passes in the roughing and hand-round grooves in the finishing rolls. The numbers of the sketched passes correspond to the cross-hatched and numbered pass openings between the rolls above.

FIG. 30-12. Rolls and passes for rolling guide rounds. The roughing rolls containing the nine gothic roughing passes are not shown. Numbers on the sketched strand, leader and finishing passes correspond to the cross-hatched and numbered pass openings in the respective sets of rolls shown immediately above.

Figure 30-11 shows a design of passes and a sketch of the rolls for rolling a hand-round, using gothic passes in the roughing and hand-round grooves in the finishing rolls. Figure 30-12 shows a typical series of passes for rolling guide-rounds, using gothic roughing passes, strand open-square passes, and oval and round finishing passes. These two methods were extensively used in the older bar and guide mills.

The gothic roughing rolls are not used to any great extent today. The design has been superseded in most hand mills by the diamond roughing set. Figure 30-13 shows one of these sets, which are also used for roughing passes for hand-guide rounds. Figure 30-14 shows a line of passes for a guide round using diamond roughing grooves, oval and square strand grooves, and oval and round in the leader and finishing passes. The three-high strand rolls shown in Figure 30-12 have a combination of oval and open-square passes, also diamond passes. The open-square passes referred to are of 94-degree

FIG. 30-13. Rolls with diamond roughing passes of the type which has largely superseded gothic roughing passes for rolling rounds by either the hand or guide method.

angularity. To make a 90-degree square using these grooves it was customary to go twice through the same size groove.

The mill with the eight-stand continuous roughing arrangement and the looping finishing mills shown in Figure 30-4 used a 4-inch by 4-inch billet of not over

FIG. 30-14. Diamond roughing passes, oval and square strand passes, oval leader pass, and round finishing pass for guide-round rolling. Dotted lines indicate shape of piece entering pass, corresponding to shape of piece out of preceding pass turned 90 degrees.

225 pounds. The continuous stands were close together and a roll design was provided which would require the least possible twisting of the bars. The roll design on this mill provided for a $1\frac{1}{2}$ -inch round in 14 passes. The first and second passes were both flat ones in box grooves. The bar then was twisted 90 degrees into a hexagon-shaped groove (pass No. 3) and then on into pass No. 4, which was a square in the diagonal position. By using this design, only one twist of the bar was required in the first four grooves. After pass No. 4, the bar was twisted 45 degrees to enter pass No. 5, which was an oval, and from there on the passes were alternately square and oval, the bars being twisted 90 degrees in the oval form and 45 degrees in the square form, before entering the next pass. The last pass, naturally, was round. Passes Nos. 9, 10, 11, 12, 13 and 14 were looped by hand on this mill.

As mentioned earlier, mills of this type rolling short 4-inch by 4-inch billets, with their close coupled roughing stands and long loops, were not able to roll bars of close tolerance on the front and back ends of the bars. These disadvantages led to the adoption for modern continuous mills of 30-foot billets of $1\frac{1}{2}$ -inch to 3-inch squares. Rolling 30-foot billets produces bars more uniform in section throughout their lengths because the back end of such a billet is still in the furnace and retaining heat while the front end is emerging from the

FIG. 30-15. Series of passes for rolling a 2-inch square billet into a $\frac{3}{4}$ -inch round in ten passes, using an alternate oval and square reduction down to the finishing oval and round. Dotted lines indicate shape of piece entering pass, corresponding to shape of piece out of preceding pass turned 90 degrees. Per cent reduction of the piece in each pass has been calculated from the cross-sectional areas, as shown.

FIG. 30-16. Steps in the reduction of a 6-inch square billet to a $1\frac{1}{8}$ -inch round in twelve passes on the cross-country mill shown in Figure 30-8. Dotted lines indicate shape of piece entering pass, corresponding to piece out of preceding pass after turning the required number of degrees for proper entry.

continuous roughing mill and, as the mills generally have good speed adjustment in the finishing stands, mill loops are kept at a minimum to insure uniformity of size throughout the rolled piece.

Figure 30-15 shows the pass design for rolling a 2-inch by 2-inch billet on a modern-type mill into a $\frac{3}{4}$ -inch round in 10 passes, using alternate oval and square reduction down to the finishing oval and round.

In the cross-country mill types, somewhat different roll designs are used. Figure 30-16 shows a roll design for the mill shown in Figure 30-8, which rolls many different grades of alloy steel, including stainless steel. The design shows the steps in reducing a 6-inch square billet to a $1\frac{1}{8}$ -inch round in 12 passes. The first four passes are flat and edge, the flat passes being in plain rolls and the edging in box passes. The principal object in using these flat and edge passes is to break and free the bar of the scale that formed in the furnace during heating. In the first pass the roll pressure is on the top and bottom of the piece; the sides are free and, being compressed, crack the scale and allow it to drop off. In

FIG. 30-17. Diagrams A, B, and C show, respectively, bar-mill roll-pass designs for rolling square-edge flats by the tongue-and-groove, diagonal, and flat-and-edge method. Diagram D shows a typical set of passes for rolling round-edge flats.

the next pass, the other two sides are free and the scale drops off here also. The next two passes repeat the same procedures. It is not practical to use this type of pass throughout the mill because box passes are not efficient in drafting in the smaller sizes, and for this reason the next two passes are diamond and square, a form of pass which effects substantial reduction in cross-sectional area and also has the merit of contacting all sides of the bar at once. In the next two passes, oval and square are used as it is desired to have a heavy reduction in order that passes Nos. 9 and 10 may be more lightly drafted. Pass No. 9 is a slabbing or flattening pass which reduces the 2 1/8-inch square to a rectangle measuring 2 1/8 by 1 1/2 inches. Pass No. 10 is called a "former" pass. The function of this pass is to round the upper and lower edges so that the following oval will be well-rounded on the sides, for when the oval is rounded at the roll parting, scale will not readily adhere to it at this point. When scale is present, it is rolled into the finished round. In some mills, a square is used to enter the round oval and, when so used on some grades of alloy steel, scale sticks to the bar at the roll parting and is rolled into the bar.

Figure 30-17 shows three roll-pass designs for rolling

FIG. 30-18. Each vertical line of roll passes illustrates steps in rolling a different size of polygon. Method C is somewhat uncommon. Dotted lines show shape of piece out of preceding pass and position on entering each succeeding pass.

FIG. 30-19. Steps in rolling (A) one-inch sharp-cornered squares, (B) triangular file steel, (C) half-oval file steel, and (D) half-rounds on a merchant bar mill.

FIG. 30—20. Steps in rolling various small sections from billets or slabs on merchant bar mills.

square-edge flats, and one design for round-edge flats, as used on bar mills. Figure 30—17A illustrates a tongue-and-groove design used on a simple four-stand old-style bar mill. Figure 30—17B shows a diagonal design used on some mills, while Figure 30—17C shows the most popular design, one used on many modern bar mills, consisting of a flat and edge layout wherein the widths of the flats are regulated by edging grooves

which at the same time give the section a square edge. This design permits the rolling of several sizes in the same grooves. Round-edge flats are commonly rolled as shown in Figure 30—17D.

Octagons are often produced as illustrated in Figure 30—18A, but the most popular design for hexagons is shown in Figure 30—18B. Figure 30—18C shows an uncommon hexagon design used in one mill.

FIG. 30—21. Roll passes for producing various bars and shapes on a rail-slitting mill such as shown in Figure 30—10.

FIG. 30—22. Roll passes for producing hoop and cotton tie on a merchant bar mill.

Figure 30—19A shows a 1-inch sharp-cornered square design and Figure 30—19B a design used for rolling triangular file steel. Figure 30—19C illustrates a half-oval design also used for file steel and Figure 30—19D an arrangement for rolling half-rounds.

On many merchant bar mills, small shapes are rolled, such as angles, channels, small beams, tees, small agricultural shapes, window sash, etc. Figure 30—20 shows a number of small sections and steps in their formation from the billet or slab.

Rail-slitting mills, such as shown in Figure 30—10, roll a variety of bars and shapes. These mills, of course, must confine their product to material which can be rolled from steel having the chemical composition of

rail steel. Figure 30—21 shows a number of typical bars and shapes produced from the various parts of a rail.

Hoop and cotton-tie passes on the older mills were made by the tongue-and-groove method. The tongue-and-groove passes restricted the spread of the bar somewhat and also regulated the width. A series of passes using tongue-and-groove in the next to the last three passes is shown in Figure 30—22A. A later design is shown in Figure 30—22B. In this design the flattening is done in plain rolls and the width is regulated by a vertical edging stand. These passes represent the design used in the first continuous hoop and cotton-tie mill of 1895. The passes used in the most modern mills are of this same general design.

SECTION 2

FINISHING AND SHIPPING MERCHANT MILL BAR PRODUCTS

Coordination of Finishing and Shipping Functions
—The operations involved in finishing and shipping merchant bar products are essentially the same in all

plants, and the coordination of these functions differs only as to location of the rolling mill or mills, the type of products, arrangement of equipment, mode of trans-

Fig. 30—23. Slow-speed saw for recutting steel bars.

portation, etc. The functions of finishing and shipping merchant bar products are: (1) To provide a method of identification, cutting, bundling or coiling the product at the rolling mill as a preliminary to its delivery to the finishing departments. (2) To straighten, surface condition, heat treat, inspect or otherwise prepare the product for shipment in the finishing departments, in accordance with specifications and in compliance with transportation regulations.

BAR FINISHING PROCEDURES AND EQUIPMENT

Relation of Mill Delivery Equipment to Subsequent Finishing Operations—The type of rolling mill delivery equipment used has a very significant bearing on the straightness of the bar delivered for shearing. Most modern mills have certain features in the design of the hot beds—straight edges, kick-off equipment, roller tables and guides—to minimize bending and kinking that result in the necessity for subsequent straightening. When rolling-mill design permits, straightening units should be installed in the hot-bed delivery roll train ahead of the shears. Such an installation generally eliminates straightening as a finishing operation and necessitates fewer material handling steps prior to loading.

METHODS OF CUTTING PRODUCT TO LENGTH

The cutting of merchant bar product in most plants is performed by one of the following methods or by combinations of these methods: (1) Cutting by mill shears, directly to ordered lengths if practicable, or in multiple lengths if necessary to facilitate mill delivery, the latter requiring subsequent recutting to a variety of shorter lengths in the finishing departments. (2) Recutting by a finishing-department shear to meet ordered requirements, or for salvaging of portions of the product which may have surface or end defects.

(3) Hot sawing of large rounds or sections which are not adaptable to hot shearing. (4) High-speed friction

sawing where recutting is necessary after the straightening operation on a product previously cut by a mill shear or hot saw. (5) Machine cutting, which consists of the use of an abrasive cut-off machine, a hack saw, a cracker shear, or a slow-speed saw (Figure 30—23),

Fig. 30—24. Sketch showing end and top views of a typical two-roll unit for straightening rounds.

where the closest tolerance on end-squareness is required, or where, by the nature of the product, recutting cannot be done satisfactorily by other methods.

(6) Flame cutting, where the nature of the product and specifications permit the application of heat for rough cutting.

MACHINE STRAIGHTENING

Many merchant bar products require straightening after hot shearing at the mill. Straightening is necessary so that the product may meet either standard commercial tolerance specifications or any special specifications. In the finishing departments this is usually accomplished by roll-type machines, or by gag presses. The selection of the type of straightening equipment depends on the characteristics of the product and the end-use requirements. There are numerous commercial types of straightening machines, but they all are similar in principle and are fundamentally designed to process a specific shape within certain dimensional limitations. On this basis, straightening equipment can be divided into three main classifications:

(1) **For flat product.** This equipment includes multi-roll units for flats, squares, hexagons, etc.; and two-way roll units for straightening in planes at right angles in one pass.

(2) **For round products.** This equipment includes roll units which rotate the product through either a two-roll (cross-roll) or a multi-roll unit, and gag presses. Figure 30—24 illustrates a two-roll straightening machine.

(3) **For standard shapes and special sections.** This equipment includes both light and heavy multiple-roll units having grooves to fit each separate section, gag presses (both vertical and horizontal, with interchangeable guides and adjustable stroke), and roll units for shaping such products as small channels or U-bars which are hot rolled in an open form and then closed by cold forming before the straightening operation.

SIZING, TURNING AND CENTERLESS GRINDING

In the manufacture of merchant bar products, the design and type of rolling mill or the characteristics of the steel frequently preclude the possibility of hot-rolling a round to within precise sectional or out-of-round limitations, or to roll a round with a surface suitable for later fabrication requirements. When such requirements must be met, rounds are further processed in the finishing departments by such operations as sizing, turning, centerless grinding, or by combinations of the latter two. Bars to be processed by any one of these methods are hot rolled over-size by an amount predetermined by experience.

Sizing is applied to bars when a moderate reduction in section or an improvement in out-of-roundness is desired. It is performed by passing the bar through a two-roll or cross-roll straightening machine in one or more passes as required. Sizing can impart a cold-drawn appearance to the surface of the bar if the rolls are new and properly adjusted; however, it is not generally used for the purpose of improving the surface appearance. As sizing elongates the bar, due to reduction of cross-sectional area, re-cutting to length must follow.

Turning improves the surface of a bar by the removing of undesirable defects that may be present in the surface. It is applied on those types of steel, predominantly the alloy type and particularly the stainless steel group, where, due to the inherent characteristics of the product, it is very difficult and in some cases impossible to obtain a hot-rolled surface which can be utilized by the customer without the removal of a portion of the "skin" of the bar. Turning is accomplished by passing

the bar through a turning machine or lathe, using one or more passes depending upon the amount of material to be removed. There are several designs of turning machines used in producing merchant bar products, but they all are constructed according to a fundamental principle. They differ only in the arrangement of the revolving heads or the manner in which the bars are supported and fed to the revolving heads. In all types, a suitable cutting oil is fed to the tool or tools in the revolving head by a pressure system. In one type of machine, two cutting heads are mounted very close together, in tandem, between two guide bearings. In another type, the revolving heads are a considerable distance apart, separated by guide bearings. Due to the arrangement of the revolving cutting heads, the former type is more adaptable for bars of short length, while the latter is more suitable for bars of long length. Turning machines are made in various sizes and can handle rounds in sizes up to and including six inches and in lengths up to forty feet. The amount of metal removed per pass is dependent on the type of steel, and the diameter and the length of the bar. Removal of approximately $\frac{1}{8}$ inch on the diameter per pass is considered normal for bars of medium or large diameter. Speeds of twelve inches to fifteen inches per minute are normal when removing this amount of metal.

In finishing some grades of alloy and stainless steels, surfaces and dimensions are required that can be met only by **centerless grinding**. Centerless grinding differs from turning in that a grinding wheel is used for removal of metal instead of a cutting tool, and more accurate dimensions and better surface finish are obtained. The centerless grinding machine is constructed so that the bar is supported under the greater portion of its length as well as under the grinding wheel, rather than at the ends. This design enables the machine to operate to close tolerances by elimination of axial thrust, always present when a bar is supported at the ends. A suitable coolant is used on the grinding wheel or wheels. Most commercial centerless grinding machines are constructed to handle round bars up to four inches in diameter, in ranges of approximately one inch in diameter. When the diameter of the bar must be reduced materially, it is more economical to remove a large portion of unwanted metal by the turning machine before centerless grinding. Standard centerless grinding machine tolerances are ± 0.002 inches on bar sizes up to two inches in diameter and ± 0.003 inches on larger sizes up to four inches in diameter.

In some cases a highly polished bar is desired rather than the standard centerless ground finish. The polished finish is produced by passing centerless ground bars through a polishing or lapping machine. This machine is similar to the standard centerless grinding machine except that the grinding wheels are composed of a fine grit and the bar-supporting apparatus is constructed to operate within very narrow limits of accuracy. Polishing or lapping tolerances are one-half of those for standard centerless grinding. In precise polishing or lapping of long bars, it is very difficult to keep within these tolerance limits because of the wear of the grinding wheel and the spring of the metal. For these reasons, more precise tolerance limits than those stated above are not considered practical for commercial products.

Processing Bar Coils—There are some manufacturers, such as bolt, rivet or cold-drawn steel fabricators, who find it more convenient and economical to obtain bars (either rounds, squares, hexagons, or flats) in coil form rather than in straight lengths. As most of the smaller bar and rod mills are not equipped with flying shears to crop the front and back ends of a coil, it is necessary to

complete this operation in the finishing department of the mill. Variations in the process for cropping coils, depending upon available equipment, will be found at the various plants. The most widely used equipment is a long conveyor, sometimes over 1,000 feet in length, equipped with hooks spaced approximately ten feet apart, which pick up the coils from the mill coiler and carry them to the end of the conveyor. While the coils are moving along the conveyor, the ends are cropped either by a small shear or by flame-cutting. As the coils proceed further, they cool considerably, and then can be inspected and wired or banded securely. A shipping tag is attached, following which each coil is spark-tested as a final check of identification. By the time the coils have reached the end of the conveyor, they are cool enough to be loaded into the railroad cars for shipment. In some plants having high speed mills, where cutting to length would seriously retard output of the mills, bars which finally are to be shipped in straight lengths first are rolled in coils; subsequently, in the finishing department, they are then uncoiled, straightened, and sheared to length on a processing line designed for the purpose.

PICKLING

Stationary or Vat Pickling—Pickling is the term given the descaling process by which the hard black oxide formed on the surface of a bar during hot rolling is removed by chemical action. The removal of hot-rolled scale by pickling may be performed in order to: (1) prepare the surface of the bar for inspection, (2) prepare the product for ultimate end use. Pickling is also used, though to a much lesser degree, to remove the slow-forming red rust that develops on bar products after long exposure to air. Stationary or vat pickling in its simplest form consists of immersing the steel bars in a dilute acid bath, which is held at a predetermined temperature, and permitting them to remain stationary until the pickling action is completed. Most modern installations have improved the method by including means of keeping the bath in motion or agitation. Stationary or vat pickling is one of a number of pickling methods which are classified according to the manner in which the operations are conducted. Other methods of pickling and equipment are described elsewhere in the text.

The stationary or vat pickling method for descaling bars has been used with success and reasonable economy where the best established procedures are followed. A number of variables, both chemical and physical, determine the procedure to be followed, the design and capacities of equipment, and the lay-out to be used in the construction of a unit. Beginning about 1935, considerable data have been published concerning the pickling process, many of these being more or less empirical. Study of these data indicates that there is considerable difference of opinion as to what actually takes place as the iron oxide is removed. One theory proposes that the scale or oxide layer is relatively less soluble than the iron underneath and that the acid solution, passing through tiny cracks or fissures in the scale (formed by differences between the cooling rates of the metal and scale), reacts chemically with the bonding structure between the underside of the scale and the true metallic surface of the bar. In this reaction hydrogen gas is liberated which, it is claimed, dislodges the scale particles. A second theory proposes that the acid solution attacks the iron oxide or scale, resulting in its actual dissolution in the pickling bath. A third theory, a combination of the first and second, proposes that there is a preferential dissolution of the surface of the scale by the acid, followed by the penetration of the acid solution through tiny cracks or holes to the base metal,

where it attacks the bonding structure and liberates hydrogen gas. The hydrogen gas, as in the first theory, is said to serve as an agent in lifting the scale in small particles from the surface of the bar.

A large majority of the various types of steel bars can be pickled by the stationary or vat method, providing all factors pertaining to the physical and chemical variables of the process are taken into consideration. The efficiency of scale removal by pickling varies considerably. The scale on some types of steel bars can be removed readily, while on others, considerable difficulty is encountered. The pickling of hot-rolled low-carbon steels, for example, is done with little difficulty and the scale can be removed readily by the use of a sulphuric-acid solution. On hot-rolled high-carbon steels or alloy steels, however, many difficulties are encountered in the removal of scale. On high-carbon steels, a bad discoloration in the form of a black smudge of carbonaceous, insoluble material is the chief difficulty. The black smudge is particularly undesirable when close inspection must follow. On alloy steels, the hot-rolled scale is not removed as uniformly as in the case of the low-carbon steels. This condition can be attributed to the differences in chemical composition of the scale. By proper selection of acid or acids, by the selection of the most effective acid concentration, by adequate agitation, by use of proper bath temperature and the inclusion of an effective inhibitor, the pickling of high-carbon and alloy steel bars can be accomplished successfully. On the very high-alloy steels, such as the stainless group, pickling cannot be accomplished successfully in sulphuric-acid solutions alone, even at high acid concentration and elevated bath temperatures. Stainless steels are pickled in baths containing sulphuric plus another acid, another acid alone, or by a combination of other acids. The choice of the acid combination and concentration depends upon the characteristics of the steel to be pickled and the finish desired. The most commonly used acid for pickling is sulphuric. Other acids used in this method are hydrochloric (muriatic), nitric, and phosphoric.

Another factor affecting scale removal on hot-rolled high-carbon or alloy steels is the thermal treatment, such as normalizing or annealing, to which the bars may have been subjected. Bars so treated are difficult to pickle and, in some cases, the attendant pitting of the product is so severe that other methods of removing the scale must be employed.

The equipment for stationary or vat pickling consists of three tanks. The first tank is used for the dilute acid solution or pickling bath; the second contains only water, for washing the steel bars after immersion in the pickling bath; the third tank contains an alkaline liquid (lime water), for neutralizing any acid which remains on the bars after washing.

Tanks or vats containing the dilute acid solution or pickling bath can be of several types and are constructed of various materials. They must be water tight and capable of resisting attack by the acids used in the pickling solution. They are constructed either of wood, concrete, brick, or metal lined with wood. When wood is used for the tank or when it is used as a lining, cypress has been found to be the most durable. Recently, improvements in tank construction have been realized by using acid-resistant brick or terra-cotta tile as a lining for either wood, concrete or metal tanks. The acid-resistant brick or tile is laid in courses, with an acid-resisting mastic cement as a binder. Rubber is also used for lining tanks and has given excellent service. The practice of lining stationary or vat pickling tanks with sheets of lead is no longer looked upon with favor, because experience over

the years has indicated that the lead lining is susceptible to cracking under the rapid temperature changes which are prevalent in this method of pickling.

In addition to the three tanks required for the pickling operation, bar-mill finishing-department equipment usually includes a steel tank, containing a rust-preventative oil into which the bars are dipped in order to provide adequate protection against subsequent rusting.

As a coating of lime may be specified on bars, particularly those to be cold drawn, an additional tank for this purpose is generally part of the equipment. The lime coating serves as a lubricant in the cold-drawing process and reduces wear on the dies. It is applied after the washing and neutralizing stages of the pickling process. The tank for lime coating generally is constructed of steel and, as the lime should be kept in suspension in the water, a means of providing continuous agitation is usually a part of the installation. Pickling, washing, neutralizing, and liming tanks should be equipped with proper means of heating the bath and provision must be made for proper means of disposing of the waste solutions.

The efficiency of a stationary or vat pickling unit depends in a large measure upon the manner in which a multiplicity of similar pieces can be arranged and immersed in the pickling solution or in the washing, neutralizing, oiling or liming baths. The entire surface of each individual bar must be exposed if the best results are to be obtained. For this reason, various designs of crates and racks have been developed, one of which is shown in Figure 30—25. The steel bar product to be pickled is placed in tiers on the crates or racks. In the tiers, the bars are kept apart by separators which are called combs. These combs are designed to permit adequate spacing between each bar to allow for free circulation of the acid solution around them. The racking or placing of the steel bars on the fixtures for pickling is done manually. The materials used in the construction of the crates, racks, separators, and combs must be of acid-resisting metal and of a strength sufficient to carry the weight of the load.

When conditions and specifications permit, steel bar

product that has been coiled is pickled by passing a chain through the open center of a group of coils, and attaching the ends of the chain to the hook of an overhead crane. Such a group of coils is referred to as a "lift," and is suspended in the pickling tank by the crane. This practice is referred to as chain pickling. Chains used in this work also must be made of acid-resisting metal. Monel metal or aluminum-bronze alloys are used in many parts and fixtures, including the chains.

Steam has been the most widely used for heating pickling baths, but, the submerged gas burner method, a relatively recent development, has become popular with many operators. Where steam is used, suitable piping for conducting the steam into the bath is necessary. Adequate and convenient steam-input controls must be provided in the form of valves, either hand operated or automatic in action, in order to maintain the bath as nearly as possible at the proper temperature. When steam is introduced directly into the bath, care must be taken to avoid direct impingement against the sides or bottom as this will result in rapid erosion and damage to the tank. Also, the introduction of steam directly into the pickling bath results in an increasing dilution of the bath, which requires the addition of more acid to maintain the solution at the proper concentration.

The submerged gas burner provides for burning gas and air under automatic control in submerged burners. The hot waste gases from the burners are conducted into lead tubes which run the length of the tank on the bottom. This method heats the pickling bath quite efficiently, and the waste gases, which are forced out under pressure through holes located throughout the length of the tubes, provide the desired agitation of the bath. When this type of heating equipment is used, however, care must be taken to avoid accumulation of sludge and scale in the bottom of the tank. If the lead tubes become completely covered with sludge and scale, they are shielded from the pickling solution in the tank, become overheated, and are destroyed.

When a new pickling bath is to be prepared, the tank first is filled to approximately three-fourths capacity with water. Acid in an amount to provide the proper concentration is run into the tank, and then enough

FIG. 30—25. Loaded pickling rack, showing how combs keep bars separated to allow free circulation of acid solution.

water is added to bring the solution to an operating level. The heat is then turned on and the bath is brought to the operating temperature. When placing products in the pickling bath, care must be taken to avoid any rapid or irregular movement that may splash acid solution over the sides of the tank, where it rapidly attacks the outer tank shell, concrete floors and tank foundations. It is very important that wash tanks be emptied frequently, as acid in damaging amounts builds up in the wash water and interferes with the proper function of the washing operation.

The surface of steel bars to be pickled must be free from oil or grease, as these materials protect the surface from the action of pickling solution. Any substance on the bars which may serve to contaminate or neutralize the acid solution must be removed before they are immersed in the pickling bath. After the steel bar product is washed and dipped into the neutralizing bath, it is further safeguarded against rusting by being thoroughly dried. Live steam and sometimes air, blown against the bars as they hang suspended in the rack, are used for this purpose.

Summarizing, the factors controlling the rate of pickling and the iron loss are: (1) acid concentration, (2) temperature, (3) time in bath, (4) percent of iron (ferrous) sulphate in the bath, (5) presence of inhibitors, and (6) agitation of the bath. Frequent tests of the bath should be made. Not only will the testing of the pickling solution reveal the concentration of the acid bath, but will also show the rate of iron dissolution into the bath, thus giving a good indication of the efficiency of the pickling operation. If the rate of iron increase in the solution is rapid, it indicates that the true metal is being attacked severely. Under such operation, not only is the wastage of acid high, but also the loss in weight of the steel bars becomes excessive. When the iron content of the pickling solution reaches approximately 0.5 lb. per gallon, the bath is considered to have little further use and is ready to be dumped. Testing the pickling solution for acid and iron can be done very readily by titration.

Temperature of the Pickling Bath—The significance of this factor should be understood clearly. By raising the temperature of the pickling bath the action of the acid solution upon the scale can be increased greatly, for the particular pickling job at hand. It should be remembered, however, that while increasing the temperature of the acid solution speeds up the pickling action on the scale, it also increases the tendency of the acid solution to attack the steel itself. When the metal is attacked, the iron reacts with the acid and goes into solution in the form of the salt of the particular acid or acids used. As the amount of iron salts in solution increase toward the point of saturation, the efficiency of the process decreases very rapidly. This may necessitate the addition of more acid to the bath or, possibly, the complete replacement of the bath with a new acid solution. The trend with some operators is toward the use of lower acid concentrations and lower bath temperatures. The practice requires more time per ton of steel pickled, but the quality of the work is improved. Less metal is lost from the surface of the bar and less acid is consumed in the process.

An inhibitor is an agent added to the pickling solution for the purpose of protecting the exposed surface of the metal of the bars, by inhibiting or retarding acid attack upon the metal without affecting, to any appreciable degree, the pickling action which removes the scale. The inhibiting action is not understood clearly but is generally explained by the electrolytic theory of corrosion. Inhibitors show little change and lose little of

their efficiency during the pickling operation. However, they may be broken down and their function destroyed by overheating. Many different substances are used as inhibitors in acid pickling. They range from vegetable or animal matter to complex synthetic organic chemicals. The prime requirements of an inhibitor are that it must disperse colloiddally in the bath, prevent hydrogen evolution and not leave a smudge or film on the surface of the steel. Many inhibitors contain substances that cause foaming, and the floating layer or blanket of foam on the bath prevents the escape of acid with escaping gases and vapors. As inhibitors are expensive and only a small amount is needed for desired results, less costly foaming substances are added separately by many operators when increased foaming activity is desired.

Common difficulties encountered in pickling are over-pickling, under-pickling, smudge and pitting. Over-pickling may be defined as the etched appearance of the surface of a product caused by over-activity of the acid solution. Conversely, under-pickling may be defined as incomplete removal of the scale due to limited activity of the acid solution and/or the use of too low a pickling temperature. Smudge is a carbonaceous precipitate or stain which forms on bars of high carbon content. Pitting may be defined as the appearance of crater-like indentations on the surface of the bar, which may result from over-activity of the acid solution on the metal in areas where scale has been loosened mechanically or removed prior to the pickling operation, or as the result of an electrolytic action taking place in areas where there are concentrations of dense scale on the surface.

GRIT-BLASTING

Grit-blasting or blast-cleaning is a mechanical process used for removing scale and rust on merchant bar products. It consists of eroding or abrading away the scale from the surface of the bar by impinging an abrasive substance like sand or aluminum oxide, or a metallic substance like cast-iron shot. The abrasive material may be directed against the work by air under pressure or by a mechanical apparatus utilizing centrifugal force. All types of steel bar products and shapes can be cleaned successfully by this method. As a result of the difference in economy of operation between the grit-blasting and the pickling method, the former generally is confined to the cleaning of one of the following types of products: (1) those which must have certain physical characteristics essential to subsequent processing; (2) those which cannot be cleaned satisfactorily by the pickling method after such thermal treatments as normalizing or annealing; (3) those with high alloy content whose scale cannot be removed satisfactorily by ordinary pickling methods.

The principal difference between the various types of grit-blasting equipment is in the means employed for throwing the grit or shot against the work. One type of grit-blasting machine makes use of centrifugal force generated by a rotor or impeller which rotates at a very high speed. Grit in the form of metal shot is fed from a hopper into the revolving rotor through an opening in the center of the rotor housing. The shot, on entering the revolving rotor, is picked up by the rotor vanes and is thrown by centrifugal force away from the center of the rotor toward its periphery. From the periphery, the shot is directed outward to impinge on the work at the angle desired for the best abrasive effect. Since this type of machine develops its abrasive characteristics on the basis of the velocity and the weight of the particles, lighter grit, such as sand, cannot be used satisfactorily.

Another type of machine employs compressed air or forced air from a blower for throwing the grit particles. There are several modifications of this principle, but in

each type the grit is permitted to entrain in a fast-moving air stream and is directed upon the surface of the work through a hose having a nozzle designed for the purpose. The lighter grit is used most effectively with this type of equipment. The material used for, and the size of, the grit or shot in blast cleaning are dictated by the requirements for a given job and, as previously noted, by the type of equipment in which it is to be used.

From the standpoint of density, grit can be divided into: (1) the light, and (2) the heavy. Light grit is a non-metallic inorganic material with excellent abrasive characteristics. It is purchased according to particle size. Examples of light grit are the widely used natural abrasive known as Ottawa sand and the synthetic abrasive, aluminum oxide. Heavy grit is principally of the metallic type such as cast-iron shot. Like the light grit, it is purchased according to particle size. Metallic grit is the type most generally used on merchant bar product.

The chief advantages of grit blasting are: (1) it leaves the surface of the bar with a bright metallic finish without any adhering scale; (2) it is capable of cleaning a number of types of products that cannot be cleaned successfully by pickling; (3) it does not produce such physical or chemical conditions as over-pickling, under-pickling, smudge or pitting which may attend the pickling process. The disadvantages of grit blasting are: (1) only a few bars can be processed at one time in the blast machine; (2) as the grit or shot builds up with scale the efficiency of the cleaning effect is decreased; (3) the bars are difficult to inspect for surface defects because of the peening action of the grit or shot; and (4) the cost per ton of steel cleaned is greater than the cost of pickling.

Grit blasting does produce minute indentations on the surface of the product which are more beneficial in some subsequent fabrication operations than they are detrimental. The size of these indentations and their shape serve to produce a surface sheen or finish determined somewhat by the particle shape and size of the grit. The character of this sheen or finish is very important where cold-drawing operations are to be performed. As a grit-blasted steel surface is very susceptible to rusting, bars cleaned by this method must be protected immediately from moisture and alkaline or acid vapors. Also, when a bar is grit-blasted with cast-iron shot, particles of the shot have a tendency to adhere to the product and will cause rapid rusting or corrosion on some types of steel if they are not removed immediately. In such cases the grit-blasting operation must be followed by a light pickling operation.

BAR INSPECTION AND TESTING

Inspection—In order to produce satisfactory bar products it is important that an adequate quality control system be established and maintained. This system should include mechanical and metallurgical testing as required, and the inspection for surface or other defects. The procedures for making mechanical and metallurgical tests and the inspection of steel prior to rolling in the merchant mills are covered in other chapters of this book. The inspection of merchant bar product in the majority of plants is carried out along the same general lines and can be divided into two divisions; (1) mill inspection, and (2) finished product or final inspection. The duties and responsibilities of the inspection forces in these divisions must be thoroughly co-ordinated to accomplish the best results.

Mill inspection is performed during the rolling process and is the means of minimizing or preventing discrepancies at the source. The duties of the inspector at the mill are: (1) to check the identity of the steel being

rolled, (2) to inspect the surfaces of the product to determine its suitability for further processing in the finishing departments or in its final intended use, (3) to check section and length of the product to determine its suitability for application on a particular order, and (4) to procure necessary samples for mechanical or metallurgical tests. The inspection of the finished bar products, on the basis of commercial standards or for dimensions, straightness, surface defects, and other items of form as may be required, is carried out upon completion of the finishing end operations at designated units.

The duties of the final inspector are in a measure a repetition of the duties of the mill inspector, with the additional responsibility of checking and posting heats. The checking and posting of heats is a method of reporting the amount of product accepted or rejected (per heat) on an order, with reasons for further processing or for rejections. The final inspector must lay particular emphasis on surface quality if the product has been conditioned and straightened. Various tools are required for inspecting merchant bar product. A list of these tools and a brief description of their use follows:

(1) micrometers and calipers, for measuring the section of rounds, flats, and squares; (2) snap gages, for precision rounds; (3) tape, for measuring length; (4) slide scales, for measuring width; (5) protractors, depth gages and radius gages, for shapes; and (6) the square tool for measuring off-squareness.

Surface defects, as well as other defects which cause the rejection of merchant bar products, may be the result of steelmaking practices which carry through from the ingot or may be caused by the rolling mill equipment used to produce the product. A list follows giving the general mill terminology of the most regularly occurring types of mill defects and a brief description of each:

1. **Fins and overfills** are protrusions formed when the section is too large for the pass it is entering, or when proper allowance has not been made for lateral spreading in the rolls. Overfills are broad and less sharp than fins. As a rule, overfills occur more frequently than fins and in many cases are associated on the same bar with underfills.
2. **Underfills** are the reverse of overfills, that is, they are areas in which the section is incompletely filled. They are formed by permitting the bar to be rolled scant in certain dimensions. Underfills appear most frequently on rounds and channels.
3. **Slivers** are loose or torn segments of steel rolled into the surface of the bar. They may be caused by a bar shearing against a guide or collar, incorrect entry into a closed pass, or a tear from other mechanical causes. Sometimes slivers are present in the billet and are carried through to the hot-rolled bar or shape.
4. **Laps** can be said to be a rolled-over condition caused by a bar having been given a pass through the rolls after a sharp overfill or fin has been formed, causing the protrusion to be rolled into the surface of the product.
5. **Seams** are crevices in the steel that have been closed but are not welded. They are a type of a defect very difficult to detect on certain types of steel products. Seams are caused by blow holes and cracks in the original ingot, or by faulty methods of rolling in both semi-finishing and finishing mills.
6. **Fire cracks and roll marks** are impressions in the product, of varying degree and pattern, caused by mill rolls becoming overheated, and cracking or spalling.

7. **Scratches** are long nicks or indentations in the product caused by the surface or surfaces of the bar rubbing against sharp or pointed objects such as guides on the mill, chutes, "dead" conveyor rolls, chain hoists or other mechanical equipment.
8. **Rolled-in scale** is a defect in the surface caused by scale, formed during a previous heating, which has failed to be eliminated during the rolling operations. It is one of the most prevalent surface defects.
9. **Buckle and kink** is a corrugated or wrinkled surface condition caused either by worn out pinions on a roll stand or uneven cooling beds. Buckle is an up-and-down wrinkle, whereas kink is a side wrinkle.
10. **Burned steel** appears as a rough area with checked or serrated edges. It is caused by steel being exposed to an excessive temperature and is always scrapped.
11. **Camber** is the deviation of the side edge of a bar from a straight line. It is caused by improper heating of the billet, uneven dimensions causing differential expansion or contraction, or improper alignment of the hot beds.
12. **Hook** is a short bend or curvature caused either by improperly adjusted delivery guides or by any obstruction which may halt momentarily the forward motion of the bar from one roll stand to another.
13. **Pipe** is a steel-making defect carried through from the ingot. The presence of pipe is detected as a small round cavity located in the center of an end surface.
14. **Shear distortion** is a mashed or deformed end on a bar caused by defective or improperly adjusted shearing equipment.
15. **Twist** is a condition wherein the ends of a bar have been forced to rotate in relatively opposite directions about its longitudinal axis. It may be caused by excessive draft, faulty setting of delivery guides, or lack of uniform temperature in the bar.

Testing—Numerous tests are made during the finishing operations, the purposes of which are to reveal defects otherwise impossible to detect during surface inspection. The tests most commonly employed are described as follows:

1. **The pickling test** consists of immersing short pieces of product for several minutes in dilute sulphuric acid. The acid removes the scale from the bar and exposes to view such surface defects as may be covered or hidden by the scale.
2. **The upset test** consists of heating small test pieces to a forging temperature and then subjecting them to severe compression under a hammer. The compression or upsetting action will force open any defects which could not be detected while the steel was in the as-rolled condition. A sound steel will be indicated by the absence of areas which open up.
3. **The magnaflux test** is used on certain types of steel for which there are very rigid surface requirements. It is carried out by placing the steel to be tested in a powerful magnetic field. A fine magnetic powder is then sprinkled over the surface. The particles of the powder seek out and cling to the local magnetic poles which may be developed by any sort of metal discontinuity at or slightly below the surface. Any irregularity in the metal surface will cause a distinct magnetic pattern to be set up, thereby disclosing any hidden defects.
4. **The file test** consists in removing the scale, by filing, on any surface area which may be suspected of

containing a hidden defect. The file test is a quick method employed by inspectors for determining the extent and depth of seams in bars.

5. **The bend test** is made on certain classes of material to determine the soundness of internal structure and to denote the degree of ductility. The test consists merely in bending a standard test specimen through a certain specified arc. Examination of the bend will disclose surface defects.
6. **The etch test** is one which is used repeatedly in standard manufacturing and fabricating processes to determine the soundness of internal structures. A test piece is cut from the desired location in a bar and from this test piece a specimen of the size required for etching is removed. The surface to be examined is polished and then dipped in a solution of hydrochloric, sulphuric, nitric or picric acid. For some products, solutions of iodine, copper ammonium sulphate, ferric chloride, cupric chloride or cupric sulphate are used. Directions for etching various products may be found in "Metals Handbook."¹
7. **The grit-blasting test** is used for much the same purpose as the pickling test. The grit removes the hot-rolled scale so that the surface of the test piece can be visibly inspected. It is not recommended for detecting fine seams on certain types of steel because of the peening action of the grit.

CONDITIONING METHODS AND EQUIPMENT

It has been noted that bars which are free from surface defects cannot always be produced. Some of these defects are common to all steel products, whereas others are more or less peculiar to merchant bar product. In order that the product may meet required quality standards, these defects must be removed by chipping or grinding. Their removal by either of these methods is known by the term "conditioning." Thorough inspection must precede conditioning. In a large number of cases pickling before inspection is necessary in order to reveal all the defects that may be present. The product requiring conditioning must be marked properly with a suitable chalk or crayon in the areas showing defects.

Conditioning is carried out by either chipping or grinding, depending upon the characteristics of the product. Conditioning by chipping is confined to soft and medium-hard steels and to those products on which subsequent fabrication procedure will permit the presence of grooves from chipping. Well-maintained pneumatic hammers operated by an adequate air supply, and chisels which have been properly heat-treated and dressed, are the principal equipment necessary for chipping. Conditioning by grinding is confined to those steels with a high hardness, or to bars or shapes whose contours would be changed by chipping grooves. The grinding operation is accomplished by: (1) pneumatic grinders, or (2) high cycle electric grinders. The choice of grinder depends upon local conditions such as air and power supply, or upon the suitability of the machine to perform the required task. Each type of grinder possesses certain advantages and disadvantages. The pneumatic grinder has the advantage of being lighter in weight and has a minimum of moving parts, which facilitates repairs. Its major disadvantage is its inability to maintain full speed on all loads. It also must have an adequate air supply (90 to 100 lb. per sq. in.) without a large drop in pressure from source to point of use. The high cycle electric grinder, because of its special con-

¹ Metals Handbook, 1948 Edition; American Society for Metals, Cleveland, Ohio; pages 384-399, inclusive.

FIG. 30-26. Automatic hoop-forming machine in operation. Finished hoops are on stand in right foreground.

struction, has the advantage of being able to maintain full speed at all loads. It has the disadvantages of being somewhat heavier to handle, of having many complicated working parts, and of requiring a frequency changer adjacent to the work. The grit, bond, shape and speed of the grinding wheels are dictated by the characteristics of the steel and by the shape of the product being worked. Of the two types of conditioning, chipping is the most economical and, when conditions permit, is most generally used.

NARROW FLAT-ROLLED PRODUCTS

Band, Hoop and Cotton Tie—Band for use in commercial packaging is usually rolled in coil form in multiple width on the rolling mill, and then slit to narrow widths on multiple slitting units installed in the bar finishing departments. Edge conditioning is necessary to eliminate the sharpness of the slit edge, before final coiling and shipment. The usual sizes are $\frac{3}{4}$ by 0.028, $\frac{3}{4}$ by 0.035, $1\frac{1}{4}$ by 0.035, $1\frac{1}{4}$ by 0.050, and 2 by 0.050 inches. It is made from a steel in the 0.50 to 0.60 per cent carbon content range, with 0.80 per cent manganese and 0.15 to 0.30 per cent silicon.

Hoop—There are four general classifications of this type of product: (1) tight cooperage hoop for barrels to hold liquids, (2) slack barrel hoop for barrels to hold dry products, (3) tobacco barrel hoghead hoop, and (4) special hoop for special packages.

Hoop (except tight cooperage hoop) is made from steel in the 0.08 to 0.10 per cent carbon content range. Tight cooperage hoop is generally made from open-hearth steel having a carbon content of 0.30 to 0.35 per cent carbon, but may also be produced from Bessemer steel having a carbon content of 0.19 to 0.24 per cent.

Hoop is made either by slitting coiled strip, rolled in multiple width, into narrow coiled strip of the desired width; or, from narrow coiled strip with a hot-rolled or mill edge. The type and width of hoop being produced influences the choice of method used.

Hoop is produced in widths increasing in increments of $\frac{1}{8}$ of an inch, beginning with a minimum of $1\frac{1}{8}$ inches and extending to and including 2 inches. It is made in thicknesses between 0.027 and 0.042 inches. It is prepared in cut lengths for making hoops ranging from 2 feet $8\frac{1}{2}$ inches to 8 feet 6 inches in circumference. Automatic machines are used in the fabrication of hoop (Figure 30-26). These machines are so designed that

the strip from the coil, passing through a machine in a horizontal position, is first run through rolls in which a slight bend is made on the edge to be beaded. This is followed by a beading operation, done in forming dies that operate horizontally at approximately 400 strokes per minute. The beaded strip next moves into a combination shear and rivet-hole punching die, where it is sheared to a specified length, and where the rivet holes are punched. Hoop is produced as "curled hoop" or a "straight length." Curled hoop is made by a pinch-roll and curved guide-shoe arrangement that permits the hoop to take a circular form. A straight length hoop is produced merely by removing the curved guide shoe.

Cotton tie is a light, narrow, hot-rolled strip used, as the name implies, to bind bales of cotton, hemp, jute, etc. It is fabricated in a manner quite similar to hoop. After being finished in pinch rolls and a vibrator it is delivered onto apron conveyors. From the apron conveyors, the strip is coiled and delivered on a coil conveyor to cold shears where it is sheared to a length of approximately 12 feet. It is then bundled by hand at which time buckles are inserted. The bundles are then dipped into a tank containing an asphalt base paint if desired. Cotton tie is shipped in bundles consisting of 30 ties and 30 buckles, either painted or unpainted. Two sizes of bundles are produced; the standard, weighing about 45 lb., of $1\frac{1}{16}$ -inch wide and 0.042-inch thick (19 gage B.W.G.) cotton tie, and a special bundle, weighing approximately 60 lb., of $1\frac{1}{16}$ -inch wide and 0.049-inch thick (18 gage B.W.G.) cotton tie.

CONCRETE REINFORCING BAR

Concrete reinforcing bar is a merchant-bar product consisting of plain rounds and deformed rounds. It is used to furnish tensile strength to concrete sections subject to bending loads and to furnish additional compressive strength in sections where unreinforced concrete would prove too bulky.

All types of concrete structures are commonly reinforced with either deformed or plain bars. Concrete reinforcing bars are usually deformed. Deformed concrete reinforcing bars are bars in which the surface is provided with lugs or protrusions (called "deformations") which inhibit longitudinal movement of the bars relative to the surrounding concrete. The surface deformations (Figure 30-27) are hot formed in the final roll pass by passing the bars between rolls having

Fig. 30—27. Photograph of a deformed concrete-reinforcing bar, showing protrusions produced by rolling the bar between rolls having a pattern cut into them.

patterns cut into them so that the surfaces of the bars are forced into the depressions in the rolls to form characteristic deformations. Plain bars may be specified at the discretion of the designer and, when so specified, the standard sizes of plain bars are designated by their nominal diameter. Deformed concrete bars are produced in accordance with the specifications for minimum requirements for the deformations of deformed steel bars for concrete bars ASTM designation A305. Ten sizes of round bars have been adopted as standards as approved through the United States Department of Commerce, Simplified Practice Recommendation R26-50. The following table furnishes dimensional data on these bars:

Table 30—I. Dimensional Data, Standard A-305 Reinforcing Bars

Bar Sizes*		Nominal Dimensions— Round Sections			
Old Designation	New Numbers	Weight (Lbs. per Foot)	Diameter (Inches)	Cross-Sectional Area (Sq. Inches)	Perimeter (Inches)
1/4" Rd.	2	0.167	0.250	0.05	0.786
3/8" Rd.	3	0.376	0.375	0.11	1.178
1/2" Rd.	4	0.668	0.500	0.20	1.571
5/8" Rd.	5	1.043	0.625	0.31	1.963
3/4" Rd.	6	1.502	0.750	0.44	2.356
7/8" Rd.	7	2.044	0.875	0.60	2.749
1" Rd.	8	2.670	1.000	0.79	3.142
1" Sq.	9	3.400	1.128	1.00	3.544
1 1/8" Sq.	10	4.303	1.270	1.27	3.990
1 1/4" Sq.	11	5.313	1.410	1.56	4.430

* The new bar numbers are based on the number of 1/8 inches included in the nominal diameter of the bar. Bar Number 2 furnished in plain rounds only. Bars numbered 9, 10 and 11 are round bars and equivalent in weight and nominal cross-sectional area to the old type 1", 1 1/8", and 1 1/4" square bars. The above weights were adopted as standards by the Concrete Reinforcing Steel Institute in 1934, and supersede former practice. These weights have been approved through the United States Department of Commerce, Simplified Practice Recommendation R26-50.

Concrete reinforcing bars are produced to the Specifi-

cations for billet-steel bars for concrete reinforcement (ASTM designation A15), rail-steel bars for concrete reinforcement (ASTM designation A16), or axle-steel bars for concrete reinforcement (ASTM designation A-160). These classifications are largely self-explanatory and the concern here is with new billet steel rolled expressly for concrete reinforcing bars produced under ASTM Specification A15. Three grades of steel are produced under this specification and selection of structural, intermediate or hard grade is predicated on design specifications. The three grades differ only in physical requirements and may be produced from either open-hearth, electric-furnace or acid-Bessemer steel.

Concrete reinforcing bars are shipped from the mills in straight lengths either cut to design length in the mill shears or in long lengths to be re-cut for fabrication, as required in specific applications.

Engineers' and architects' designs and specifications are prepared in accordance with the Manual of Standard Practices of the Concrete Reinforcing Steel Institute. Bar fabricators furnish concrete reinforcing bars either straight and cut to the proper length or bent or curved in accordance with plans and specifications.

PACKAGING AND LOADING

The packaging of merchant bar products in most plants is performed according to: (1) standard practices, or (2) special practices as required by the customer. Standard practices are controlled by such factors as: (1) the weight of the bundle or lift, (2) the means of binding or fastening the bundles or lifts, (3) the means of identification, (4) the means of protecting the product in transit, and (5) the geographical location of the customer. Special practices are predicated upon the type or capacity of handling and processing equipment used by the customer.

Either wiring or banding may be applied for binding or fastening bundles or lifts, depending upon the shape, size and length of the product. Special practices for binding or fastening bundles or lifts are applied only when specified. Wiring is used generally on large rounds and heavy sections, whereas bands are used most generally for small sections or for flat products. Standards have been established which specify the spacing and the number of wires or bands to be used for various sizes of bundles. Additional wiring or banding, either for domestic or export shipment, is handled as special practice. Special practice also applies when stack piling is required, as the number of pieces and the dimensions of the bundle are limited as well as the weight. Wiring and banding is accomplished by such special tools as stretchers and sealers.

Identification of merchant bar products requires that each bundle or lift for domestic trade be identified by a standard manila tag, approximately three inches by five inches, attached to one end. Where coils are involved the same type of tag is used on each coil. The information on the identification tag will vary somewhat in different plants but it generally contains a part or all of the following information: customer's name, destination, customer's order number, mill order number, part number or special markings, number of pieces, section, length, weight, heat number, bundle or lift number, and the grade of steel. On products for export, additional identification is required on each bundle or lift in the form of duplicate manila tags on opposite ends and a metal tag attached to the center of the bundle. This is necessary because of the possible loss of a single manila identification tag when the product is rehandled at railroad terminals, shipping docks, or aboard ship. In addition to the standard manila tag, as mentioned above, the

identification of merchant bar products also requires the die stamping of heat numbers on the ends of bars of certain dimensions. These specifications are as follows: heat numbers are stamped on one end of all bars (round, squares or hexagons) of 2½ inches or above, and on all flats three inches by one inch and above. When special practices are involved, bars are stamped with codes or symbols as specified. When the product consigned for export is to be shipped loose, each piece is stenciled with the necessary information for proper identification.

Standard practice for color-marking for identification provides for painting one color (as prescribed by the customer) on one end of each bar on sizes of 1½ inches up to 2 inches and two colors (as prescribed by the customer) be painted on sizes 2 inches and over. In special practices, either for export or domestic trade, special marking is applied only when required by the customer.

Bundles or lifts are loaded in open cars without protection from the weather. When shipping carload lots, bars and bar shapes are shipped loose or in large lifts in open cars. When special practices are required, lifts may be wrapped or shrouded individually, or the entire carload may be shrouded as a unit. Loading, like packaging, is divided into (1) standard practice, or (2) special practices as required by the customer. The gondola car is the standard means of transit, either for magnet,

chain, or crane unloading. Standard practice for loading and bracing is conducted in accordance with the rules of the American Association of Railroads. Special practices as requested by the customer generally fall into one of the following categories: (1) modified methods of gondola-car loading for chain or crane unloading, or magnet unloading alone; (2) flat-car loading for chain or crane unloading, magnet unloading, or tractor unloading; (3) box-car loading for either tractor unloading or hand unloading; (4) double loads or sets for chain or crane unloading; (5) other methods of special blocking. Double loads are used principally for long lengths of structural material which exceeds the length of a single standard gondola car. Box-car loading generally is used on products which cannot be exposed to the weather and which require the best handling methods.

Material-Handling Equipment—Numerous and varied types of handling equipment are used in the finishing and shipping of merchant bar products, depending upon the type of product and the arrangement and design of the finishing department equipment. The types of handling equipment most generally used are: (1) overhead electric cranes, (2) tractors (principally the lift or peel type), (3) transfer buggies, (4) jib cranes, (5) box-car loading machines, (6) conveyors, and (7) such auxiliary apparatus as coil hooks, spreaders, package lifters, chains, and slings.

SECTION 3

HEAT TREATING CARBON AND ALLOY BAR STOCK

Heat treating may be defined as an operation or combination of operations in which a metal or alloy in the solid state is heated and cooled, under controlled conditions, according to a predetermined schedule, to obtain desired properties.

The purpose of heat treatment is to develop the full effect of the various elements in the steel as related to desired properties, through structural or phase changes. "As-rolled" bars vary in hardness and microstructure in relation to the chemical composition of the steel and, therefore, usually require some form of heat treatment to obtain a physical condition best suited for the final product. Low- and medium-carbon bars often are used in the as-rolled condition, but higher-carbon steels and most alloy steels require heat treatment. This treatment consists of some form of annealing, normalizing, or quenching and tempering, or a combination of any two or even three of these.

It has been found that the results of heat treating conform to certain definite principles, a detailed discussion of which will be found in Chapter 42. Application of these principles makes it possible to obtain transformation of a particular steel at a stipulated temperature by controlling the rate of cooling from temperatures above its critical range of temperature, and thus obtain desired mechanical properties. More detailed descriptions of how this is accomplished will be given in the following discussion of the various types of heat treating.

PROCESSES AND THEIR EFFECTS

Annealing—The term annealing is used rather loosely to describe several types of heat treatment which differ greatly in procedure yet all accomplish one or more of the following effects:

1. Remove stresses
2. "Soften," by altering mechanical properties
3. Refine the grain structure
4. Produce a definite microstructure

In most commercial operations, more than one of these effects usually are obtained simultaneously, although only one may be desired specifically. Therefore, the selection of a specific annealing process is dependent on the particular predominant or overall effect desired and the grade of steel being processed.

Full Annealing—If, for example, it is desired to refine the grain structure and produce a lamellar pearlite, a full annealing cycle should be used. This consists of heating the steel to a temperature above the transformation range, holding for one to two hours, and then cooling at a predetermined rate to obtain the desired microstructure (see Figure 30—28A). Grain refinement is accomplished in this instance by the recrystallization of the steel in passing through the critical range both in heating and in cooling, as explained in greater detail in Chapter 42. The microstructure obtained in cooling any steel from above the critical temperature range is dependent both upon the temperature range in which transformation occurs and the time required for completion of transformation in that range. Thus, it is obvious that the rate at which any steel is cooled determines the final microstructure, since the degree of transformation will depend on the amount of time allowed for it to occur. Therefore, the slower the rate of cooling and the higher the temperature at which complete transformation occurs during full annealing, the coarser the pearlite will be with correspondingly lower hardness. Such treatment is performed usually on steel of 0.30 to 0.60 per cent carbon content which is to be machined.

Isothermal annealing is a type of full annealing in which the steel first is cooled to the temperature at which it is desired to have transformation occur, at a rate sufficiently rapid to prevent any structural change above that temperature. The steel then is held at the selected temperature for the time necessary to complete such transformation (see Figure 30—28B). Thus it is possible, with this process, to obtain a more uniform

TYPES OF ANNEALING

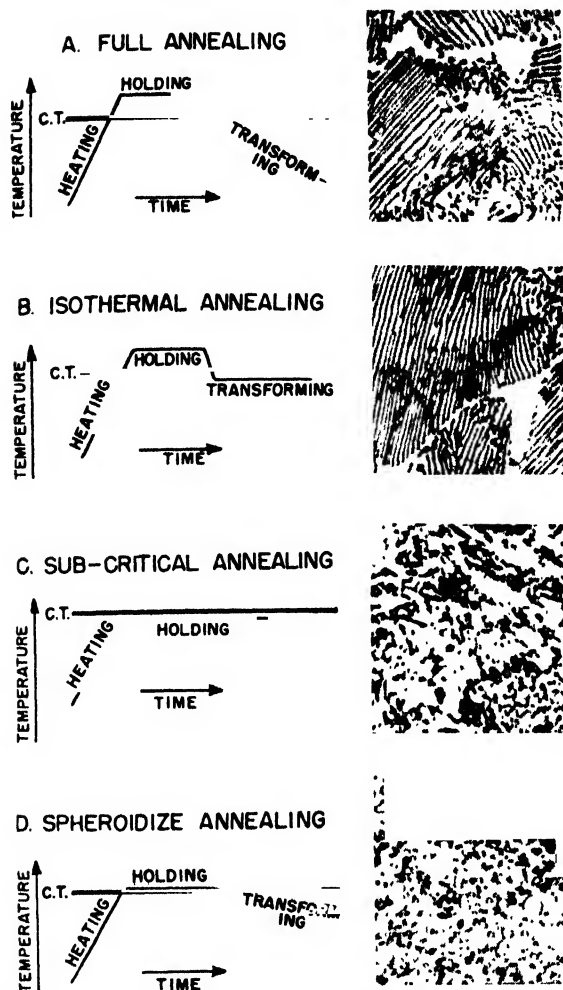

FIG. 30-28. Thermal cycles and resultant microstructures obtained from the four basically different types of production annealing.

microstructure than could be expected by continuous cooling. However, since it is necessary to drop the temperature rapidly to prevent any transformation above the desired temperature, there are definite limitations as to the mass that can be so treated. It is applicable, therefore, only to smaller sections and would not be suitable for large bars or large loads in batch-type furnaces, since it would be impossible to cool them at a rate sufficiently rapid to prevent some transformation.

A modified application of isothermal annealing is possible, however, in which the charge is heated in one furnace and transferred to another, which has been set at a temperature somewhat lower than the desired temperature of transformation, in order that the temperature of the charge will drop rapidly to that required. The selection of the temperature of the second furnace will be governed by the temperature to which the charge first is heated, the mass of the charge and the desired transformation temperature. Suitable handling equipment must be available to transfer the entire charge rapidly, since any undue delays might result in portions of the charge being cooled to too low a temperature. Continuous furnaces also are applicable to this type of cycle.

Process or Subcritical Annealing—Another type of annealing called process or subcritical annealing consists of heating the steel to a temperature just under the lower critical (A_{c1}) and holding at this temperature for the proper time (usually 2 to 4 hours) followed by air cooling (see Figure 30-28C). This type of annealing results in softening the steel due to a partial coagulation of the carbide to form spheroids or small globules of carbide. It is not suitable when a close control of hardness or structure is desired, because the prior structure of the steel determines to a marked degree the extent of spheroidization which will occur. For example, an originally coarse lamellar structure may show very little evidence of spheroidization after this treatment, whereas an originally fine lamellar or martensitic structure would show a marked degree of spheroidization. The treatment is, however, quite satisfactory for rendering bars more suitable for cold sawing or shearing, and is used to a great extent for these purposes. Since the temperature to which the bars are heated is somewhat lower than in a full anneal, there is less scaling, and warping can be controlled.

Spheroidization—Spheroidization is a type of annealing which causes practically all carbides in the steel to agglomerate in the form of small globules or spheroids. There may be a wide range of hardness with such a structure for any grade of steel since the size of the globules has a direct relation to hardness, i.e., the larger the globules the lower the hardness. Spheroidizing may be accomplished by heating to a temperature just below the lower critical and holding for a sufficient period of time. However, as pointed out in the discussion under subcritical annealing, the prior structure of the steel affects to a marked degree the final result of such a treatment. Therefore, if a well spheroidized uniform structure is desired, such a treatment is not suitable because too many uncontrollable variables are encountered. A more desirable and commonly used method for spheroidizing is to heat to a temperature just above the critical and cool very slowly (about 10°F per hour) through the critical range (see Figure 30-28D) or to heat to a temperature within the critical range but not above the upper critical and cool slowly.

This treatment is used for practically all steels containing over 0.60 per cent carbon that are to be machined or cold formed and for bearing steels such as AISI-52100 prior to machining. For the latter, the size and distribution of the spheroidal carbide particles is extremely important since they all are not dissolved in subsequent heating for hardening but remain in the condition obtained in the annealing process. Small well-defined spheroids are the most desirable and coarse elongated carbides should be avoided at all times.

Normalizing—Normalizing is a process wherein the steel is heated to a temperature about 100° to 150°F above the transformation range and cooled in air. The resulting structure will differ greatly for steels of different chemical composition, since no attempt is made to regulate the temperature at which transformation on cooling occurs. It is used for the purpose of producing a more uniform structure and removing the irregularities caused by high or low rolling or forging temperatures for large sections. It also is applicable to a wide extent in treating low-carbon steels of all sections to produce a more uniform structure, and is preferred to full annealing for these steels as the more rapid cooling minimizes banding (marked segregation of carbide and ferrite) which is very undesirable for machining.

Quenching and Tempering—The heat treating processes described so far have all been for the purpose of "softening" the steel by regulating the rate of cooling

HEAT, QUENCH AND TEMPER

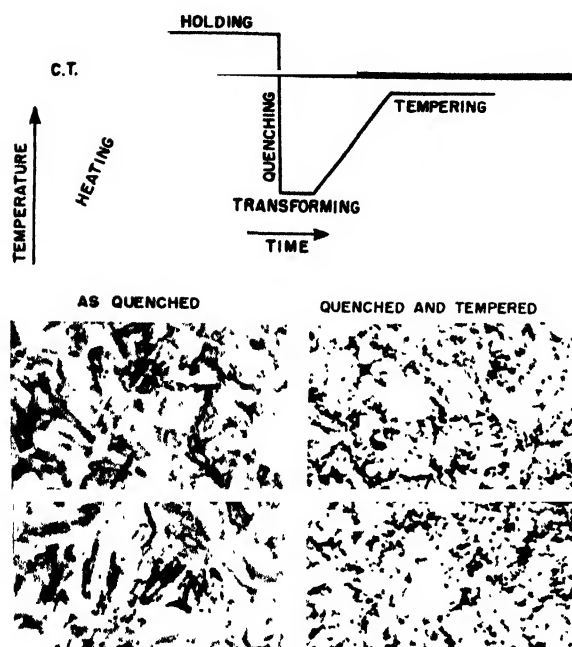

FIG. 30—29. Thermal cycle and microstructures obtained in (a) quenching and (b) quenching and tempering.

so that transformation occurs at relatively high temperatures. Such processes are necessary to render the steel suitable for further operations such as machining and cold cutting. However, this condition does not represent the optimum mechanical properties which can be developed in the steel, and a further treatment termed quenching and tempering is employed to develop these properties. When the amount of machining or cutting to be done is not great, steel sometimes is given this treatment in the bar form in preference to an annealing treatment.

The combination of quenching and tempering consists of first heating the steel above the critical range, and then cooling it rapidly by immersing it in a liquid

cooling medium such as oil or water. If the rate of cooling is sufficiently rapid, transformation does not occur until the lower temperature ranges are reached with the resultant formation of martensite or bainite. These structures are much harder than the structures obtained by transformation at higher temperatures. Martensite, however, is quite brittle and would be unsuitable for most applications where the steel may be subjected to shock. Therefore, the steel is given a tempering treatment which consists of heating it to an intermediate temperature, very seldom higher than 1200° F and usually somewhat lower. This treatment reduces the hardness by coagulation of the carbide and increases the toughness or shock resistance of the steel. A schematic illustration of quenching and tempering with the resultant microstructures after each operation is shown in Figure 30—29. It is possible to obtain any desired hardness within a wide range, with corresponding variations in strength and ductility, by selecting the proper tempering temperature. This can be seen readily by examining the chart in Figure 30—30.

Tempering is sometimes called *drawing*. Tempering is the preferred nomenclature. In ancient times and in the early days of relatively modern steelmaking practices, steel for swords, tools, etc., was said to be "tempered" after it only had been hardened. Since the hardened steel was too brittle, some of its "temper" was "drawn" by suitable heat treatment, giving rise to the term "drawing." At present, temper is considered as describing the final condition of hardened and tempered steel, and it is more logical to give the operation that regulates the final condition the name "tempering."

HEAT-TREATING PLANTS

Modern heat-treating plants vary widely with respect to type of furnaces, auxiliary equipment and general arrangement. No matter how widely they may differ in these general aspects, all must have adequate and reliable means for controlling and checking temperatures and have handling facilities suitable for transferring the heated steel from the furnace to the quenching tanks with a minimum of delay. These are factors which must be given careful consideration when planning new units or additions to existing units, and will be governed to a great extent by the type of product to be processed and the heat treatment to be given.

Another important factor to be considered is the pro-

FIG. 30—30. Effect of tempering temperature on the final hardness of three grades of steel after quenching and tempering.

vision of adequate space for accumulating and building up charges so that they may be ready to load into the furnace as soon as it is available. This lessens time lost in charging the furnaces and increases the efficiency of these units.

Furnaces—In general furnaces which are suitable for annealing are not the most desirable for quenching and tempering, nor are the most desirable furnaces for quenching and tempering entirely suitable for annealing. This can be shown by analyzing the basic requirements for furnaces considered most suitable for these operations. Many of the factors discussed in Chapter 21 on "Construction and Operation of Heating Facilities" should be considered in conjunction with the following discussion.

A furnace to be suitable for quenching and tempering must be capable of maintaining uniform temperatures over a rather wide range throughout the entire charge. It can be heated by either gas or electricity, and possibly oil, although the latter fuel is not too desirable at temperatures below 1200° F.

Since uniform temperatures must be maintained in furnaces to be used for quenching or tempering, and rapid cooling of the charge in the furnace is not required, such furnaces usually are insulated heavily to minimize heat losses due to radiation. Since only single-layer loads are charged for quenching, the height of the heating chambers need not be very great. This enables a more uniform temperature to be maintained throughout the charge since the differential in temperature between the top and bottom of the furnace is much less than would be the case in a larger heating chamber.

Uniformity of temperature is also very desirable in furnaces used for annealing, but the requirements are not necessarily as exacting as for furnaces used for quenching and tempering. However, it is essential that a rather wide range of cooling rates be attained. Therefore, furnaces that cool too slowly, such as the heavily insulated type referred to in the discussion on furnaces for quenching and tempering, are not suitable for very

many annealing cycles. A furnace which will lose heat at a fairly rapid rate can be adapted to a wider range of cycles because various rates of cooling can be attained by control of the heat input. Thus, if the heat input is cut off entirely, the furnace and charge will cool rapidly; by firing at reduced rates, the heat losses from the furnace and charge can be balanced to any desired degree to control the net heat loss and, consequently, the over-all rate of cooling. Possible methods for increasing the rate of cooling in a heavily-insulated furnace would be to blow air into the furnace or to open it. This is not very desirable, however, because it is extremely difficult to regulate the temperature drop uniformly throughout the charge and erratic, non-uniform results may be obtained. Furnaces have been developed recently which are equipped with large fans that circulate the furnace gases over water-cooled pipes, thus reducing the temperature to around 800° to 900° F. The partially-cooled gases are then forced into the furnace chamber at the bottom and up through the charge, causing a rapid drop in temperature. Such equipment has many potential advantages but care must be exercised in its use to avoid non-uniform cooling.

Since annealing cycles are usually rather long and tie up a furnace for some time, it is desirable that they be large enough to accommodate the maximum size load that can be cooled uniformly. For this reason, furnaces designed for annealing have a great deal more height in the heating chamber than those designed exclusively for quenching. Consequently, there is more danger of greater differential in temperature between the top and bottom of the chamber. This affects selection of the type of furnace to be used.

Control of Temperature—As stated previously, adequate and reliable control and checking of temperature is absolutely essential for all types of heat treating. Furnaces equipped with automatic temperature-control devices are generally more reliable and can be operated more economically than manually controlled units. Thermocouples to indicate and control temperature gen-

FIG. 30-31. Partially-loaded car-bottom of a heat-treating furnace, showing use of spacer bars between layers of the load, which is supported above the refractory hearth on heat-resisting alloy castings.

FIG. 30-32. Car-bottom batch-type heat-treating furnace with bell-type cover in operating position.

erally are located near the top of the heating chamber, as this location will be the first to reach the desired temperature on heating; placing the controlling thermocouples in this position prevents overheating. In the case of furnaces designed primarily for quenching and tempering, these couples will be close to the charge (which consists of only one layer of bars or other sections) so that additional couples should not be needed to assure uniform heating. However, in the case of furnaces designed primarily for annealing, in which the chamber height is much greater and in which there is a correspondingly greater possibility of temperature differentials, provision should be made to insert couples in the charge also, being sure that some are located so that they indicate the temperature of the bottom layer. With couples so located, the temperature throughout the

charge will be known and sufficient time can be allowed to attain uniformity.

Methods of Loading—As stated previously, loads to be quenched should consist of only one layer; if there is more than one layer the load would not be uniformly quenched because the efficiency of this operation is dependent on the entire surface of the bar being in contact with the quenching medium. The same principles apply to normalizing, since uniform properties are dependent on attaining a uniform rate of cooling along the entire length of the bar, which can only be obtained by having the entire surface exposed to the air and not in contact with other hot bars.

Loads for annealing are generally more than one layer high but care should be taken to avoid having a load that is too compact, as this would prevent uniform

FIG. 30-33. The bell-type cover (upper left corner of illustration) of the heat-treating furnace of Figure 30-32 has been raised and hot load is being moved on furnace car bottom toward crane carrier arms.

FIG. 30—34. Hot steel bars, supported on crane carrier arms above the quenching tank in the foreground (see also Figure 30—35).

cooling throughout the entire charge. A common practice is to separate the load into layers by the use of spacer bars, as shown in Figure 30—31. The load also may be separated lengthwise down the middle, leaving an open space approximately six inches wide. These methods of loading provide for better circulation of gases throughout the charge, thus enabling the operator to cool the entire charge at a reasonably uniform rate.

Auxiliary Equipment—Effective quenching is dependent on immersion of the steel in the quenching medium while the temperature is still above the critical range. If there is too great a delay in moving the load from the furnace to the quench tank, it may air cool below the

critical range, especially at the ends of the bars. Thus, there is the danger of obtaining some products of transformation in the higher temperature ranges. To offset this hazard the quench tanks should be located close to the furnace and cranes or lifting devices should be provided which are capable of moving the entire load to the tanks at a rapid rate. By moving the entire load at one time, all bars will receive the same treatment. If only one bar or any portion of the load is quenched at a time, there is always danger that the last bars quenched will have cooled below the critical temperature before reaching the quenching tank.

Figure 30—32 shows a car-bottom batch-type furnace

equipped to handle loads rapidly from the quench tank to the furnace. This is a rectangular bell-type furnace with a car bottom. To discharge the load, the furnace bell is raised (there are no doors on this furnace) and the car is moved out from under it, alongside the quenching tank which is in front and to one side (see Figure 30-33). The entire load then is picked up by a crane, equipped with carrier arms or bales as shown in Figures 30-34 and 30-35, which moves it quickly into the quenching medium. Agitation is obtained by alternate raising and lowering of the load in the tank through a travel distance of approximately four feet. This particular unit is equipped with automatic controls so that the entire sequence of movements of the equipment is initiated by closing a single control switch. This eliminates delays which might be caused by improper timing in closing successive switches by the operator. The time required from the instant the bell of the furnace is lifted until the load is immersed in the quenching medium is one and one-half minutes.

A roller-hearth furnace with similar handling equipment is shown in Figures 30-36, 30-37, 30-38 and 30-39. In this furnace, the bars in single layers are placed on the charging table indicated in Figures 30-37 and 30-38. From here they progress through the three separate chambers of the furnace, where they are pre-

heated to about 1200 ° F in the first chamber, then progressively heated above the critical temperature range and soaked in the other two. Progress is not continuous through these chambers, the bars being held for a sufficient period of time in each chamber to be heated throughout to the prescribed temperature. The time required in each chamber, of course, is determined by the size and number of bars being treated. After the bars have been soaked properly in the last chamber, they are run out on the delivery table, which is suspended over the quenching tank (Figure 30-36), and immediately are immersed in the quenching medium. When bar temperature has fallen sufficiently, they are raised from the tank and run into the succeeding furnace for stress relieving, after which they may be removed from the transfer table or continue through the remaining three furnaces for tempering.

Facilities should be available for quenching in either oil or water. The choice of quenching medium is to be determined by the grade of steel and the section, as explained in greater detail in Chapter 42. Facilities also should be provided for cooling the oil between the quench loads to maintain a uniform temperature of the quenching medium, because variations of an appreciable magnitude in this temperature will have a marked effect on results. Storage facilities for the oil also should be provided since a reserve supply is necessary to replenish that lost through dragout. One quenching tank can be used for either oil or water, the oil being pumped back to the storage tank when it is necessary to use water in the quenching tank. However, this is not the most desirable arrangement since there is always danger of contaminating the oil with water. It is more desirable to have separate tanks for oil and water when the size of the unit warrants such an installation.

Chapter 31

PRODUCTION OF WROUGHT - STEEL WHEELS

Introduction—Classified according to methods of manufacture, steel wheels are either fabricated from several pieces joined by riveting or welding, or they are made in one piece and designated as solid iron or steel wheels. Very light wheels, such as automobile wheels, and extremely large wheels generally are fabricated. Solid steel wheels are either cast from liquid metal or wrought from a solid block of metal. According to modern practices, therefore, the term wrought-steel wheel is applied to wheels formed from a suitable block of metal by forging alone or by forging and rolling operations. This chapter describes the production of wrought-steel wheels by both forging and rolling.

Parts and Classification of Wrought-Steel Wheels—Wrought-steel wheels generally are used in heavy traction service. Such wheels are designed with contours which are considered as being composed of five parts, namely, the hub, the web or plate, the rim, the tread and the flange. These parts, for the case of a railroad wheel, are illustrated in Figure 31—1. The flange may be single or double, and the hole in the hub into which the axle is fitted is called the bore. The tread is the outer surface of the rim on which the wheel rolls or makes contact with the rail. The flange keeps it from leaving the track. The dishing, or coning, refers to the curvature of the web section. All traction wheels have an inside contour and an outside contour. The flange, the rim, the service to which they are applied, the methods of forming, the finish, and the finishing treatments are all bases for classifying wheels. Thus, they may have a single flange (a flange on the inside only) or a double flange (a flange on both sides) and a rim thickness that will permit worn treads and flanges to be machined one or more times to

their original contours. **One-wear wheels** have the rim thickness designed so that it is unusual for the rim to be recontoured after one period of wear. **Multiple-wear wheels** have a rim thickness of $2\frac{1}{2}$ inches or more, and may be machined two or more times to the original tread and flange contour.

Classifications based upon the service to which the wrought steel wheels are to be applied are defined as:

(1) **Industrial car wheels** are single-flange wheels designed for use under cars used for industrial purposes, such as mine cars, railroad hand cars, and cars or buggies used in steel mills.

(2) **Industrial locomotive wheels** are single-flange wheels designed for use under electric and other types of locomotives used in mines, and in industrial plants.

(3) **Crane track wheels** may have either a single or a double flange, and are used under such equipment as traveling, gantry and bridge cranes, transfer and turn tables, and floor-type charging and drawing machines.

(4) **Railroad freight-car wheels** are commonly rolled to finish on treads and flanges, and have hub faces as forged.

(5) **High-duty wheels** are manufactured to closer tolerances than freight-car wheels and are used under railroad and electric-railway passenger cars, and under tenders, and engine and trailer trucks of locomotives.

Wrought-steel wheels are completely covered by standard specifications including the type and kind of steel used, the design of the wheels, the dimensional tolerances, and the inspection and tests. While alloy steels are used in some circular shapes, wrought-steel wheels, heretofore, have generally been made of carbon

FIG. 31—1. Sketch showing cross-section of a wrought-steel railroad wheel mounted on an axle, giving nomenclature of the principal parts of each.

steel. The remainder of this chapter will be devoted to the manufacture of freight-car and high-duty wrought-steel wheels.

Classified according to methods of manufacture, wrought-steel wheels may be forged; forged and rolled; rolled to finish; machined on tread, flange, and hub faces; or machined all over. With respect to heat treatment, wheels are no longer air cooled from forging or rolling temperatures, but are always controlled cooled, rim toughened, or oil-quenched and tempered by processes to be described later.

Classes of Wrought-Steel Wheels—Wrought-steel wheels are manufactured to Association of American Railroads and American Society for Testing Materials specifications. These specifications call for four classes of wrought-steel wheels. The four classes differ in chemical composition and hardness and were developed after extensive research followed by many studies of wheels in different types of railroad service. Each class is processed and treated for a definite service and it is important that wheels of the proper class be used in the service for which they are intended.

American Association of Railroads specification M-107 and American Society for Testing Materials specification A-57 cover one class of untreated wheels (Class U) and three classes of heat-treated wheels (Classes A, B and C) grouped according to carbon content, as follows:

Element	Per Cent
Carbon	Class U..... 0.65-0.77
	Class A, not over..... 0.57
	Class B..... 0.57-0.67
	Class C..... 0.67-0.77
Manganese.....	0.60-0.85
Phosphorus, not over.....	0.05
Sulphur, not over.....	0.05
Silicon, not less than.....	0.15

Classes A, B and C are heat treated to the following hardness requirements:

Class	Brinell Hardness Number	
	Minimum	Maximum
A	255	321
B	277	342
C	321	363

These specifications state:

"The Brinell measurement shall be made on the front face of the rim with the edge of the impression not less than $\frac{3}{16}$ inch from the radius joining face and tread. Before making the impression, any decarburized metal shall be removed from the front face of the rim at the point chosen for measurement. The surface of the wheel rim shall be properly prepared to permit accurate determination of hardness."

These specifications require that heat-treated wheels be stamped with the class letter A, B or C, together with the letter E for wheels entirely quenched, and the letter R for wheels that have the rim quenched, and that both letters be enclosed in angular brackets as follows:

Mark	Significance	
	Class	Treatment
[AR]	A	Rim Treated
[BR]	B	Rim Treated
[CR]	C	Rim Treated
[AE]	A	Entire wheel treated
[BE]	B	Entire wheel treated
[CE]	C	Entire wheel treated

Outline of Methods for Forming Solid Wrought-Steel Wheels—All methods for forging and rolling solid wrought-steel wheels require a cylindrical, or nearly cylindrical, block of steel for the initial forming operations. Originally, the blanks were sheared from slabs, but this method located the central portion of the ingot diametrically across the wheel, so that the line of segregation terminated at opposite points in the tread. The objections to this method are obvious. Therefore, the procedure was changed, as shown in Figure 31-2, so that

FIG. 31-2. Cross-section showing steps in the procedure of making a wrought-steel wheel by a combination of forging, rolling and pressing operations.

metal in the line of segregation, or central portion of the ingot, would be punched out in forming the bore.

To accomplish this, the steel blocks may be prepared in any one of three ways, namely, (1) by casting the metal for each wheel as an individual ingot, (2) by cutting the blanks from ingots, or (3) either by hot shearing or cold cutting the blanks from a round bloom. The United States Steel Corporation, one of the producers of solid steel wheels, uses the third method. After the blocks have been press forged to the general form of a wheel, called the **wheel blank**, the shaping is completed by rolling the blank in the wheel mill which may be one of two types, designated from the position in which the blank is held in the mill during the rolling, as a vertical mill (Figure 31-3) and a horizontal mill (Figure 31-4). The practice will be described in detail as an example of the manufacture of wheels.

PREPARATION OF BLOCKS

Wheels are produced by the United States Steel Corporation at Gary Steel Works and at the Wheel and Axle Division of Homestead District Works. While the practices of these two plants differ somewhat as to equipment and details of manipulation, this difference is not

Fig. 31-3. Schematic arrangement of the rolls in a vertical mill for rolling wheels.

of a fundamental nature. Both plants are equipped for controlled cooling of wheels and for heat treating by all the approved methods. At Homestead the steel to be rolled into round blooms for wheels is cast in 25-inch by 25-inch hot-top molds with rippled or corrugated walls, and rolled on the 52-inch mill into round blooms either 15 inches or 17½ inches in diameter, according to the weight of the wheels to be made. With proper allowance for discard, these rounds are cut, while still hot, into blocks to form a wheel of the desired weight and dimensions, by a special shear which cuts the bloom almost in two but leaves a central core about 5 inches in diameter to be fractured when the bloom has cooled to atmospheric temperature. Instead of air cooling, however, the partially sheared blooms from the shears are put into special, insulated containers and allowed to cool slowly to 300° F. The cooling is thus controlled as a

precaution against the possible formation of minute internal cracks in the blocks. The blooms are then unloaded at the shipping yard, inspected, surface conditioned, and fractured. At Gary, the steel is cast in 25-inch by 25-inch big-end-up hot-top molds and rolled into 18-inch round blooms on the 42-inch mill. While still hot, these blooms are sliced into blocks by a special shear which cuts to the center of the bloom, and the blocks are individually inspected and surface conditioned as may be necessary. As each block is separated from the bloom, it is hammer stamped with numbers to identify it. At both plants the smallest wheel that can be rolled is about 26 inches in diameter, and the maximum sizes are 40 inches in diameter at Gary and 46 inches at Homestead.

FORGING OF WHEEL BLANKS

Heating the Blocks for Forging—This operation is carried out in two stages, referred to as the "preheat" and the "forge heat." Hence, at the wheel plant the blocks are first placed in a gas-fired preheating furnace where they are slowly and uniformly heated to a temperature of 800° F in a period of 6 hours or longer. The object of this slow heating is to avoid abrupt temperature gradients and resulting high internal stresses that occur in a block when its surfaces are suddenly exposed to a high temperature while the central portion is cold. The preheating furnaces are preferably of the continuous type in which the blocks may move from the cold end to the hot end, but it is possible to obtain similar heating effects in sand-bottom furnaces, in which the blocks remain stationary, by charging a number into the furnace when it is relatively cool and gradually raising the temperature.

After preheating, the blocks are transferred by charging machine (Figure 31-5) to the forge furnace, which is of the sand-bottom type. This furnace is held at a uniform heating temperature so that the blocks reach a forging temperature in about 2½ hours, and the blocks are charged and drawn in a definite order, so that none will be overheated or underheated. Full control of the heating combines automatic pyrometric control with skill and judgment of the heaters, who become expert in estimating both steel and furnace temperatures.

First Forging of the Block—As indicated in Figure 31-2, the forming of the wheel blank preliminary to

Fig. 31-4. Elevation (above) and plan (below), showing disposition of the rolls in a horizontal mill for rolling wheels.

FIG. 31-5. Operator of a charging machine drawing a heated wheel block from furnace preparatory to transfer to the forging press.

FIG. 31-6. Hot wheel block in position between the dies of a forging press at the start of the first operation in forging a wheel.

FIG. 31—7. This shows the wheel blank after the second forging operation. Note indentation formed in center of hub to facilitate punching of the bore.

the final forming in the rolling mill is carried out in three steps spoken of as the first forging, the second forging, and punching the bore. However, in the forging operations it is essential that the block or bloom be free of scale formed during the reheating. In some plants this scale is removed by mechanically-operated chain beaters; in others various procedures are used. An effective method is carried out as follows: When the block is removed from the forge furnace and delivered by the charging machine, the scale on the ends is knocked off with long handled steel scrapers. The block is then placed in the bottom die of the press and held in a vertical position, while the press is started slowly. When the top die contacts the block, the first deformation cracks off the scale, which is immediately blown out of the die by jets of compressed air. The press then continues the stroke to complete the first forging. From this point, the practices at different plants vary somewhat. Thus, the first forging may be merely an upsetting of the block and punching of the bore to form a circular bloom. At present, the practice at plants of the United States Steel Corporation is to do some forming in the first forging, and punch out the bore after the second forging (Figure 31—2). However, this procedure is subject to some variation, for the forging may be done in one heat, or in two

heats and on one press or on two different presses.

When two heats are used, two presses are usually employed for the forging. In this method, the scale is removed from the two ends of the block and it is then placed vertically in the first press, where it is first centered by two arms which engage it from opposite sides of the press and so support it until the top die has descended upon it (Figure 31—6). In this press, the bottom die corresponds to the outside face of the wheel, while the top die is not contoured, but may be slightly convex to cause a radial flow of the metal in taking the shape. The pressure, applied in successive steps through accumulators and intensifier, starts with about 700 pounds per sq. in., then increases to 2500 pounds per sq. in., and finally, to as much as 5000 pounds per sq. in., if needed. In general, the presses used for forging wheel blooms and blanks vary from 5000 to 12,000 tons capacity. This pressing is, in itself, a severe test upon the metal, and any occasional flaws, such as seams or cracks, are sure to be exposed. When such flaws do develop, the blank may be reconditioned if the flaws are of a minor character, but if they are of an injurious nature the blank is scrapped. The perfect blanks are now placed in a second reheating furnace, where their temperature is equalized and they are again brought to forging temperature.

FIG. 31—8. Forged steel wheel after the operation of punching the bore.

Second Forging—If both the first and second forgings are done on one heat, sometimes designated as double forging, the press is provided with two top dies, one plain or slightly convex and the other conforming to the inside of the wheel. These dies are mounted upon two crossheads in such a manner that either may be brought beneath the ram of the press, thereby dispensing with one forging press and permitting the forging to be accomplished in one operation when the conditions are favorable. Generally, however, the plain die is used first, then the inside die is moved into position and the pressure applied, thus forming the blank in two stages, but with a single heating. With this press, the procedure can be varied to permit reheating if necessary, but the object is to accomplish the forging of the blank in one heat. When the forging is done in two steps with intermediate reheating, the procedure is about as follows: When the temperature of the blank formed in the first forging has been restored and equalized, the blank is brought to the press, cleaned of scale, placed in the bottom die which is lubricated to prevent sticking, and formed by a stroke of the press, the top die of which conforms to the inside of the wheel (Figure 31—7).

Punching the Hub Bore—By the process described, the next step consists of punching the bore in the hub. This operation is carried out with a small press such as that shown in Figure 31—8. During punching, the outside of the hub of the wheel is supported in neatly fitting dies in order to avoid forcing this part of the wheel out of shape.

ROLLING OPERATIONS ON WHEELS

Reheating the Blanks for Rolling—The forging now resembles a wheel and is called a wheel blank. However, a great deal of work must still be done on the blank to produce the finished wheel. While in general the blank may lack tread and flange, these parts have been partly formed in the forging operations. As to dimensions, the forged blank is 3 to 5 inches undersize in diameter, some three-fourths of an inch oversize in that part of the web near the rim, and considerably oversize in the rim. These oversize parts contain metal for the working and shaping to be done in the rolling mill, and dimensions will vary with different sizes of wheels and the method of rolling. The hub and a small annular section of the web next to the hub are forged to correct size for the finished wheel. In some processes the forged blank is not reheated for the rolling, but when forged as described above, certain parts, such as the web, are liable to become cooled to a greater extent than other parts, and temperature equalization becomes desirable. This reheating is done in flat-bottomed gas-fired furnaces, similar to the reheating furnaces mentioned in connection with the forging. The reheating furnace has other advantages, also, as it provides means of holding the blanks during interruptions in mill operations from any cause and of reheating blanks in which slight flaws have developed. To eliminate these flaws the blanks are cooled under controlled conditions, the flaws are removed by chipping or grinding, and the blanks are re-

heated in two stages as described for the heating of blocks. These temperature equalizing furnaces, as well as the reheating furnaces, are equipped with recording pyrometers as an additional precaution against overheating or too rapid a heating of the blanks.

The Rolling Mill—Mills for rolling wheels are of two types, vertical and horizontal, already shown diagrammatically in Figures 31—3 and 31—4. The following description, however, is confined to mills of the vertical type used at both the Homestead and Gary plants of the United States Steel Corporation. Even these two mills vary somewhat as to details of construction and operation, and each represents a somewhat complicated piece of machinery in which 5 or 7 rolls are made to bear on the wheel during the rolling. These rolls consist of one tread, or back roll, two web rolls, and two or four (2 sets) rim rolls, which are supported, together with all of their bearings, pinions or gears, adjusting screws, levers, etc., in a single pair of horizontal housings. These housings are large steel castings placed one above the other. The bottom housing lies directly upon the mill foundation and forms the support for the rolls and for the top housing some four feet above it.

The housings, between which the rolls are located, are held apart by suitable pillars or posts and are bound firmly together by large bolts. The rolls may be described as follows: The largest roll is the back roll, which resembles a wheel in form, approximately 33 inches in diameter, and is located in the same vertical plane as the car wheel blank, to the rear of the central axes of the housings. This roll is either driven or revolves by friction, bearing on the rim of the wheel, forming the tread

and flange. The Homestead mill is equipped with a variable-speed motor, while the Gary mill uses a constant-speed motor.

On the opposite sides of the tread roll are located the two web rolls. They are about three feet in length, lie in a horizontal position and extend inward, so that their center lines form nearly 30 degree angles with the mill center line and intersect at a point near the center of the wheel that is being rolled. On their front ends they carry the rolling heads, or surfaces, which conform to the shape of the wheel beneath the rim, while their rear ends are anchored in rotating coupling boxes. Light steel spindles, some five feet in length and provided with suitable wobblers, connect these couplings to the two bevel gears, one of which stands on each side of the mill at the rear. These gears mesh into similar gears mounted on the driving shaft of a 750-horsepower, direct-current motor (130 r.p.m.), used to drive these rolls. This motor is located at the rear and on the center line of the mill. Just back of the rolling heads, these rolls are supported in sliding bearings which permit them to be spread as desired. The pressure for rolling is transmitted to these bearings through radial levers, the long arms of which are each attached to the same screw above the housings (see Figure 31—9). By this arrangement, with the same motion, but in opposite directions, equal pressures are imparted to the two rolls at the same time. This screw, which corresponds to the adjusting screws on ordinary mills, is actuated by a 15-horsepower, direct-current motor (550 r.p.m.). By this means, the power of the motor is multiplied many times and is capable, at its maximum, of exerting sufficient pressure

FIG. 31—9. Steel wheel being rolled in a vertical-type wheel mill.

on the web rolls to stall the mill. As to the orientation of these three rolls, they are so placed that their lines of contact with the wheel in rolling, and the axis of the wheel itself, all lie in the same horizontal plane. The friction driven rim rolls are located below the web rolls, so that all the rolls lie within an arc of 180 degrees of the circumference of the wheel being rolled. In mills using four rim rolls, one set is located above the web rolls. These rolls are approximately twelve inches in length and nine inches in diameter and are so placed that the projected axis of rotation of the roll on either side of the wheel intersects the axis of rotation of the wheel. They are mounted upon sliding frames attached to the front of the mill housings. These frames are moved by horizontal screws connected by vertical worm shafts and gears to a common shaft, which extends in front of and beneath the housings, and is operated by an electric motor set eight or ten feet to the right of the housings. In this way the spread of these rolls is made uniform. However, the bottom set of rim rolls, due to the manner of rolling, do nearly all the work. An indicator, mounted on the upper horizontal screw attached to the sliding frame on the right side of the mill, is in plain view of the operator, who is able, by this means, to read the spread of the rolls and thus control the width of the rim. These rolls may be so formed that they will roll the sides of the rim at a slight angle to the vertical, so that these surfaces will lie in parallel planes after the dishing, or coning process. Two shelves attached to the housings in front of the tread and web rolls and separated by a space a little greater than the thickness of the wheel at the hub, give support for the wheel, which is mounted on a loosely fitting mandrel during the rolling. This mandrel is provided with removable bearings, which rest, unattached, upon the shelves, thus leaving the wheel free to move forward after the rolls have gripped it.

The Rolling Process—After the forged blank has reached the proper temperature for rolling, it is removed from the furnace and carried to the mill by a charging and drawing machine, where it is gripped beneath the rim by tongs suspended from a small jib crane standing on the housing above the rolls, or by a floor crane especially designed for the purpose. The wheel, held vertically, is guided between the two supporting shelves, and the mandrel is inserted through the punched bore. Then the wheel, resting on the mandrel, is pushed back against the tread roll into position for rolling. The web and rim rolls are then brought to bear on the wheel, the latter rather lightly at first. The large driving motor is started, and the wheel is made to revolve by the action of the roll or rolls upon it. The web rolls, working upon both sides of the web and the under side of the rim, force the metal back into the grooves of the tread roll with considerable pressure, until this part of the wheel has reached the dimensions for which the mill is set, or the diameter desired, while the spread of the metal and the width of the rim is controlled by pressure applied to the rim rolls. The diameter of the wheel is ascertained by a gage, or caliper, one end of which is attached to the tread-roll housing, so that it is moved simultaneously with this roll, in the same direction and through the same space. The other end of the caliper projects in front of the mill, and is provided with a hinged arm or pointer, so that it may be raised out of the way for inserting the blank or removing the wheel. The end of this pointer is curved toward the mill at right angles to its length. At the beginning of the rolling, the roller lowers this pointer to rest on the left hand shelf, in which position its curved end extends toward the tread roll and is

opposite its line of contact with the wheel, the pointer having been adjusted so that the distance between its point and the tread roll is equal to the diameter of the wheel desired. The wheel increases in diameter during the rolling and moves forward on the loose sliding mandrel until a circle on the center of its tread comes in contact with this pointer, when the roller stops the mill and spreads the rolls for the release of the wheel. During the rolling, jets of water are directed against the surfaces being rolled to remove the scale and give a smooth finish to the wheel. In addition to the water, a salt jet is also directed against the tread. The actual rolling process requires about one minute, so that the maximum capacity of the mill is high.

Effect of the Rolling—All the work of the rolling is concentrated upon the outer part of the web, the rim, the flange and the tread, where the additional grain refinement due to rolling is most needed. This refinement is marked as is shown by the visible difference in the structure of the metal in the hub and in the tread. As machining the tread removes much of this fine-grained metal, it would appear that the wheel rolled to a finish should be superior in wearing properties to the machined wheel, on first run at least. However, where wheels must be perfectly circular, machining is necessary. Furthermore, although the most careful mill practice is employed in producing rolled-to-finish wheels, some of the wheels thus produced require machining in order to eliminate slight surface blemishes.

FINISHING WROUGHT-STEEL WHEELS

Stamping—After each wheel has been rolled, it is taken on a small buggy to a stamping press, where markings fully identifying it are stamped on the inside rim. Stamping practice, however, varies at different plants. For example, at Gary the stamping is done in the coning press. These markings include the brand, the month and year of manufacture, the serial and heat numbers, and occasionally other markings such as type of heat treatment.

Punching Web Holes—Although standard specifications generally omit this requirement, a few wheels are still ordered with holes punched in the plate, or web, and the mills are equipped to punch these holes when the wheels are so ordered. After the rolling and stamping, the wheel is taken on the buggy to a small press, where the web holes are punched when required. This press is fitted to punch either two or four holes, 1¼ inches in diameter, equally spaced on radii of 9, 10, 11, or 12 inches, the standard radii for all the different sizes of wheels. Later these holes are reamed to a diameter of 1¾ inches and have the edges rounded to a given radius.

Coning—If web holes are not required, the wheel is taken from the punching press, or from the rolling mill, to the coning press for dishing. In this operation the form of the web, or plate, is changed from that of a flat ring to that of a truncated cone sloping from the hub to the rim. This form of the plate is important for it serves to prevent the development of the high internal stresses that would be set up by the cooling of the wheel if the plate were left flat. Coning presses are of various designs, but essentially they consist of a set of two dies, the top one of which is attached to the ram of the press. In the generally preferred method of coning, the hub is held rigidly and coning accomplished by the use of top and bottom dies shaped to contact the outer diameter of the hub and the underside of the rim. The top die descends a fixed distance, exerting pressure on the underside of the rim until

FIG. 31—10. Wrought-steel wheel undergoing finish machining on a lathe of special design.

contact is made with the bottom die. It has been found that, with this method of coning, improved control of geometry of the wheel is obtained.

Controlled Cooling—After coning, the wheel is allowed to cool to a temperature below the critical range. It is then control cooled under proper conditions to 300° F. Various methods of controlling the cooling are in use and have been found to give satisfactory results. The requirement is that every part of the wheel must

be kept at the same temperature until the heaviest portion has cooled to 300° F or lower.

Inspection of wheels is very rigid and may be said to begin with the making of the steel and to continue through every step of manufacture until the wheel is ready for shipment. For example, the wheels are inspected after rolling and, when cold, each wheel is rolled to the inspection platform for the initial finished wheel inspection. This inspection covers surface defects,

FIG. 31—11. Wheel undergoing quenching of the rim by being rotated in a special machine designed so that only the rim of the wheel contacts the quenching medium.

location of the hub, rotundity of tread, and the size, which is measured in standard tape sizes. These tapes are graduated in eighths of an inch, beginning with seven feet for a zero mark for wheels 28 inches and over in diameter, and with four feet for wheels under 28 inches in diameter. The surface defects consist principally of overfills, underfills, slivers, scale pits, and block marks, and as they are seldom deep, they may be removed by machining. The tape size is plainly marked on each wheel.

Machining and Final Inspection—After this preliminary inspection, the wheels are machined as required to meet the specifications or to remove the defects. On rolled-to-finish wheels, the machining consists of rough boring, while the outer part of the plate, the rim, tread and flange remaining as rolled and the hub as forged. The lathes used for machining wheels are massive and include many ingenious features of design, as indicated by Figure 31—10. The wheels are then rolled back to the platforms for final inspection, which is even more rigid than the first. In this inspection the wheels are tested for size, eccentricity and size of bore, position and size of hub, thickness and height of flange, radius of throat, thickness of rim, coning, rotundity, and soundness. After being re-stenciled with tape size and marks requested by the customer, such wheels as come within the allowable tolerances are mated and sent to the shipping platform.

Machining includes either rough machining or rough and finished machining operations. Extra machining not covered by standard specifications includes:

1. **Finish boring** covers machining of the hub bore to a smooth finish and to permissible variations in dimensions, so that the wheel may be mounted on the axle.

2. **Machining rim and outside of hub** consists of machining the back and face of the rim, the tapered surfaces on the diameter of the hub and on the inside diameter of the rim and the fillets joining these surfaces to the web, or plate, of the wheel.

3. **Finish machining hub faces** refers to finish machine work on a hub face when a hub projection or depression is machined to closer tolerances than required by standard specifications.

4. **Machined all over** is applied to a wheel the dimensions of which must be close to the nominal dimensions and the weight of which must be distributed symmetrically about the axis. All surfaces of the hub, the plate and the rim are machined.

5. **Hub recessing** consists of counterboring or turning a recess in the face of the hub for installation of a bearing plate to prevent hub wear from lateral pressure.

6. **Turning outside of hub** is performed on wheels for electric railways, and consists of turning the end portion of the outside hub to a cylindrical section for a gear casting seat.

HEAT TREATMENTS FOR WROUGHT-STEEL WHEELS

In addition to the controlled cooling mentioned above, three methods of heat treating wheels have been developed since 1925, designated as **normalizing**, **rim toughening**, and **oil quenching and tempering**.

In **normalizing**, the rolled wheels are permitted to cool to a temperature well below the critical range, and then are placed in a continuous reheating furnace and heated to a temperature above the critical range to refine the grain structure. Upon being withdrawn from this furnace, the wheels are cooled in air to a temperature below the critical range, approximately 950° F, and are then control cooled to 300° F or below. This treatment develops a uniform grain structure in all parts of the wheel, prevents formation of internal defects, and raises the ductility markedly. In this case, they are heated very gradually to above the upper critical temperature and then cooled as described.

For **rim toughening**, the wheels are cooled and heated as for normalizing, but upon removal from the furnace they are immediately placed in a special quenching machine (Figure 31—11) and rotated at a uniform rate with part of the rim submerged in water. This method prevents the water from coming in contact with either the plate or the hub of the wheel. After the rim has been quenched in this manner for a given period, the optimum duration of which has been predetermined, the wheel is removed from the quenching machine, transferred to a furnace and heated to a proper tempering or drawing temperature to remove internal stresses and obtain the hardness desired. The wheel is then placed in pits and control cooled to 300° F or below. This treatment leaves the hub and the plate in a normalized condition, and increases the hardness of the wearing zone of the rim from the normal Brinell hardness number of about 260 to approximately 340.

To **oil quench and temper** the wheels, they are heated as described above, withdrawn at a temperature slightly above the critical range of the steel, and totally immersed in oil contained in a tank constructed to permit the wheels to be rotated for the period of the quench. The wheels are then placed in a reheating furnace, heated to the required tempering temperature, and control cooled to 300° F or below. This treatment refines the grain structure and toughens equally all parts of the wheel, developing the hardness to about the same extent as in the rim-toughening treatment.

Chapter 32

PRODUCTION OF RAILROAD AXLES

Axles are important because of their functions and the number in service. They form vital parts of every kind of vehicle and vary in size from a few ounces to several thousand pounds. The larger sizes manufactured by the United States Steel Corporation include axles for railroad freight and passenger cars, Diesel locomotives, locomotive tenders, engine trucks, trailers, electric motor trucks, electric street cars, and driving axles. The Homestead District Works is cited as an example of a plant manufacturing these larger axles, although they are also produced at Gary Steel Works of United States Steel.

Composition and Heat Treatments—As to composition, axles are generally made of carbon steels of various grades, ranging from 0.40 to 0.55 per cent carbon and 0.60 to 0.90 per cent manganese, with phosphorus and sulphur each under 0.05 per cent.

They may be ordered "as forged;" annealed; normalized; normalized and tempered; quenched and tempered; or normalized, quenched and tempered, the quenching being in either oil or water according to the size of axle, the kind of steel, and the mechanical properties it is desired to develop.

THE AXLE WORKS

The essential equipment of the plant includes continuous gas-fired furnaces for heating the blooms; double-acting steam forging hammers; manipulator; gag press straighteners; double cutting-off, facing and centering machines; as well as rough-turning and finishing lathes, boring lathe, hollow drill machine, and a complete heat-treating plant. Maximum weight of forgings that can be produced is 6000 pounds; maximum length, twelve feet; maximum diameter, sixteen inches; minimum diameter, three inches.

As to arrangement, the layout of the plant provides for the most economical handling of the materials. The blooms start at one end of the plant and continue in one direction, progressing step by step through the various operations, until arrival at the other end of the plant where they are in a form ready for shipment.

METHODS OF FORMING AXLES

In general, axles are formed by a combination of rolling and forging operations, and the practices of different plants vary somewhat. Thus, with a suitable mill properly equipped for the work and located near the forge shop, it is possible, by starting with an ingot of proper size, to roll the bloom and complete the forging in one heating. The axle bloom is rolled either round or square and the forming is completed by forging. In other plants, where it is necessary to start with cold steel after it has been rolled into blooms (which must correspond in dimensions and weight to the size of the axles for which it is intended), the various steps in the process of manufacture are as follows:

Inspection of the Blooms—The blooms are subjected to a rigid inspection before the steel is shipped to the axle works. Those blooms that show any signs of pipe

or insufficient discard at the blooming mill shears are rejected. Surface defects, such as seams, slivers, and surface cracks, are eliminated by surface-conditioning treatments. Blooms passing this inspection are shipped to the axle works, where they are stored under cover until needed.

Heating the Blooms—Proper heating of the blooms for forging requires that they be uniformly heated throughout and brought gradually to the forging temperature, which should be kept as low as possible and yet permit the work to be done. The advantages of a low finishing temperature in obtaining maximum grain refinement were discussed in Chapter 19, under "Hot Working." The importance of heating slowly is obvious; rapid heating may cause the outside of the bloom to become somewhat hotter than the core, which condition would prevent uniformity in grain structure and in the flow of the metal during the forging operations. In addition, high internal stresses would be developed. Slow heating gives the heat a chance to "soak" into the bloom and thus produce that uniformity in temperature from center to surface so necessary to secure a finished forging of the best quality. Reheating furnaces of the continuous type are used, and these are equipped with recording pyrometers. In addition, the temperature of the steel is periodically checked with an optical pyrometer as the bloom is drawn from the furnace. With this type of furnace, the bloom is placed in the furnace at the cold end and is slowly pushed or rolled toward the hot end. The bloom reaches a full forging temperature only a short time before it is drawn from the furnace.

The Forging Operation—Having been brought to the proper temperature for forging, the blooms, within a certain range of sizes, are pushed out of the hot end of the heating furnaces upon a conveyor, which serves one furnace, and are carried by it to a roll table that distributes the blooms to five of the plant's seven hammers arranged in a row on one side of the table. Square blooms pushed out of the second reheating furnace are delivered to the other two hammers by the manipulator, as shown in Figure 32—1, and forming begun as described below with the exception that all manipulation of the forging is performed on one side of the hammer only. Adjustable deflecting rails built in the side guards of the roll table serve to divert the blooms to small receiving tables, of which there is one for each hammer. This leaves the blooms in positions to be most conveniently grasped by the hammer tongs, which are suspended from cranes.

The tongs having been quickly clamped on, the bloom is swung around between the forging dies of the hammer (Figure 32—2). These dies are provided, when desired, with one or more grooves; one, the plain groove used to do the greater part of the forging, is located directly under the piston rod, while the other grooves, used to form special sections, such as the journals, are placed beside the plain groove. The forging is begun at the middle of the bloom, which is rapidly reduced by heavy blows of the hammer, the forging progressing toward

FIG. 32-1. Axle being forged from a heated square bloom on a hammer equipped with a manipulator. One end of the forging (that gripped by the manipulator tongs) has been completed, the bloom has been turned, and the opposite end will now be worked.

the free end of the bloom. Here, the journal or other special section is formed by the special grooves in the die in a few blows. The piece is again placed in the plain groove, and the forging is smoothed up and brought, by light blows of the hammer, to correct diameter, which is determined by caliper. The tup is then brought to rest upon the axle, which is held between the dies while the

tongs are released, and tongs on the opposite side of the hammer are made fast to the finished end. The other end of the axle is then forged down like the first, except that, in addition to diameter, the length is also fixed. The crane is then swung around, and the axle is placed on the hot bed, which is supported about three feet above the floor by two rails.

FIG. 32-2. Forging an axle on a hammer where the manipulation of the bloom is performed manually. When one end has been forged, the bloom is gripped by tongs on the opposite side of the hammer and forging is completed without reversing the bloom.

FIG. 32-3. General view of a special lathe, known as a double combination cutting-off, facing and centering machine, for machining forged axles.

FINISHING PROCESSES FOR AXLES

Straightening—Except in the case of heat-treated axles and driving and trailing axles, the next step after the forging is straightening, which is accomplished in gag presses while the axles are still hot. From the hot beds, the forgings are carried by overhead cranes to similar beds in front of the presses. Here each axle is inspected for straightness, and those which require it are straightened before their temperature drops below 950° F. At this temperature, the axles are placed on cradles and put into pits for controlled cooling down to approximately 300° F. Heat-treated axles are straightened after being treated, but driving and trailing axles which are too large to be straightened by the gag press, are straightened under the hammer when necessary. Bored axles are straightened before they are bored, which operation precedes the heat treatment.

Cutting-off and Centering—After removal from the controlled-cooling pits, the forgings are moved forward by overhead cranes and distributed to the cutting-off lathes. These lathes are double combination cutting-off, facing and centering machines (Figure 32-3) and are designed to work on both ends of the forging at the same time. Upon being inserted in this machine, the forging is grasped at the wheel seats by adjustable revolving centering clamps, which hold it firmly to the central axis of rotation. Cutting tools adjusted to the correct length then are brought to bear and cut off the excess metal at the ends. Ends are faced in this operation, a tolerance of one-eighth inch over length and nothing under being permitted. When these tools have cut to within about $\frac{1}{16}$ inch of the center the crops drop off and, with the forging still held by the centering clamps, the revolving centering tools are brought to bear at each end. These tools are shaped to cut a 60-degree cone-shaped centering hole (to the dimensions shown in Figure 32-4) with a five-sixteenths inch in diameter clearance hole for points at the bottom of the centering hole. When axles are ordered to be smooth-forged only, the operation of cutting-off and centering completes the work done by the mill.

Rough turning before shipment is of decided advantage to both the shop and the customer, because certain flaws can be detected only after rough turning, and a considerable saving can be effected in handling and transportation by holding excess weight to a minimum. Lathes of the type shown in Figures 32-5 and 32-6 are used for this work. Rough turned material falls into two classes, known as "rough turned on journals and wheel seats," and "rough turned all over." Axles of the first class are put into service with the center portions between the wheel seats as forged. In the case of axles rough turned all over, the center portions are forged slightly over size to provide for the metal removed in

FIG. 32-4. Standard dimensions of centering holes cut in the ends of axles in United States Steel Corporation plants.

FIG. 32-5. Lathe of the type used for rough turning only journals and wheel seats of forged axles, after cutting-off, facing and centering (Figure 32-3).

turning to size; in such case, the center portion is furnished with body finish when no further machine work is to be done by the customer. In the case of car axles or other axles with a tapered body, this metal is removed at the same time (or after) the journals and wheel seats are rough turned in a lathe (Figure 32-6). In finishing rough turned axles, the wheel seats are finish-turned only, while the dust guards, journals and collars are finish-turned and burnished, and in order to provide the excess metal required for this work, these parts are rough turned one-eighth inch over size on their diameters.

Boring—A hollow forging permits a more efficient transfer of heat in both the heating and cooling cycles

of heat treatment than is possible with a solid forging, and this results in a more uniform grain structure. The practice of boring forgings longitudinally through the center—adopted particularly for those of large diameter to be subjected to a quenching operation—is also effective to a degree in other heat-treatment procedures.

Boring has other advantages. It eliminates any uncertainty about traces of piping or segregation that may have escaped detection by discard or close inspection; and a considerable reduction in weight may be made with no appreciable loss in effective strength of the forging.

Boring is desirable for all sizes larger than 7 inches in diameter. The diameter of the bore should be equal to

FIG. 32-6. Lathe of the type used for rough machining of the entire surface of forged axles after cutting-off, facing and centering in the machine shown in Figure 32-3.

at least 20 per cent of the minimum diameter of the forging.

Boring consists in a single cutting operation which may leave tool marks or slight ridges on the wall. When the boring is from both ends of the forging, the junction of the bores need not be concentric. Standard tolerance for boring is minus $\frac{1}{16}$ inch minimum, and plus $\frac{1}{8}$ inch maximum. Bored axles often are reamed and the ends plugged and centered to permit finish machining.

AXLE HEAT-TREATING PLANT

The heat-treating plant is housed in the same building with the hammers and lathes and consists of furnaces for heating forgings, a quenching tank containing water, a tank holding quenching oil, and all the necessary supplemental equipment for handling and testing the material.

Heat-Treating Furnaces—The inside working space of each of the furnaces is twenty-one feet in length and eight and one-half feet in width, and is designed to heat forgings uniformly. The furnaces are provided with removable bottoms of the car type, which facilitate the charging and drawing operations. This bottom is moved into and out of the furnace by a toothed rack attached to the bottom of the car and a stationary pinion actuated by an electric motor, the car itself resting on rollers that move over a double track. The doors of the furnace are of the vertically lifting type, and are hydraulically operated. These features, together with the close proximity of the quenching tanks, permit the drawing and quenching of a charge in the least possible time, less than a minute being required to transfer a charge from the closed furnace to either of the quenching tanks. The measures taken to obtain uniform heating are particularly noticeable in this furnace. The furnace is of the bottom cross-fired type, in which gas is employed as fuel, and is heated by burners firing into passageways at spaced intervals in the car bottom, thus permitting the temperature at any point in the furnace to be controlled closely. The furnaces have sprung-arch roofs, arched from side to side. In order that the entire surface of the material may be exposed to heat of the same intensity, the charge is supported at a height of about eighteen inches above the floor of the car bottom by two stools that extend the entire length of the car. These stools are spaced about four feet apart. The floor of the car bottom is constructed of brick laid upon a bottom of

steel plates, and is of a thickness that will give the plates ample insulation from the heat of the furnace. The bottom is made to fit the furnace neatly, and the escape of hot gases from the heating chamber is prevented by sand seals. Means are provided for taking the temperature of the charge at regular intervals during the heating. Recording pyrometers are used throughout the heating cycle.

Advantages of Heat Treating Axles—The proper heat treating of axles, because of their size, is accomplished with some difficulty. However, with proper equipment, care, and judgment, decided advantages result therefrom. It is the only way in which the grain structure of the as-forged axle can be refined and made uniform and, in doing this, variations in the as-forged grain structure which result from the heating and working of the bloom are overcome. Stresses remaining in the piece after forging also are eliminated. The principle advantage is the control of and improvement in mechanical properties effected through correct heat treatment. For example, annealing refines the grain and develops the maximum ductility of the steel; normalizing refines the grain of the as-forged axle and increases both its strength and ductility; and quenching and tempering refine the grain to give maximum control over the final mechanical properties. The latter treatment offers the only positive means of markedly increasing the strength as well as the torsional and shock-resisting properties that are very desirable under modern conditions of road traffic.

Testing equipment includes all the latest devices for testing materials. In the shop, hollow drill machines are provided for cutting out tests. A drop-testing machine, adapted for testing axles in accordance with standard specifications, is provided. Other mechanical tests are made in the physical laboratory, which is equipped with all the necessary appliances for accurate testing in accordance with standardized methods.

Chapter 33

THE MANUFACTURE OF HOT-STRIP MILL PRODUCTS

SECTION 1

HISTORICAL DEVELOPMENT

The mills used for rolling flat-rolled steel products include the following, named in the order of their development:

- (1) The two-high mill for hot rolling sheets in packs.
- (2) The two-high mill for rolling sheared plates.
- (3) The universal mill for rolling plates.
- (4) The three-high or Lauth mill for rolling sheared plates.
- (5) The continuous or tandem hot-strip mill for rolling sheets, strip and hot-rolled breakdowns for cold reduction in coils.
- (6) The cold-reduction (cold-rolling) mill for sheets and strip.
- (7) The continuous sheared plate mill.

The plate mills mentioned above are described in Chapter 27.

The method for rolling sheets on two-high, single-stand mills (described in detail in a later part of this chapter) originated between 1720 and 1728 and antedates all other methods for rolling iron and steel. Up to about 1890, the finished flat-rolled steel products could be classed as sheets, plates and bars, although many thin products, such as pipe skelp, were rolled on the merchant-bar mills. The bar mills also rolled thinner sections, and about this time there developed such a demand for very thin flats that special mills were built to supply the material. The differentiation first took place in the narrower widths, ranging from $\frac{3}{8}$ inch to 3 inches, and from 0.065 to 0.028 inch in thickness. The higher grades of this material were designated as hoop; a common grade was known as cotton tie. In 1890, bands 14 $\frac{1}{2}$ inches by 0.14 inch were rolled at Warren, Ohio and, in 1892, a mill designed to roll sheets in tandem rolls was built in Austria. In 1893, a mill at Bridgeport, Connecticut produced thin sections up to 7 inches in width and, in 1895, a semi-continuous mill was built

there to produce thin hot-rolled products up to 10 inches wide. In rolling on these first mills it was found that the limits as to width and thickness bore a certain relation to each other. In the Bridgeport mill, the ratios of width to thickness of product varied between 100 and 160. From these beginnings, the widths within the same range of thicknesses were increased at intervals by various producing mills until, in 1920, steel 22 inches wide and 0.105 inches thick was rolled successfully at Weirton, West Virginia. Some of the product of the successful strip mills subsequently was pickled and cold rolled, when it was designated as **cold-rolled strip steel**, but much of it was used as rolled and was known as **bands**, **band steel**, or **hot-rolled strip**. In 1920, therefore, flat-rolled products were classed commercially as **sheets**, **plates**, **bars**, **bands** and **hoop**, although the use of the term "strip" commonly was applied to the light products, which were somewhat narrower than the heavier sheets rolled on pack mills.

Up to 1920, it was customary to observe a certain width-to-thickness ratio in the hot rolling of strip, and the maximum ratio for successful hot rolling was considered at that time to be 250. In 1923, however, a continuous hot-rolling mill at Ashland, Kentucky, began rolling much wider strip, the widest and thinnest being 36 inches by 0.065 inch. This mill can be considered the forerunner of the modern continuous wide hot-strip mills described later in this chapter.

In 1926, at Butler, Pennsylvania, the first mill was built to combine successfully use of the following principles: (a) four-high finishing stands; (b) control of the direction of travel of steel through the pass line of the tandem finishing mills by progressively decreasing the product crown in successive mill passes, and (c) hot-coiling equipment at the discharge end of the mill. This installation was the first of the modern wide continuous hot-strip mills as known today.

SECTION 2

CLASSIFICATION OF FLAT-ROLLED STEEL PRODUCTS

About half of the rolled steel products now made in the United States may be classed as flat-rolled material. Flat-rolled steel products (including sheets, strip, tin plate, black plate, flat bars, slabs, plates, skelp and hoop) may be distinguished from other forms of rolled steel in two general ways. First, flat-rolled steel is produced on rolls with smooth faces in contrast with the cut or grooved roll faces employed in the manufacture of shapes and, second, in flat-rolled products the ratio of

width to thickness is generally high as distinguished from other rolled products. The ranges of dimensions are wide, varying in thickness from 0.005 inch in light strip to 15 inches in heavy plates, and in width from $\frac{3}{16}$ inch in narrow strip to 204 inches in wide plates.

Sheets, strip and tin plate comprise about three-fourths of the total tonnage of all flat-rolled steel products. Total shipments of these commodities from mills in the United States in 1953 was as follows:

Hot-Rolled Sheet and Strip.....	9,964,071 net tons
Cold-Rolled Sheets and Strip, Galvanized Sheets, Long Ternes and Enameling Sheets.....	16,214,232 net tons
Tin, Terne and Black Plate.....	5,410,427 net tons
Total	31,588,730 net tons

Flat-rolled steel products fall into two major categories: hot rolled, and cold rolled. Hot-rolled products are reduced to final thickness by heating and rolling at elevated temperature. Hot rolling usually is conducted at temperatures between 2200° and 1200° F, except in the case of pack-rolled sheets for some purposes where the finishing temperatures may be as low as 900° F. In ordinary practice, virtually all hot rolling is conducted well above 1300° F, the "lower critical temperature" of plain carbon steel. Cold-rolled products are really "cold finished" products, since much of the reduction from ingot to final thickness is, of course, done while the product is hot, in a manner similar to that employed for hot-rolled products. Cold rolling is carried out on products which have not been heated immediately prior to the cold-rolling operation in which they are reduced to final thickness. However, the temperature of the steel is raised due to frictional effects of rolling. The temperature of the steel in coils immediately after cold reduction has been measured, and coil temperatures ranging from 250° to 450° F have been recorded: the temperature of the steel in the actual nip of the rolls is probably higher than this, but is quickly lowered by the coolants used in rolling. The important distinction is that cold-rolled products receive enough cold reduction in the final rolling operation to affect the surface and mechanical properties of the finished product.

The list of flat-rolled steel products includes both semi-finished and finished materials. Among the semi-finished products which have already been discussed are slabs (Chapter 25) and flat bars (Chapter 30). An important semi-finished flat-rolled product of the hot-strip mill, which will be discussed in this chapter, is hot-rolled breakdowns for cold reduction, in coils.

Flat Hot-Rolled Finished Products Classified—The chief hot-rolled finished flat products are divided into four major groups, namely, bars, plate, hot-rolled strip, and hot-rolled sheets. Dimensions, particularly thickness and width, are the principal bases of classification, as shown in Table 33—I.

Table 33—I. Product Classification by Size of Flat Hot-Rolled Carbon-Steel Products.

Width (Inches)	Thickness (Inches)				
	0.2300 and thicker	0.2299 to 0.2031	0.2030 to 0.1800	0.1799 to 0.0568	0.0567 to 0.0449
To 3½, incl.	Bar	Bar	Strip	Strip	Strip
Over 3½ to 6, incl.	Bar	Bar	Strip	Strip	Strip
Over 6 to 12, incl.	Plate	Strip	Strip	Strip	Strip
Over 12 to 48, incl.	Plate	Sheet	Sheet	Sheet	Sheet
Over 48	Plate	Plate	Plate	Sheet	Sheet

Table 33—II. Product Classification By Size of Flat Cold-Rolled Carbon Steel

Width (Inches)	Thickness, Inch		
	0.2500 and thicker	0.2499 to 0.0142	0.0141 and thinner
To 12, incl.	Bar	Strip ^{1, 2}	Strip ¹
2 to 12, incl.	Bar	Sheet ³	Strip
Over 12 to 23-15/16, incl.	Strip ³	Strip ³	Strip
Over 12 to 23-15/16, incl.	Sheet ⁴	Sheet ⁴	Black Plate ⁴
Over 23-15/16	Sheet	Sheet	Black Plate

¹ When the width is greater than the thickness with a maximum width of ½ inch and a cross-sectional area not exceeding 0.05 sq. in., and the material has rolled or prepared edges, it is classified as flat wire.

² When a particular temper as defined in A.S.T.M. specification A109, or a special edge, or special finish is specified, or when single-strand rolling is specified in widths under 24 inches.

³ Cold-rolled sheet coils and cut lengths, slit from wider coils with No. 3 edge (only) and in thicknesses 0.0142 inch to 0.0821 inch incl., carbon 0.20 per cent maximum.

⁴ When no special temper, edge or finish (other than Dull or Luster) is specified, or when single-strand rolling widths under 24 inches is not specified or required.

Flat Cold-Rolled Products Classified—The chief cold-rolled products, all classified as "finished," are divided into four major groups, namely, bars, strip, sheets and black plate. The dimensional bases for differentiating between these commodities are shown in Table 33—II.

Plates are flat, hot-rolled, finished steel products, rolled either direct from ingots or from slabs, and are defined further in terms of width and thickness as shown in Table 33—I. Sheared plates are rolled in widths up to 204 inches and are sheared on all edges to the widths and lengths desired. Universal-mill plates are rolled to all widths up to 60 inches, and sheared on the ends to the lengths desired. Plates vary widely in composition, and are ordered to specifications based on chemical composition, mechanical properties, or both.

Bars are hot-rolled, finished steel products having various cross-sectional forms, including small shapes. Flat bars are rectangular in section, and are 1¾ (0.2031) inch and over in thickness and 6 inches and under in width. The larger sizes may be sheared hot or sawed, but the smaller sizes generally are sheared cold to length. The edges may be finished practically square or rounded, and the narrower sides of the thinner sections may be flat, convex, or slightly concave. As to chemical composition, practically all grades and kinds of steel are rolled into bars.

Hoop, as already indicated, was formerly an important commodity and was made in various widths and thicknesses ranging from about ⅝ inch to 6 inches in width, and from about 0.109 inch to about 0.035 inch in thickness. The narrower widths, made of low-carbon plain steel and used to hold the staves of barrels, casks, etc., together, were subjected to special forming operations after rolling, but the material applied to other purposes varied greatly in composition, and much of it required special care in finishing and handling.

Strip, Sheets, and Black Plate are classified according to dimensions, as shown in Tables 33—I and 33—II. Continuous mills roll product in very long lengths, ranging in general from 100 feet to 2000 feet or longer according to the width and thickness of the strip and the size and equipment of the mill. The products are either cut to specified lengths after rolling, or utilized in coiled form.

The distinction between the hot-rolled and the cold-rolled classes of these commodities lies, as mentioned above, in the methods used to attain finished thickness. The cold-reduction process, however, applied to the hot-rolled and pickled steel imparts, after proper heat treating and finishing operations, greatly superior surface and mechanical properties to the hot-rolled coun-

terpart of each commodity. The starting material for the cold-reduction process consists of the semi-finished product of the hot-strip mill designated as hot-rolled breakdowns in coil form.

Further sub-classification of sheets, strip and black plate is necessary to approach an understanding of the diversity of characteristics which enables steel in these forms to be applied to so many important uses. As one example, most black plate actually is not used as such, but is coated with tin to produce tin plate of many varieties for many uses, including the common "tin" can. Such group subdivisions are based on steel type, product treatment, characteristic properties, and final use, and will be discussed after description of the manufacturing methods used.

SECTION 3

SOURCES AND TYPES OF STEEL FOR SHEETS, STRIP AND TIN PLATE

Chemical Compositions—Steel compositions used for the manufacture of thin, flat steel products range from so-called "pure iron," in which the sum of all elements other than iron in the product is less than one-third of one per cent of the total weight, to the high-alloy stainless and heat-resisting steels composed of as much as 50 per cent alloying additions. About four-fifths of the sheet, strip and tin plate tonnage rolled, however, is made from steel compositions within the following ranges (based on ladle analyses):

Element	Per Cent
Carbon	0.03 to 0.12
Manganese	0.20 to 0.60
Phosphorus	0.04 maximum
Other elements	Low as possible

This general range of compositions provides the best combination of rollability during manufacture and formability in most of the applications for which these products are used. Such compositions, too, are well suited for the production of rimmed steel, which is preferred for flat products because of the superiority of its ingot surface. Deviations from this basic composition range are deliberately employed to obtain specific desired properties in the steel, according to principles discussed later. Within the basic composition range, however, most steel plants further subdivide the indicated ranges for individual elements to fit particular production conditions or consumers' special needs. The end result of such adjustments of composition will differ from plant to plant; accordingly, most consumers' requirements are expressed best in terms of suitability for particular applications or of desired properties, with composition restricted only where a direct relationship between composition and performance is known.

Sulphur, silicon, copper, nickel and chromium generally are considered as the "other elements" of the basic composition given above. Except in the steels where they are added deliberately to produce alloy steels with definite properties, these elements offer no advantages and, when present in greater than certain amounts may even be detrimental to the rolling or fabricating properties of steels for sheets, strip and tin plate. An effort is made to keep sulphur and chromium contents each below 0.05 per cent, and copper and nickel contents below 0.15 per cent. Silicon content naturally falls under 0.02 per cent in the rimmed and capped steels popularly used for sheets, strip and tin plate, but is present in amounts up to 0.15 per cent when this element alone is

used as the deoxidizing agent in the manufacture of steel in the range of the basic low-carbon composition. Other elements seldom are found in undesirable amounts, although unusual local conditions affecting the scrap or ore supply may result in the presence of enough molybdenum or tin or both, in the steel to cause it to be somewhat harder in the finished condition than would be the case if these elements were absent or present in only very small amounts.

Steelmaking Processes—The steel for sheets, strip and tin plate is made in this country by the open-hearth, Bessemer or electric-furnace process, each being used where it is best suited to produce steel having the desired composition and properties. Bessemer steel, for example, inherently contains larger amounts of phosphorus (totaling about 0.10 per cent) and nitrogen (about 0.015 per cent total) than open-hearth steel of otherwise similar composition; the additional stiffness imparted to certain products by the presence of these elements in the steel causes Bessemer steel to be selected for such limited applications. Stainless and some other alloy steels are melted in the electric arc or induction furnace for conversion to sheet and strip, the processes in these cases being chosen for their ability to produce alloyed grades of steel with minimum loss of valuable alloying elements in melting and finishing the steel in the furnace. However, about 95 per cent of the steel for sheet, strip and tin plate is produced in the basic open-hearth furnace, for the following reasons.

The basic open-hearth process provides the most economical means for the utilization of scrap, pig iron and Bessemer blown metal, and for the positive control of phosphorus content of the steel by permitting its removal to the desired degree, while producing steels of suitable composition and properties for most flat-rolled products. Furnace charges vary from the duplex and "liquid metal" processes in which no scrap is used, to the opposite extreme of charging up to about 75 per cent cold scrap. Melting practices vary widely to produce steels which, although they may be made by different practices, possess closely similar characteristics when rolled into end products.

Rimmed, capped, semi-killed and killed steels all are used for conversion to thin, flat steel products. Rimmed steels comprise more than half of the sheet, strip and tin plate tonnage made, since steel of the basic low-carbon composition given above, when properly refined, tapped and teemed, provides a naturally rimming steel that can be cast into ingots with sound surfaces and possesses a high degree of cleanliness and ductility.

Mechanically-capped steel retains most of the surface qualities of rimmed steel and provides more uniformity of hardness throughout the cross-sections of rolled products, while increasing the yield of sound steel obtained from each ingot. This modification of rimmed steel by mechanical capping is, therefore, of importance in producing steel for such an application as tin plate where a controlled degree of uniform stiffness is desirable in the end product. Aluminum capping or top killing also is employed; in this practice, the rimming action is stopped after having progressed to the desired point by adding aluminum to the molten steel in the top of the mold. The aluminum killed ("special killed" or "fine-grained") extra-deep-drawing steel is a highly specialized modification of the low-carbon type, having virtual freedom from age-hardening and, hence, unique suitability for some types of drawing operations.

Rimmed, capped and even the "special killed" low-carbon steels are cast into ingot molds without hot tops. "Semi-killed" grades, usually made to possess somewhat higher carbon and manganese contents, still allow sufficient deoxidation control (with aluminum or silicon) of gas evolution and shrinkage to provide a sound ingot from an open-topped mold. Steels having high contents of carbon or alloying elements, those fully killed to attain certain desired end properties, and occasionally the "special killed" grade, are hot-topped to eliminate the formation of "pipe" resulting from the shrinkage characteristic of the solidification of such grades. The stainless steels are the best known hot-topped steels converted to thin flat-rolled products.

Slabs—Slabs are the raw material for the modern continuous hot-strip mill. A slab is defined as a rectangular steel section having a minimum thickness of 1½ inches and minimum width not less than twice the thickness. Slabs are generally provided in thicknesses of 2 to 7 inches, widths of 12 to 64 inches, and lengths of 60 to 240 inches, depending on strip-mill requirements. They must be accurate enough in dimensions and sound enough in structure to permit conversion in subsequent rolling operations with a minimum of difficulty, and their edges and surfaces must be free of injurious defects which would carry through to the finished product.

Two methods are practiced in converting steel from ingot form to slab and then to hot-rolled sheets, strip or breakdowns for cold reduction. By one procedure, the ingots may be heated in soaking pits and rolled on a blooming or slabbing mill to slabs of the required width and thickness, then sheared to length and immediately passed along to the hot-strip mill for final reduction to desired thickness, without reheating. The second and most generally used method is similar to the foregoing, except that the slabs are allowed to cool after being sheared to length at the slab-producing mill. The cooled slabs then are laid out for inspection to locate visible surface and edge defects which are marked for conditioning by the procedures described in Chapter 26. The conditioned slabs then are charged into reheating furnaces at the continuous hot-strip mill.

The first or single-heating method described above results in substantially lower fuel costs and minimizes handling and conditioning expenses, but does not provide sufficient flexibility in scheduling hot-strip mills

rolling a widely varying product mix or a substantial proportion of small orders. The reheating method (the second described above) has proven more advantageous as it provides full flexibility of hot-strip mill scheduling, permits closer metallurgical control of steel-rolling temperatures and minimizes injurious steel-surface defects resulting from defective slab areas.

In accordance with the latter practice, conversion of ingots to slabs is effected by the following typical steps: After stripping, the ingots are charged in the soaking pits of a blooming or slabbing mill and brought to a uniform temperature, approximately 2400° F for the low-carbon steel grades which comprise the bulk of this tonnage. They then are removed by crane-borne tongs to ingot buggies that convey them to the entry roll table of the slabbing or blooming mill. Some mills are equipped with turntables at this point which automatically record ingot weight and place the ingots butt first with respect to the rolling stands and shears; this practice is advantageous as it provides a close check on ingot weight and efficient control of end scrap. Ingots then are passed along a roller table to the reducing stand, consisting of a slabbing mill or a blooming mill of the single stand, reversing type. The slabbing mill is equipped with both horizontal and vertical rolls that work on all four sides of the ingot simultaneously, while the blooming mill operates with horizontal rolls only (see Chapter 25). Greater tonnages and wider slab sections can be produced on the slabbing mills as a result of this difference in design. After reduction to the prescribed slab thickness and width, the elongated slab is advanced toward a shear at the end of the mill roller table. Some mills, at a point between the reducing stand and the shears, are equipped with automatic flame scarfing equipment for the purpose of removing all but the worst edge or surface defects from the slab. The shears cut the slab product to the designated lengths, cropping sufficient scrap from the two ends of the slab, corresponding to what originally was the top and bottom of the ingot, respectively, to insure elimination of pipe, porosity, mechanical end laps, slag deposits, and so on.

Immediately after hot shearing, the slabs are hot stamped with identification markings, such as heat number, ingot number and cut number. After shearing and stamping, the slabs are piled on cooling beds and permitted to cool to a workable temperature, then laid out individually for inspection and marking of surface and edge defects such as scabs, ingot cracks, spongy surface, breaks, tears, and so on which, if not removed, would result in surface slivers, scabs, skin laminations or cracked edges on the finished strip. The defects are removed by scarfing with an oxy-acetylene torch or, on stainless steels, by grinding with abrasive wheels or powder scarfing. The slabs then are repiled, and each is painted with identifying information normally including heat, ingot and cut numbers, thickness, width, weight and code letters or numerals representing chemical composition and steelmaking process.

The finished slabs finally are transported to the storage yard of the hot-strip mill, where they are stacked in orderly fashion according to size and steel grade to facilitate their selection and charging into magazines feeding the reheating furnaces of the hot-strip mill.

SECTION 4

CONTINUOUS HOT-STRIP MILLS

Development and Output—The terms "strip" and "sheet," as applied to the finished products, have definite

reference to width and gage limitations, as shown in Section 1 of this chapter, and the term "hot-rolled

breakdowns for cold reduction" defines a semi-finished product for subsequent rolling by another process. These distinctions do not exist when the terms are used in connection with a continuous mill rolling such products; thus, a mill rolling continuous lengths of strip, sheet, or breakdowns commonly is known as a "strip mill." The history of development of continuous hot-strip mills was summarized in Section 1 of this chapter.

At the end of 1954, about forty wide continuous hot-strip mills were in operation in the United States, their combined annual capacity being approximately 40,000,000 net tons. As a group, the wide strip mills roll flat steel in thicknesses of 0.04 inch to 1.25 inches, widths of 24 to 96 inches, and lengths up to 2,000 feet. Each mill has its own limitations as to sizes of finished product though, as a general rule, no mill exceeds a product width-to-thickness ratio of 1000:1.

General Arrangement of Modern Mills—The modern wide hot-strip mill has become quite standardized in its general layout. Slabs are heated in two or more continuous reheating furnaces. A typical rolling train will consist of a roughing scalebreaker, four four-high roughing stands, a finishing scalebreaker, and six four-high finishing stands. Driven table rolls convey the steel from furnace to mill and also from stand to stand. If the mill is to produce strip, sheets or breakdowns of greater width than the maximum width of slab available, the first rougher or roughing stand is a broadside mill in which the width of the slab is increased in a single pass by cross rolling. In this case, turntables for manipulating the slab must precede and follow this stand. A slab squeezer also follows the broadside mill. The next three roughing stands usually are provided with integral vertical edgers in front of each stand. Separating the roughing train from the finishing train is a holding table, while the finishing end is a closely grouped tandem train composed of the finishing scalebreaker and six finishing stands.

High-pressure hydraulic sprays to remove scale from the hot slab are located after the two scalebreakers and perhaps at several roughing stands. Water is supplied to the spray nozzles by suitable high-pressure pumps.

Following the last finishing stand there is usually a flying shear for cutting the rolled product into lengths, if so desired. As the steel proceeds from the mill, it is carried over a long table called the runout table, consisting of individually driven rollers. Two or more coilers are located in this table; they operate to coil the material when continuous long lengths are required. If short lengths are cut at the flying shears, the coilers are inoperative and the steel passes over them and onto a piler at the end of the table. Additional tables may be installed parallel to the central runout table, with suitable transfers for moving material to them; this equipment is used principally when the heavier gages are being rolled.

The most commonly used hot-mill arrangement just described, employing continuous roughing and continuous finishing trains, provides high rolling capacity and rapid steel travel with little loss of heat, but entails a high installation cost and a fixed number of passes, with some loss of flexibility in making rapid changes in the mill set-up when the size of product to be rolled is changed. An alternate arrangement, used in several instances, employs a reversing roughing mill and a continuous finishing train; this arrangement has a lower original installation cost, requires less floor space, and is flexible with regard to the number of passes available, but at a sacrifice in capacity and operating cost. Another modification of the conventional mill (the single-heating practice already described) provides for

rolling the slab direct from the blooming operation, utilizing retained heat and by-passing the slab-reheating furnace; this practice saves fuel but sacrifices flexibility of scheduling rolling operations on the continuous hot mill.

Still another arrangement for continuous hot rolling of steel calls for the use of a reversing hot mill for finishing. This mill may have a conventional roughing train or single reversing stand for roughing, followed by the single reversing finishing mill. The reversing finishing mill has a pair of pinch rolls and a paddle-type coiler located on both sides (entry and exit) of the mill. The coilers operate inside of small heating furnaces which keep the steel hot and permit the finishing rolling operation to be carried out by repeated reversing of the finishing stand. This type of mill entails low initial cost and is highly satisfactory for the production of small orders or the rolling of alloy steels.

Control of Finished Product Quality—When an order is accepted for production by a particular mill, the first step taken is to determine the proper grade of steel and the size and surface quality of the slab necessary to make the order. The order is then grouped with others and scheduled in its proper rolling sequence. The principal factors taken into consideration at this important stage are rolling width, gage, and steel composition.

The next step in production requiring control is the operation of heating the slabs to rolling temperature. The slabs must be heated uniformly throughout, and also must have a uniform "scale jacket" that will "clean up" readily in rolling. Many rolling delays and mechanical difficulties are a direct result of poor heating practice; the steel may not be "soaked" sufficiently, may be too hot, too cold, or unduly hard to clean.

The third step is to rough down the slab to a predetermined intermediate thickness. As the slab leaves the last roughing stand, it should be flat, straight, free of furnace scale, true to width and of a cross-section suitable for further reduction on the finishing stands. The first rolling pass on the slab is done on a scalebreaker which is followed immediately with a high-pressure hydraulic spray to facilitate removal of the furnace scale. In addition, there are usually one or two more descaling sprays following the second or third roughing stands and numerous steam and air sprays available to remove any further scale that may be loosened during rolling or edging. Proper use of the broadside mill, slab squeezer and the three vertical edgers normally will guarantee the uniform width essential for all subsequent operations.

Next, the finishing train must be operated with careful regulation to obtain a finished hot-rolled product of prime quality. Surface, gage, width, finishing temperature and cross-sectional contour of the product, all are required to meet given standards depending upon the subsequent treatment or ultimate use of the material in question. As an example, metallurgical requirements may dictate a definite finishing temperature for a particular gage and width to be rolled. Time on the holding table prior to coiling, number of descaling sprays used during rolling in the finishing stands, speed of the finishing train, and method of drafting, all affect the finishing temperature and may be varied at the discretion of the operator to help meet requirements. Defects in the surface of the rolled steel, if not evident in the rough slab, usually can be traced to defects in the surfaces of the work rolls on the finishing stands and are corrected readily by substituting newly-surfaced work rolls. The principal factors affecting the overall dimensional accuracy of the finished hot rolled product include contour of the work rolls and back-up rolls as installed, changes

HOT STRIP ROLLING MILL

TYPICAL REDUCTIONS PER PASS IN FINISHING STANDS

FIG. 33-1. Typical reductions per pass in the finishing stands of a hot-strip rolling mill.

in the contour of the work rolls and back-up rolls due to intermittent heating and cooling, method of drafting (i.e., amount of reduction in successive passes), and rolling sequence of various gages and widths.

Figure 33—1 shows typical reductions per pass in the finishing train of a continuous wide hot-strip mill.

The final step in rolling an order on a strip mill is disposition of the hot-rolled product. On some mills, the product may be cut into shorter lengths on a flying shear located at the exit end of the mill, the sheared pieces progressing along the runout table to a hot piler. The greater portion of hot-rolled flat material, however, is handled by the hot-coiling method; this includes the semi-finished product designated as hot-rolled break-downs in coils for subsequent cold reduction, as well as hot-rolled sheets in coils which may be shipped as such or transferred to the finishing department where they are uncoiled and processed into the form of flat cut sheets. The essential requirements of the coiler are to receive the material at mill speeds and coil it tightly without excessive tension, telescoping, scratching or marking and, finally, discharge the finished coil quickly without damage.

A Modern Wide Continuous Mill—The 80-inch hot-strip mill at the Gary Sheet and Tin Mill of United States Steel Corporation serves as a modern example of the wide continuous mill. This mill was built originally in 1935 and was modernized completely in 1948.

Slabs for the mill may range in size from 4 to 7½ inches in thickness, 18 to 64 inches in width and 80 to 216 inches in length. The conditioned slabs, as needed, are carried by overhead crane to the individual storage machine located in front of the charging end of each of the five slab-reheating furnaces, which extend at right angles into the hot-strip mill building. The slab pushers of each furnace travel under the corresponding storage magazine and push the bottom slab of the pile in the magazine onto the charging table. This table is equipped with driven rollers to position the slabs properly before the furnace doors. When the slabs are in position on the

charging table, they are shoved over skids into the furnace by pushers (Figure 33—2) operated by 150-horsepower, 500 r.p.m., DC motors through worm reduction drives. These are controlled from an operating platform behind the charging end of the furnaces. The doors of the furnaces also are controlled from there and are arranged so that, when the charging door is opened to push a slab into the furnace, the door on the delivery end simultaneously opens, permitting a slab to be discharged over an apron onto a roller table (Figure 33—3).

The five furnaces all are of the zone-controlled, triple-fired, recuperative, continuous type. Each furnace is 80 feet long by 20 feet wide and is capable of heating approximately 105 tons of steel slabs per hour to a maximum of 2400° F. The furnaces normally are fired with coke-oven gas or fuel oil, and are equipped with automatic combustion and temperature controls. Natural gas also may be used or a mixture of natural and coke-oven gases. Approximately 340,000 cu. ft. of coke-oven gas per hour are required to heat each furnace. Preheated air at 700° F is obtained for combustion by passing the hot products of combustion from the furnaces through recuperators. Air is pushed through the recuperators for each furnace by a motor-driven fan, rated at 50,000 cu. ft. per minute. Flue gas is conducted through underground flues to individual stacks, 150 feet high, or can be diverted to be used on two waste-heat boilers.

The slabs move through the first 60 feet of the furnaces on water-cooled skids which permit heating on both tops and bottoms. These skids use about 60,000 gallons of cooling water per hour for each furnace. The last 17 feet of the furnaces, known as the "soaking zone," have a flat bottom (combination steel and brick) where the slabs are brought to a uniform temperature throughout. Accurate control of temperatures, furnace atmosphere composition, and pressure in all parts of the furnaces is facilitated by a battery of recording and indicating instruments. Doors are provided along the sides of the furnaces for observation purposes and to permit manual positioning of slabs if desired.

FIG. 33—2. Charging end of heating furnaces for an 80-inch mill, showing slabs in position before the furnace doors. In the foreground are the pushers which force the slabs through the nearest furnace.

FIG. 33—3. Discharge ends of a group of three heating furnaces for an 80-inch mill.

FIG. 33—4. Broadside stand of an 80-inch mill. Here slabs receive their first heavy reduction in thickness. The slab shown here has received a broadside (sideways) pass to extend it to the proper width. The turntable (slab turn-around) next will turn the slab 90 degrees before it goes on to the following roll stands.

FIG. 33-5. View of part of an 80-inch continuous mill from the operator's pulpit from which the speed of the roughing stands is controlled.

Slabs are discharged from the heating furnaces at temperatures ranging from 2000 to 2400° F, depending upon the grade of steel and thickness of finished product. They are carried to the mill by a roller table 245 feet long. This table is made up of six units, each driven by a 50-horsepower motor. The table is reversible, so that, when necessary, slabs can be returned to slab storage by a transfer located parallel to the furnaces.

The first mill stand in the 80-inch hot strip mill is the No. 1 scale-breaker. This mill is a two-high, 36-inch by 80-inch stand, operated at 212 feet per minute, and driven by a 1250-horsepower, 490 r.p.m., AC motor through a double reduction-gear drive equipped with two 12½-foot flywheels. The descaling water spray following this stand operates at 1300 lb. per sq. in. pressure. Slabs travel 100 to 200 feet per minute over a 26-foot reversible table between this scale-breaker and the first roughing stand.

The first roughing stand is a four-high 40-inch and 54-inch by 130-inch mill operated at about 182 feet per minute, driven by a 3500-horsepower, 6600-volt, 340 r.p.m., AC motor through a gear set and two 13½-foot flywheels. This stand is a broadside mill in which slabs up to 127 inches long can be spread to a maximum of 77 inches wide in a single pass, when it is necessary to produce widths greater than the original slab (Figures 33-4 and 33-5). A rack-type slab pusher on the entry side of this stand assures square and proper entry of the slab between the rolls. Slab turn-arounds are provided before and after this stand to rotate the slab through 90 degrees when the stand is used for broadsiding. Following the broadside mill, a slab squeezer serves to true up slab edges and widths and to flatten them for subsequent rolling. This squeezer has a 24-foot head with a maximum stroke of 6½ inches on a 6-inch thick slab. Slabs reach the squeezer and pass to the second roughing stand over a reversible roller table 100 feet long, in three independent sections, each driven by a 50-horsepower, 550 r.p.m., reversible DC motor. Table speed is 120 to 240 feet per minute. A slab shear is located between the squeezer and the second roughing stand.

The second roughing stand is a 44-inch by 80-inch universal two-high mill with vertical edging rolls mounted on the entry side of the stand. This mill is driven by a 3500-horsepower, 490 r.p.m., AC motor. The gear drive is equipped with two 13½-foot flywheels. The edging rolls are driven through twin worm reduction sets by a 350-horsepower, 400 to 1000 r.p.m., DC motor. After leaving this stand, the slab passes over a reversible roller table 51 feet long, driven by a 50-horsepower, 550 r.p.m., DC motor at speeds of 178 to 356 feet per minute.

No. 3 rougher is a four-high 32-inch and 53-inch by 80-inch universal stand, as is No. 4 rougher, located 94 feet beyond No. 3. Both of these stands have vertical edging rolls mounted on the entry side, duplicates of those on the second roughing stand. Each mill is driven, through a gear set with two 13½-foot flywheels, by a 3500-horsepower, 490 r.p.m., AC motor. A holding table, 200 feet long, lies between the roughing and finishing trains. This table is divided into two sections, each driven by two 50-horsepower, 550 to 1100 r.p.m., DC motors, providing table speeds from 100 to 400 feet per minute. The rolled product is cooled by holding on this table, if necessary, to attain proper finishing temperatures to meet requirements. A rotary crop shear is installed at the finishing end of the table, so that both the front and back ends of the material can be squared off before finishing.

A second scalebreaker, two-high, 36-inch by 80-inch, followed by high-pressure descaling sprays and driven by an 800-horsepower, 150 to 450 r.p.m., DC motor, precedes the finishing train. The finishing train is six four-high, 26-inch and 53-inch by 80-inch stands spaced on 22-foot centers (Figure 33-6). Each stand of the finishing train is driven by a 600-volt, DC motor. Numbers 5, 6 and 7 stand motors are of 4500-horsepower capacity, operate at 125 to 282 r.p.m., and drive through gear sets. No. 8 (4500-horsepower, 85 to 190 r.p.m.), No. 9 (4500-horsepower, 100 to 230 r.p.m.) and No. 10 (3000-horsepower, 110 to 255 r.p.m.) motors drive direct.

FIG. 33-6. General view of an 80-inch continuous hot strip mill. In the background are the roughing stands. In the center are the six finishing mills. The cooling sprays over the runout table are in the left foreground.

Product speed leaving No. 10 stand reaches a maximum of 1960 feet per minute. Loopers are provided between the finishing stands, each driven through a worm reduction unit by a 200 pound-foot torque DC motor. Steam sprays are provided on the delivery side of each stand and tachometers are installed in control stations to indicate mill speeds.

The screwdown on each finishing stand in the mill is operated by two 75-horsepower, 575 r.p.m., DC motors equipped with magnetic clutches and dynamic brakes. Single 35-horsepower, 575 r.p.m., DC motors drive the screwdowns on the two scalebreakers and the first two roughing stands through cutout clutches; two similar motors with magnetic clutches and dynamic brakes are used on No. 3 and on No. 4 roughing stands. The top roll on all stands, except No. 2 scalebreaker, has a hydraulic roll balance. No. 2 scalebreaker has a spring balance.

Oil-film bearings are used on all back-up rolls in the four-high finishing stands. Grease-lubricated roller

thrust bearings are used on Nos. 1 and 2 scalebreakers and 3 and 4 roughing mills, while fabric bearings are used on the back-up rolls of No. 1 roughing mill and the work rolls of No. 2 roughing mill. The mill is lubricated automatically by five separate recirculating oil systems servicing the oil-type back-up roll bearings, the pinion-stand gears and bearings of the large mill-drive motors and motor-generator sets. Grease requirements are maintained automatically by several central-station greasing systems strategically located throughout the mill.

Hydraulic requirements for the descaling systems are met by three units made up of two 1000-gallon per minute, 1300 lb. per sq. in. pressure pumps driven by a 1250-horsepower, 6600-volt, 1800 r.p.m., AC motor. Temperature of the product is watched carefully throughout its passage in the mill by use of one recording pyrometer and three recording-indicating pyrometers placed at the entry to No. 1 roughing stand, on the

FIG. 33-7. Motor room of an 80-inch hot-strip mill. At the left are the motor-generator sets which supply direct current to the finishing-stand mill motors in the right foreground.

holding table, at the entry to No. 10 stand and at the entry to the coiler.

The hot-strip mill building is 95 feet wide and 2352 feet long; it is served by three 60-ton cranes with 10-ton auxiliary hoists, one 60-ton crane with 15-ton auxiliary and one 15-ton crane, all of 90-foot span. A building 92 by 624 feet, conveniently located alongside the hot mill, houses service and roll shops. The latter include roll lathes, roll grinders and special degreasing equipment for cleaning bearings. The hot-strip mill motor room, 65 by 644 feet, is served by one 50-ton crane having a 60-foot span. The twelve hot mill drives, with their reduction gears, control equipment, switchgear, etc., are located in this room (Figure 33-7). The motor room is equipped with a recirculating-type ventilating system forcing air through coolers located in the motor-room basement into the motor room proper. All make-up air is filtered before distribution. The ventilating system is designed to handle 525,000 cubic feet of air per minute at 95° F.

Power is supplied from the outdoor substation via a metal-clad bus system at 6600 volts to the switchboard and is distributed to equipment through conduit laid in the concrete floor. Variable-voltage direct current is supplied to the main motors driving the finishing train from three 3-unit, 6000-kw, 600-volt synchronous motor-generator sets, each consisting of two 3000-kw, 600-volt, DC generators driven at 360 r.p.m. by an 8600-horsepower, 6600-volt synchronous motor.

Product Disposition—After leaving the last finishing stand of a continuous hot-strip mill, the rolled product is delivered onto a long runout table where it is carried either in long lengths to coilers, or to a sheet piler in cut lengths. The 80-inch hot-strip mill being described produces only coiled product. It has a flying shear, spaced 11 feet 9 inches from the last finishing stand,

which is used to crop either or both ends of product that is to be coiled as a single piece. The shear is driven by twin 150-horsepower 450 to 900 r.p.m., DC motors.

After leaving the flying shear, the steel passes over a roller table 364 feet long, having 243 rollers, each driven by a 4-horsepower, 0 to 800 r.p.m., DC motor through rubber-ball couplings. The table is equipped with cooling sprays both above and below the rollers. Three mandrel-type coilers are installed at the end of this table, each driven by a 350-horsepower, 1200 r.p.m., DC motor. Coils with a maximum width of 77 inches, an inside diameter of 32 inches and an outside diameter up to 69 inches can be accommodated. Air-operated pushers remove the coils from the mandrels onto a coil tilter, which places coils on end onto a chain conveyor which carries them to the coil-storage building (Figure 33-8). Heavy-duty scales are installed in the hot-coil conveyor, giving an accurate check on production and yield figures.

Two 900-kw, DC generating sets and several smaller units furnish power for all of the product-disposition equipment. Two generator sets normally are allotted to flying-shear service, two to the three runout-table sections between the flying shear and coilers and one to the three coilers. One generator is a spare which can be switched into any of the other services.

Metallurgy of Hot Strip—Wide hot-rolled strip from a modern continuous mill may be used in the as-rolled condition, in which case it is referred to as "hot-rolled sheets," with or without the application of such auxiliary treatments as pickling, shearing and flattening. When produced as hot-rolled breakdowns for cold reduction, it is pickled in coil form, cold reduced as much as 90 per cent of its original thickness, heat treated and further processed to cold-rolled sheets, strip, black plate, or the various coated sheet-mill and tin-mill products. In any case the metallurgical requirements of the great bulk

FIG. 33-8. Coiled product leaving the coiler of an 80-inch continuous hot-strip mill.

of the product are relatively simple and lend themselves to best operating conditions on the hot-strip mill and subsequent processing units.

The last hot-rolling operation (in the last finishing stand) should be conducted above the upper critical temperature on virtually all continuous hot-mill flat-rolled products. Such a practice permits the rolled steel to pass through a phase transformation after all hot work is finished and produces a uniformly fine, equiaxed ferritic grain throughout all portions of the steel. For the low-carbon steels generally used, proper finishing temperatures will have been attained when the apparent product temperature emerging from the last rolling stand is over 1550° F. This finishing temperature is practical over most thicknesses rolled on most modern mills at normal maximum rolling speeds.

If part of the hot rolling is conducted on steel which already has transformed partially to ferrite, the deformed ferrite grains usually will recrystallize and form patches or layers of abnormally coarse grains during the self-anneal induced by coiling or piling at the usual temperatures of 1200 to 1350° F. Such a structure is more likely to occur at the surface of the product, which is colder than the interior during rolling. Very thin hot-rolled material, inadvertently finished far below the upper critical and coiled or piled too cold to self-anneal, may retain microstructural evidence of hot-working. Neither condition is suitable for some types of severe drawing applications; both may be corrected by normalizing the sheet.

A special case occurs in the steels of the so-called "pure iron" or "enamel sheet" compositions, in which the sum of the carbon and manganese contents may be well under 0.10 per cent. Such compositions often exhibit a hot-short temperature range between 1650° to 1900° F, and normal hot rolling in that range may produce deep cracks on the edge of the product. Accordingly, it is the practice on many mills to complete the roughing operations above the hot-short range, to allow the steel to cool through the range by holding it on the conveyor table between the last roughing stand and the finishing train, and to resume rolling by passing the product into the finishing train below the hot-short range. By this practice it is impossible to finish above the upper critical temperature of these steels.

The runout table following the last rolling stand of most hot-strip mills is long enough and equipped with

enough quenching sprays to cool the single thickness of rolled product 200 to 500° F below the finishing temperature before the continuous length or the hot-sheared sheets become a part of the 2 to 20-ton mass of steel being formed in the coiler or on the piler. In addition, some mills have auxiliary tables or holding beds which allow single-thickness cooling to a take-off temperature of 500° F or lower. The cooling practice employed largely determines the metallurgical properties of the steel, its suitability for further processing and its final applicability to the intended use.

On hot-rolled products properly finished above the upper critical temperature, a uniform ferrite grain has been established and the runout cooling practice determines the carbide characteristics and, to some extent, the grain size. The self-annealing effect of a large mass of steel coiled or piled at around 1350° F produces considerable carbide agglomeration, a coarse ferrite grain and a soft, ductile sheet. Coiling or piling around 1200° F yields a fine, dispersed spheroidal carbide in a finer ferrite matrix, resulting in a somewhat harder sheet, which still retains excellent ductility. Even more drastic quenching produces various transformation states of carbide, down to and including martensite. For most low-carbon steel made either for use as hot-rolled sheets or as breakdowns for subsequent cold reduction, coiling temperatures of 1200 to 1300° F are employed; this range provides optimum uniformity of mechanical properties without excessive scale formation or over-annealing. A few mills have resorted to quenching the hot coil in a tank of water to inhibit scale formation and provide a surface oxide which can be pickled very readily. Steels of 0.15 to 0.30 per cent carbon content and alloy steels often are quenched drastically to attain higher strength levels from finer carbide dispersions, or are coiled very hot to facilitate cold reduction.

As most heat treatment after cold reduction is carried out below the lower critical point, the cold-reduced, box-annealed microstructure usually bears a relationship to the microstructure of the hot-rolled material. In the somewhat unusual case of the aluminum-killed, cold-rolled deep-drawing sheet, coiling temperatures under 1200° F are employed when rolling breakdowns on the continuous hot mill to provide the best drawing properties in the finished cold-reduced, box-annealed sheet.

SECTION 5

HAND HOT MILLS

Development—Prior to the advent of wide continuous hot-strip mills, all sheet and tin plate products were rolled on single-stand sheet and tin plate hot mills. These mills were patterned after the crude water-power or horse-driven units used to roll lead and copper as early as 1600, which were adapted to rolling thin steel sheets for tin plating in England about 1728. Until the middle 1930's, mills of this type, designated "jobbing" mills, were used to roll heavy-gage sheets, and "pack" or "finishing" mills were used for light-gage sheets and tin plate. Except for a few isolated instances, the hand hot mill is now obsolete for the rolling of flat-rolled products. For this reason, the process will be described in the past tense.

Process—In the original manual process of hot rolling, sheet bars, a semi-finished product rolled to a specified weight per linear foot and in various widths and thicknesses, were used to produce sheets. Packs made up of multiple thicknesses of steel first were prepared by

"breaking down" or cross rolling sheet bars cut to the correct length to produce the width of sheet desired. The bars were heated in a bar or "pair" furnace to near the upper critical point for the steel, and then passed through the rolling mill repeatedly in pairs, one bar closely following the other through the rolls of a two-high or three-high roughing mill. A number of final passes with the bars "matched," that is, placed one on top of the other, might be given the "breakdown" if desired to form a "pack" for finish rolling. For light gages, the pack usually was "doubled" or folded over prior to finish rolling. It should be noted that the term "breakdown," as now applied to a semi-finished hot-rolled product of the hot-strip mill, does not describe the same physical type of hot-rolled product as in older practice, but does connote still an intermediate stage in the production of flat-rolled products.

In jobbing mills where sheets heavier than 16 gage and up to 90 inches wide were produced, packs or bar break-

downs, after roughing, might be rolled immediately on a two-high finishing mill, down to desired finished thickness. In plants equipped with wide continuous hot-strip mills, breakdowns and packs eventually were made from hot-rolled breakdowns produced on the continuous hot mill, thus eliminating the operation of breaking down sheet bars (roughing) that is described later.

The number of sheets in the finished pack varied from two to eight according to the finished gage. While practices in different mills varied somewhat, a typical arrangement was for sheets of 14 to 18 gage to be finished in packs of twos; 19 to 22 gage, in threes; 23 to 27 gage, in fours; 27 to 29 gage, in sixes, 29 to 34 gage, in eights.

Light-gage sheets and tin plate were rolled from packs on two-high finishing mills. The packs were heated and then given successive passes through the mill until the desired thickness was obtained. Finished packs were allowed to cool, then side and end sheared to desired width and length and placed on the opening floor. During the rolling operation, the individual sheets of the pack became firmly stuck together. They were pulled apart manually with the use of tongs and "sticker-opener swords."

At this stage of production, the sheets were classified as hot-rolled only. For most uses they had to be heat treated, generally by box annealing. Additional treatments, such as pickling, cold rolling, and oiling, might be given to the sheets. The sheets also might be used as the base for galvanized, terne or tin coatings. For high-grade sheets, requiring a smooth surface free from all defects, the bars or the breakdowns might have been pickled prior to rolling. The pickling operation, in addition to removing scale, exposed defects which might cause imperfections and rejection of finished product.

Equipment and Operation—The processes and equipment required to convert ingots to finished rolled products by the foregoing methods are illustrated by the flow diagram, Figure 33—9. As shown, sheet bar was

delivered from the bar mill to the bar shears. When received, the bars were usually 30 feet or more in length, up to 1 inch in thickness, and 8 to 16 inches wide. As the length sheared from the bar finally became the width of the finished sheet, bars of length and width suited to produce desired sheet length and thickness were selected for each order. The bars were sheared to length on guillotine or alligator-type bar shears, pickled when desirable, inspected and delivered in piles to the heating furnaces adjacent to the roughing mills.

The bar furnaces were simple, rectangular, brickwork chambers located and arranged for efficient handling of bars to the roughing mills. Original furnaces were heated with coal, first hand-fired and later fired by automatic stokers. The furnaces still in use usually are equipped for gas or oil firing. The furnaces might be equipped with pushers which mechanically pushed a solid row of bars, standing on edge, into the entry door, through the furnace and out the exit door. For low-capacity specialty furnaces, the bars might be laid in the furnace and removed by hand tongs, one at a time through a single door.

When the bars had been heated, they were moved by hand or on roller or chain conveyors to the roughing mills, which might be two-high units with about 28-inch diameter rolls or three-high units with 28-inch diameter top and bottom rolls and middle rolls approximately 16 inches in diameter. The rolls, which were water-cooled during rolling, were chilled cast iron of lengths determined by the maximum width of sheet to be rolled. Ordinarily only the bottom roll was driven. The driving mechanism included a motor, gear reducer, spindles and couplings. Bearings were usually brass, lubricated by grease. The housings which formed the mill frame work were of cast steel, mounted on cast-iron bed plates. The amount of pressure exerted by the rolls on the bars was controlled by adjustment of two large screws which passed through bronze nuts located

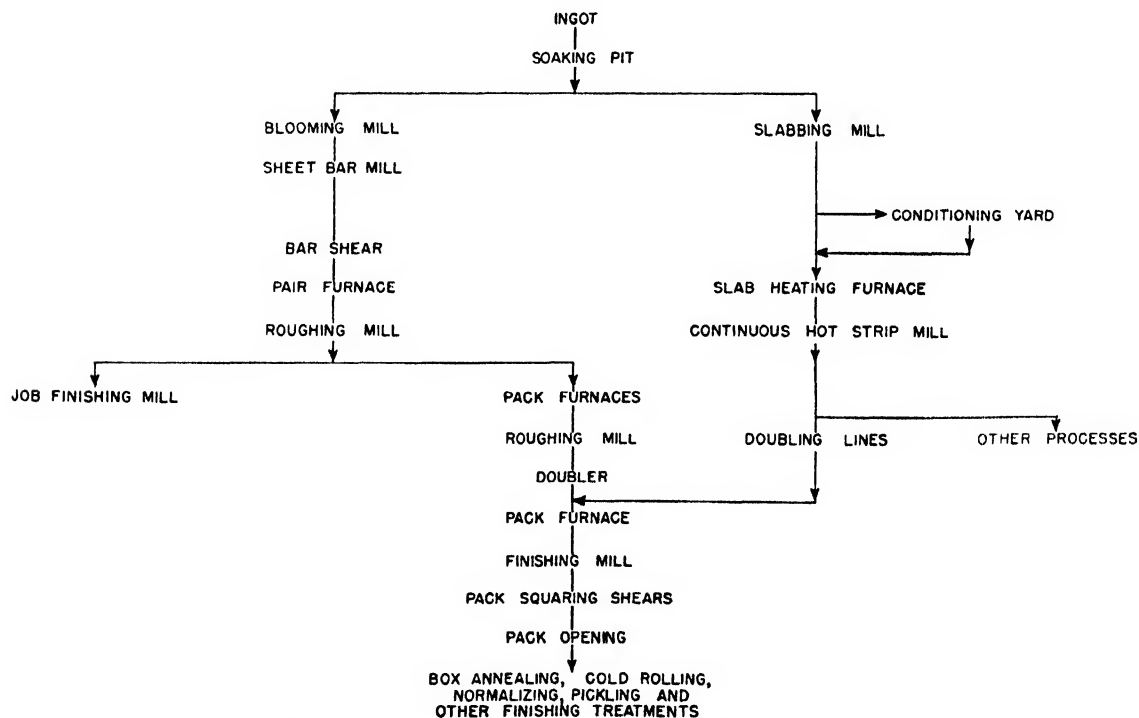

FIG. 33—9. Comparison of sequences of operations in the production of flat-rolled products.

in the tops of the housings. The screws normally were adjusted manually through hand wheels or notched spanner wheels and spanner bars, though electric motors were preferred for the larger mills. Rest bars, guides and support rolls were located between the housings at strategic points for feeding, catching and returning the bars. Mills of this type usually were installed in trains, with a number of units driven by the same drive through interconnecting spindles and couplings.

The rolls used in the finishing mills were chilled cast iron, varying from 22 inches to 32 inches in diameter, and up to 96 inches long. As the rolls were not cooled, and expanded while rolling the heated packs, they had to be shaped properly prior to use to compensate for expansion. In order to obtain the desired sheet surface, the roll surfaces had to be smooth and free from imperfections which would be transferred to the sheets.

Breakdowns from the bar mills were rolled on finishing mills either as packs of sixes or doubled sheets. The hot-mill breakdown doubler was a steam or compressed air hammer with a long face. The pack partially was folded over by hand, and the curl flattened by the hammer.

When breakdowns from hot-strip mills were used instead of bar breakdowns, they were doubled on special-purpose shearing and doubling lines which consisted of uncoilers for holding and paying-off the coiled hot-rolled breakdowns, a roller leveller which served as the flattener and feeding device, a shear and gage to cut the strip to desired breakdown length, a matching table on which two or more breakdown sheets were

piled one on top of another and a roller-type doubler.

From the doublers, the packs were taken by crane or conveyor to the entry end of the finishing-mill pack-reheating furnaces. On older-type units, or for specialty purposes, these furnaces might be rectangular heated chambers, very similar to the bar furnaces, into which the packs were placed by hand or the furnaces might be used as high-production continuous units, through which the packs were conveyed by special alloy conveyor chains. In either case, the packs were heated to desired temperature and then delivered manually or by conveyor to the finishing mills.

The finishing mills were two-high units very similar in appearance and arrangement to the two-high roughing mills. On the more modern high-production mill units (both roughing and finishing), mechanical feeder and catcher tables were used to handle the pack during the rolling operation. These tables were tilting units, on which were mounted rapidly reversing conveyor chains, side guides and stops, so arranged as to eliminate completely the need for manual handling of hot packs with tongs. On the finishing mills the sheets were rolled to final gage in lengths up to a maximum of about 12 feet.

The completed packs, consisting of from 2 to 8 sheets, were conveyed across cooling beds and then sheared to required size on guillotine-type squaring shears. All four edges were sheared and the knives were made long enough, when possible, to shear each edge of the largest rolled sheets in one stroke. The sheared packs were removed to the opening floor and the individual sheets pulled apart and piled for delivery to other processes.

SECTION 6

OXIDE REMOVAL

(Pickling and Shot Blasting)

Necessity for Removal—The presence of oxide (scale) on the surface of strip, sheet, or breakdowns, is objectionable when they are to be processed further. For example, the oxide must be removed and a clean surface provided if satisfactory results are to be obtained from the hot-rolled sheet or strip in any operation involving deformation of the material. If the sheets are for drawing applications, removal of the oxide is essential, as its presence on the steel surface tends to shorten die life, cause irregular drawing conditions and destroy surface smoothness of the finished product. Oxide removal is also necessary if the sheet or strip is to be used for further processing involving coating in order to permit proper alloying or adherence of metallic coatings and satisfactory adherence when a non-metallic coating or paint is used.

In the production of cold-reduced steel sheet and strip, it is necessary that the oxide resulting during hot rolling the steel slab to breakdown form be removed completely before cold reduction to prevent lack of uniformity and eliminate surface irregularities.

Types of Oxide—The term "oxide" as used here refers generally to the chemical compounds of iron and oxygen formed on the surface of the steel by exposure to air while the metal is at an elevated temperature. "Scale" is specifically the oxidized surface of steel produced during heating for working and during hot working of steel. Hence, the oxide produced on steel surfaces in hot-rolling processes is known as mill scale. Chemical compounds thus formed are iron oxides FeO , Fe_2O_3 , and Fe_3O_4 .

The mechanism whereby mill scale is formed generally is considered to be of a dynamic nature, whereby

alternate formation and reduction of the higher oxides of iron occur. Fe_2O_3 is formed first and then reduced

FIG. 33-10. Comparative effects of temperature and atmosphere on the scaling of plain carbon steels, all exposed for a constant time.

successively to Fe_2O_3 and FeO by the availability of iron. Additional Fe_2O_3 is formed at the atmosphere-surface interface and the process becomes continuous; the final result is a scale composed of layers richest in oxygen at the scale surface and richest in iron at the metal surface. FeO , the layer next to the steel, constitutes about 85 per cent of the scale thickness, Fe_2O_3 about 10 to 15 per cent and Fe_3O_4 about 0.5 to 2 per cent. There is evidence, too, of a molecular or ionic diffusion process involving oxygen moving inward and iron moving outward through the scale.

The rate of oxide formation is dependent on the temperature, composition and physical characteristics of the steel, and temperature, character and rate of flow of the atmosphere, as well as the length of time the steel is exposed to oxidizing conditions. Figure 33-10 shows graphically the oxide development at temperatures of 1000° to 2200° F for a low-carbon steel exposed for two hours to atmospheres of oxygen, dry air, carbon

FIG. 33-11. Comparative effects of time of exposure and nature of the atmosphere on the scaling of plain carbon steels at 1520° F.

dioxide and water vapor. It is noted that rate of scaling increases uniformly with temperature when water and carbon dioxide atmospheres contact the steel surfaces and that interruptions occur in the rate of scaling when oxygen and dry air are employed. These interruptions are attributed to blistering of the scale which leads to pitting of the undersurface.

Figure 33-11, in which scale loss is plotted against time for samples of low-carbon steel exposed to carbon dioxide, air and oxygen atmospheres, shows increasing loss for an increasing time at a given temperature. Figures 33-10 and 33-11 also show relative oxidizing activity of the four atmospheres, with carbon dioxide the least oxidizing and dry air, oxygen and water vapor more strongly oxidizing in the order named.

PICKLING

Pickling is the process of chemically removing oxides and scale from the surface of a metal by the action of water solutions of inorganic acids. While pickling is only one of several methods of removing undesirable

surface oxides, this process is used the most widely in the manufacture of sheet and tin mill products, due to comparatively low operating costs and ease of operation. Considerable variation in type of pickling solution, operation and equipment is found in the industry. Among the types of pickling equipment may be mentioned the batch picklers, modified batch, semi-continuous and continuous picklers.

The reaction occurring when steel or iron materials are immersed in dilute inorganic acid solutions includes the solution of metal as a salt of the acid and the evolution of hydrogen. Steel pickled in dilute sulphuric-acid solutions is an example of this reaction, with the end products of reaction being ferrous sulphate and hydrogen. Adherent films of oxides are undermined by the acid attack through the pervious scale on the base metal. FeO is not dissolved as readily as the steel, but does have higher reaction rates than Fe_2O_3 and Fe_3O_4 , both of the latter being soluble very slowly in the acid. Ferric sulphate is formed first and then is reduced to ferrous sulphate by the free hydrogen. Sulphuric-acid baths rarely contain significant amounts of ferric sulphate since this compound is unstable in the presence of reducing agents. Certain metals, such as copper, chromium and nickel, retard the rate of pickling when they occur in the steel base, since the scale bearing these alloying metals inhibits acid attack. Silicon and aluminum form refractory-type oxides, which in turn lower the solubility rate of the oxide in the acid.

The rate of pickling is affected by numerous variables, including the aforementioned steel-base constituents and type and adherence of oxide to be removed. Solution temperature and concentration, ferrous sulphate concentration, agitation, time of immersion and presence of inhibitors influence the rate of acid attack. While the rate of pickling increases in direct proportion to the concentration of the acid from zero to 25 per cent by weight, the influence of temperature is much more pronounced. For example, in 15 per cent sulphuric acid an increase in temperature over the range 70° F to 210° F doubles the pickling rate for each rise of 15° or 20° F in temperature. Rate of solution of iron at 180° F is about five times the rate at 140° and about 100 times greater at boiling than at room temperature. The trend in recent years in batch pickling of hot-rolled steels is to maintain temperatures at 150° to 175° F if possible and to increase or decrease pickling activity with adjustment of the concentration, thus affording some savings in fuel for heating and avoiding decomposition of the inhibitor. Acid concentration is varied over a relatively wide range in the industry, dependent on the amount of pickling required to prepare the surface for the succeeding process. Much higher concentrations are used in continuous pickling methods, as the desired surface must be secured in the shortest possible time; hence, temperatures are maintained at 200° to 220° F and concentrations at 12 per cent to 25 per cent. These specific examples pertain to the commonly-used sulphuric-acid baths. The required concentration is also a function of the kind of acid used; for example, hydrochloric acid can be used in concentrations of 5 per cent to 50 per cent.

The retarding or inhibiting effect of ferrous sulphate is recognized widely and provisions are made in every pickling operation for adequate control of the salt build-up in the bath. Continued use of the bath without replenishment results ultimately in complete ineffectiveness of the solution. It is usually considered good practice to permit build-up of ferrous sulphate to 25 per cent and work the bath until the free acid content is reduced to less than 5 per cent.

FIG. 33—12. Schematic arrangement of the equipment comprising a continuous pickling line.

Agitation of either the work or the bath saves time, metal and acid and is a practice used widely throughout the industry. Several methods have been adopted, such as raising and lowering the work in the bath, agitating the bath with plungers or circulatory systems or passing the work through the bath horizontally.

Inhibitors—The effect of inhibitors has been known and used commercially for years. An inhibitor is any substance added to a solution that inhibits or lessens acid attack on the steel itself, while permitting preferential attack on the iron oxides. Originally such substances as wheat bran were used but in recent years complex synthetic organic chemicals have been manufactured for this purpose. For economic reasons, some of the by-products or waste materials of the agricultural and oil industries have been used with varying success; these still retain a competitive position with the synthetic inhibitors. The principal requirements of an inhibitor are that it must be effective in very low concentrations, its effectiveness must be constant at all bath temperatures and concentrations, it must not leave an oily or otherwise harmful film on the steel, and it must be economical for use on the basis of cost per ton pickled. Many inhibitors promote foaming to restrict acid and heat losses from the bath so blanketed.

Wetting agents, while often constituting a supplementary ingredient to inhibitors, in most cases are somewhat of an inhibiting agent in themselves and are used principally to improve rinsing and wetting of the surfaces. Wetting agents are organic compounds that lower the interfacial tension between the steel and the liquid. Some improvement in pickling rate is believed to result from their use and improvement in rinsing is definite.

Continuous Pickling Lines—With the advent of continuous cold-reduction mills, it was necessary to design and develop suitable equipment to remove the oxides resulting from the continuous hot-rolling operation and prepare the hot-rolled breakdowns for cold reduction in coil form. This operation is performed in a continuous pickling line (Figure 33—12). The primary function of a continuous pickling line, as of other pickling processes, is the removal of oxide from the steel surface. This serves to promote maximum reduction with a minimum

of power, to assure good roll life in the cold-reduction mills and to secure the increased surface density possible with cold work.

The thickness of the oxide varies considerably on steel rolled on the hot-strip mill. Loose coiling permits greater atmospheric penetration into the wraps, with corresponding heavier oxide formation on the edge areas. Flexing of the steel in passing through the pickling line tends to break this scale or oxide film and permits more rapid attack by the acid bath.

The continuous pickler has other advantages or supplementary functions. The product of the hot-strip mill is subject to fluting (formation of creases when the steel is bent or otherwise deformed) due to lack of springiness. Continuous pickling lines usually are equipped with suitable apparatus for cold working the material so that severe local strains are eliminated and fluting largely is prevented. Another advantage is that they permit individual lengths to be joined into a single coil containing multiple lengths, often necessary because of coil-length limitations of the continuous hot-strip mill. The result is a much longer continuous coil for the cold-reduction mills. The pickling line permits inspection of the steel for defects and suitability for the next operation, and finally oiling of the steel as a protection against rusting and as an aid to cold reduction.

At the coil entry end of a typical continuous pickling line are facilities for handling and charging coiled product into the line. These usually consist of conveyors on which the coils are placed in proper sequence by overhead cranes, upenders in cases where the coil is delivered with the axis vertical, and a motor-driven integrated buggy or hoist for placing the coil in the uncoiling or pay-off equipment. The cold-working equipment, or "processor," integral with the uncoiling equipment, consists of a mandrel on which the coil is placed, a hold-down roll, and a series of smaller diameter rolls. After the coil is charged on the mandrel and the lead-end entered into the small diameter rolls, the hold-down roll is brought down and pressure applied to the material. This action alternately flexes the steel around the rolls, thus effectively "breaking" the surface scale into numerous fine cracks, and increasing the available

sub-oxide area for pickle attack. This flexing also cold works the steel enough to eliminate, in large part, the fluting tendencies of the hot-rolled steel. The group of small driven rolls immediately following the hold-down or breaker roll applies tension to the steel and also serves to straighten and flatten it. A stationary shear is located immediately after the processor for the cropping and squaring of the coil ends for butt-welding or stitching.

While most of the pickling lines in the industry include stitchers for fastening coil ends for continuously processing hot-rolled product, many also have installed flash butt-welding as supplementary equipment. The main advantage of this method of joining coil ends is that it provides a joint which can be cold reduced, whereas the lapped and stitched joint cannot.

Following welding, the flash, or excess metal resulting from the upsetting action of the welder, is trimmed off by a cutter designed for the purpose. The looping pit is next in line and provides a continuous storage space for material to compensate for short delays at the charging end and to permit a uniform rate of travel through the acid tanks. The looping pit is usually 10 to 12 feet deep and 20 to 40 feet long, depending on equipment speed. Construction is generally of concrete with adjustable wood side guides for retaining the lapped-over material and preventing twisting. Water is kept in the pit to minimize scratching and increase wetting action in the first pickling tank.

The pickling zone consists of several individual acid-proof tanks located in a series, comprising an effective immersion length of about 250 to 300 feet. While most lines have from three to five tanks, each about 70 to 80 feet long, some modern lines have only one long tank, divided by weirs into four or five sections, thereby increasing effective immersion depth about 10 per cent to 15 per cent. The inside dimensions of these tanks has been more or less standardized at four feet in depth and about one foot wider than the maximum product width. A steel shell is used for support with layers of rubber bonded to the steel and the rubber is protected from abrasion by a lining of about 9 inches of silica-base acid-proof brick. For operating temperatures in excess of 200° F, a bakelite-base cement generally is used for bonding. In modern high-speed lines operating at 200° to 220° F, the brick facing gradually is eroded away, so that replacement is required after several years of operation. Occasionally, small leaks in the rubber lining and the steel tank require patching. However, if care is taken to prevent acid attack on the outside of the tanks, the tank assemblies may be regarded as permanent for the life of the line.

Following the acid tank are rinsing tanks consisting of a cold-water spray rinse and a hot-water tank. The cold water rinses the acid carry-over from the steel. The hot-water rinse is a tank with an effective product immersion length of 15 to 20 feet. This tank completes the rinsing and by warming the steel, promotes flash drying prior to entering the succeeding set of pinch rolls. Situated between the final rinse tank and the pinch rolls are one, two or three banks of hot-air driers operating at low pressures. Pinch rolls at the exit end of the pickling tanks control the speed of product travel and, in conjunction with the pinch rolls which provide back tension at the entry end of the line, help to maintain the proper loops in the tanks.

The delivery end of the continuous pickling line has, in the order listed, a looping pit, pinch rolls, shear, oiler, recoiler and suitable supplementary equipment for conveying the finished product from the line. The pinch rolls preceding the shear are located so that product delivery

to the shear is facilitated. Stitches are removed at this point, as well as short sections which inspection has shown to be inferior quality. Some lines are provided also with rotary side trimmers at the entry end or, more commonly, at the delivery end.

Control of acid concentrations in four separate tanks within one pickling line posed a critical problem for some time. Until recently, it was considered good practice to measure the free acid and ferrous sulphate concentrations about four times per eight-hour period and make raw-acid additions to each tank on the basis of these frequent tests, until iron salts had increased to a very high concentration, at which time the tank was dumped and a new pickling solution made up. It was developed, however, that high concentration of iron salts in the entry tanks was not particularly harmful to pickling performance but that a similar condition in the final tank resulted in extremely poor line performance. The practice of adding raw acid, water and inhibitor (the latter being optional) to only the last pickling tank was then developed, and this practice, or slight variations of it, is now in general use in most continuous pickling lines. Tanks are connected with large rubber-lined or acid-proof tubes so that the acid solution will flow countercurrent to the product travel from the last pickling tank to the first pickling tank. This practice is called "cascading." The acid and water are added continuously at a prescribed rate, usually about 35 to 50 pounds of acid per ton of steel pickled. Hence, if the line production rate is 50 tons per hour, acid flow into the make-up pickling tank would be equivalent to about one-half to two-thirds gallons per minute. Steam is used generally for heating the solutions and temperatures are controlled automatically.

Maintenance of coil identity through the pickling operation is essential. Schedules are made out showing the coil number and other unit identification opposite a pickling sequence number. The coils are then charged into the line in the sequence listed on the schedule and unit identity is reassigned to the coil in the same sequence following pickling. Product delivered to the cold-reduction mills carries complete identity as to coil number, heat number, width and gage. Means of transporting the pickled coil to the storage area ahead of the cold-reduction mill varies from plant to plant, depending on the plant layout, nature of transportation available and the most economical method. Occasionally, long gravity-type conveyors are installed to deliver coils to a central point, from which a tractor or overhead crane stores the coils in areaways adjoining the cold-reduction mills. Slat-type conveyor-tractors also are employed and where the distances involved become greater, rail transportation is resorted to.

Inspection of the raw pickled product is carried on continuously at the exit end of the pickling lines. Each coil is inspected for surface and edge quality, width and gage. Some of the defects commonly causing rejection or diversion are as follows: slivers, cracked edges, laminations, off gage, off width, roll marks, underpickling, overpickling, handling damage and pitting.

Underpickling results when the steel has not had sufficient time in the pickling tanks to become free of adherent scale and occurs when acid concentration, solution temperatures and line speed are not balanced properly. Variations in the oxide and composition of the steel are also factors in underpickled product, as well as such factors as coiling temperature off the hot-strip mill and inadequate amount of cold working through the processor. Overpickling results from line delays which permit sections of the steel to remain in the acid too long. The presence of an inhibitor reduces iron loss, but

FIG. 33—13. General view of a mill department containing four continuous pickling lines.

when an inhibitor is not used, iron loss during a short delay period appreciably reduces thickness of the steel and raises the hazard of hydrogen embrittlement. Pitting is related to overpickling, the presence of non-metallic inclusions near the steel surface and to rolled-in scale, slag or a refractory substance. While overpickling is not common in continuous pickling operations, its occurrence does have a very serious effect on cold-reduction performance and surface appearance of the finished product. Product damage from handling or improper equipment adjustment can render the steel unsuitable for further processing.

Prior to recoiling, the pickled steel passes between a set of oiling rolls which cover both surfaces with a small amount of oil. The type of oil used to lubricate the steel, and protect it from rusting during storage and from scratching during handling, is determined by the type of lubricating system on the cold-reduction mill unit. Hence, palm oil, sometimes diluted with light mineral oil, is applied to the steel at the pickling lines when a straight palm oil or a solution containing palm oil is used on the cold-reduction mill. Finally, the pickled and oiled product is recoiled on a conventional up-type or down-type coiler.

Figure 33—13 shows a typical continuous pickling department consisting of four lines.

Batch Pickling—Pickling of steel sheets and other light-gage sheared lengths is performed with specialized equipment in which a batch of sheets are processed together. In general, there are two basic methods of batch pickling and several modifications of them, but the employment of agitation as a means of increasing pickling rate is common to both. One method is to employ a large wooden or acid-resistant concrete tank installed in the floor so that the top of the tank rises about two feet above floor level. The tank is divided into two sections by a wooden partition extending between 6 to 10 inches from the tank bottom; one section is smaller than the other. A large float is inserted in the smaller compartment and the material to be pickled is placed in the larger side. Forcing the float down into the bath

displaces acid solution in the smaller section and raises the level of the acid solution in the other compartment. The wood float is attached to a gear-driven crank, making the motion quite rapid, and effectively agitating the bath. Sheets are placed in a near vertical position on an acid-resistant metal rack, and pins inserted between every few sheets to facilitate exposure of all surfaces. The rack is then placed in the bath by an overhead crane and allowed to remain for several minutes. After sufficient pickling, the sheets are rinsed in a cold-water tank to wash off any iron-salt residue. This type of pickling is employed commonly in shops where a clean surface free from scale and mill dirt is required for hot-dipped galvanized or long terme products. Acid concentration is varied from 4 to as high as 12 per cent, depending on the amount of surface etch required. Temperatures usually are maintained between 150° F and 190° F.

In the second general type of batch picklers, the work is agitated instead of the bath. Equipment consists of a minimum of two, and more often three, tanks recessed into the floor and located at 90 degree steps to each other on about a 15-foot radius. At the center is a vertical mast topped by a four-armed spider from which the holding racks are hung. The pickling sequence begins at the loading station, followed by a high-concentration acid bath and, in a two-tank system, succeeded by rinsing and unloading stations. In the three-tank system, the first pickle tank is followed by either a more dilute acid solution or a cold-water rinse, followed in turn by a hot-water rinse. Racks must be unloaded at the fourth station prior to loading. A variation of this method has the tanks installed in tandem, with the first tank containing the highly concentrated acid solution, followed by a very dilute acid or cold-water rinse and finally with a hot-water rinse. The racks are suspended from a sectionalized conveyor system which plunges the work in the bath, the section immediately above the tanks being separated from the return rack conveyor off to the side of the pickle tanks. In this manner, racks are never removed from the overhead conveyor system, except

FIG. 33—14. A rack loaded with black plate is being pushed into position before a plunger-type pickling machine for "white pickling" of the plate prior to tinning.

for maintenance, and the product flow assumes a more continuous aspect. When pickled sheets are furnished the customer for use in that condition, it is necessary to force-dry them to minimize rusting. Equipment for drying consists of a short hydrochloric-acid bath, water spray rinse, high-volume V-type dryers, and pilers. Roller leveling frequently is included to obtain standard mill flatness and a rotary brush scrubber may be incorporated in the drying sequence.

Figure 33—14 shows a plunger-type pickling machine used for "white pickling" of plate for tinning.

Adjustment of the pickling bath for batch-type picklers is accomplished by adding raw acid after the water has been brought to the correct level. Sulphuric acid is used for low- and medium-carbon steels in concentrations ranging from 1½ per cent to 4 per cent for tin plate and from 4 per cent to 8 per cent for sheet products, with the temperature maintained between 150° F and 190° F. During working of the solution the acid is depleted and fresh acid must be added periodically as indicated by suitable tests for free acid and ferrous sulphate. Inhibitors generally are used so that iron loss is low and the hazard of hydrogen embrittlement reduced to a minimum.

After pickling certain steels containing small amounts of copper or nickel, a "smut" or dark film appears on the sheet surface. As a rule, the film contains relatively high percentages of the alloying elements and a dilute solution of hydrochloric acid must be used to attain the necessary cleanliness.

SHOT BLASTING

Shot blasting is employed in the flat-rolled steel industry for cleaning and smoothing the edges of plate, and for the removal from sheet surfaces of mill dirt, scale and rust in the manufacture of sheet for special applications such as galvanized culvert stock, where service requirements demand good adherence of relatively heavy coatings. In this operation, hot-rolled prod-

uct is fed continuously from coils or as cut-length sheets through the equipment, which consists usually of two separate shot blasters, one for each surface, interconnected with common abrasive-feeding auxiliary equipment. The type of abrasive used for this application is crushed-steel shot, which is more effective than round shot in giving the desired cutting action with a minimum of peening. Auxiliary equipment includes abrasive storage and feeding facilities and dust separators to eliminate the fines that result from the breakdown of the particles upon striking the sheet surface.

Shot blasting, or more correctly, grit abrasive blasting, has several advantages over pickling for preparing heavy sheet for galvanizing. The principal advantage is that of obtaining better adherence with heavy zinc coatings. Secondly, hydrogen embrittlement in heavy-gage sheets presents a greater hazard than in lighter gages, hence this type of cleaning is preferred over pickling. Storage of blasted product in dry areas permits processing of product ahead of the galvanizing pot, while pickling must necessarily be tied in with pot operations as pickled product rusts rapidly after pickling. On the other hand, shot-blasting equipment requires considerable maintenance, as the wear of abrasives on all contacting parts is relatively high under a wide range of operating conditions, and production rates are relatively low on such units.

Chapter 34

MANUFACTURE OF COLD-REDUCED FLAT-ROLLED PRODUCTS

SECTION 1

PRINCIPLES OF COLD REDUCTION

Introduction—Cold-reduced flat-rolled products are made by cold rolling hot-rolled breakdowns in coil form from the continuous hot-strip mill after the breakdowns have been descaled by continuous pickling. The purposes of cold rolling are to reduce thickness (25 to 99 per cent), to produce a smooth, dense surface and, with or without subsequent heat treatment, to develop controlled mechanical properties. The dimensional classifications of cold-reduced products are given in Table 33-II of Chapter 33.

The introduction of continuous methods for cold reduction of steel was the final step in the development of present-day rolling facilities for sheets and tin plate. As in the case of the hot-strip mill, cold reduction of wide hot-rolled breakdowns in coil form was developed from the rolling of narrow products. The original purpose of cold rolling was, however, to achieve the desired surface and mechanical properties, and reduction in thickness was of incidental importance. Cold rolling of strip probably originated in Germany early in the nineteenth century as a process for cold rolling high-carbon wire to produce a flattened cross-section. Similar practices were adopted thereafter in this country. Low-carbon cold-rolled strip, the forerunner of today's cold-reduced strip sheets and tin plate, was first made in this country at the Stanley Works at New Britain, Connecticut. For years, the raw material for such strip was produced on merchant bar mills. Later, cold-reduction equipment developed rapidly, concurrent with the introduction of narrow continuous hot-strip mills and their evolution to the modern wide mills. Today, the narrow and wide cold-reduction mills provide the major outlet for hot-rolled breakdowns in coil form.

In the cold reduction of wide hot-rolled breakdowns in coil form, the prime objective is reduction in thickness of the material, since the modern hot-strip mill cannot reduce the steel to the gage required for many applications (such as tinplate). The development of the cold-reduction process for wide products has been even more rapid than that of the continuous hot-strip mill. The first efforts toward cold reduction of wide hot-rolled breakdowns in coil form were made in the 1920's and the process changed rapidly from single-stand non-reversing mills through single-stand reversing mills and then to the present-day high-speed tandem mills. Using tin plate as an example of the rate of change in the methods for reducing very thin flat-rolled steel, it is found that, in 1936, 24 per cent of the black plate for this country's tin plate production was cold reduced, with the balance made by the old hot pack-rolling method. By 1939, 75 per cent of all tin

plate was made by the cold-reduction process and this figure reached 100 per cent by 1943.

Sequence of Operations in Cold Reduction—After hot rolling, the hot-rolled breakdowns in coil form are uncoiled, passed through a continuous pickler, dried, oiled, and re-coiled. The oil serves as a protection against rusting and as a lubricant during cold reduction. There are several types of cold-reduction mills which vary in design from single reversing two-high, four-high or multiple-roll units to continuous four-high stands with up to five units in tandem. In rolling on any of the single-stand reversing mills, the product is rolled back and forth between the work rolls, through which very high pressures are exerted, until the desired thickness is reached. The steel may be forced through the roll pass by rotation of the power-driven rolls or may be pulled through non-driven rolls by tension reels in front and back of the mill or a combination of these effects may be used. In tandem rolling, the product is given one pass through three, four or five stands (Figures 34—1, 34—2, 34—3 and 34—4), each contributing to thickness reduction and each driving the material being rolled, usually at speeds so synchronized that the steel is under tension at each of the stages between the pay-off reel, the various sets of work rolls and the re-coil reel. The total thickness reduction may vary from 25 per cent to as much as 90 per cent of the hot-rolled thickness for sheets and black plate and up to 99 per cent for strip. Unlike hot-rolling, no scale is formed, but much greater pressures and driving forces are required to effect a given reduction in thickness.

For any given pass in the cold-reduction process, the resultant of the compressive forces of the rolls on the steel and the tensional forces along its length between the reels and rolls must exceed the elastic limit of the steel to produce permanent deformation. For the first pass after hot rolling, these forces are at their minimum, and for each succeeding pass they increase progressively, because the effect of the cold working through each pass is to increase the elastic limit sharply. The ultimate strength also is increased, but more slowly. As a result, much of the cold reduction is done on very hard steel having very little residual ductility.

Heavy reductions at high speed on any of the various types of mills generate considerable heat and not only raise the temperature of the product but also that of the rolls. The heat generated must be dissipated by a system of flood lubrication in which a water-soluble oil or a mixture of oils is directed in small streams or jets against the roll bodies and the surface of the steel. Some mills use palm oil on the steel and high-pressure water on the rolls. In any event, the resultant steel

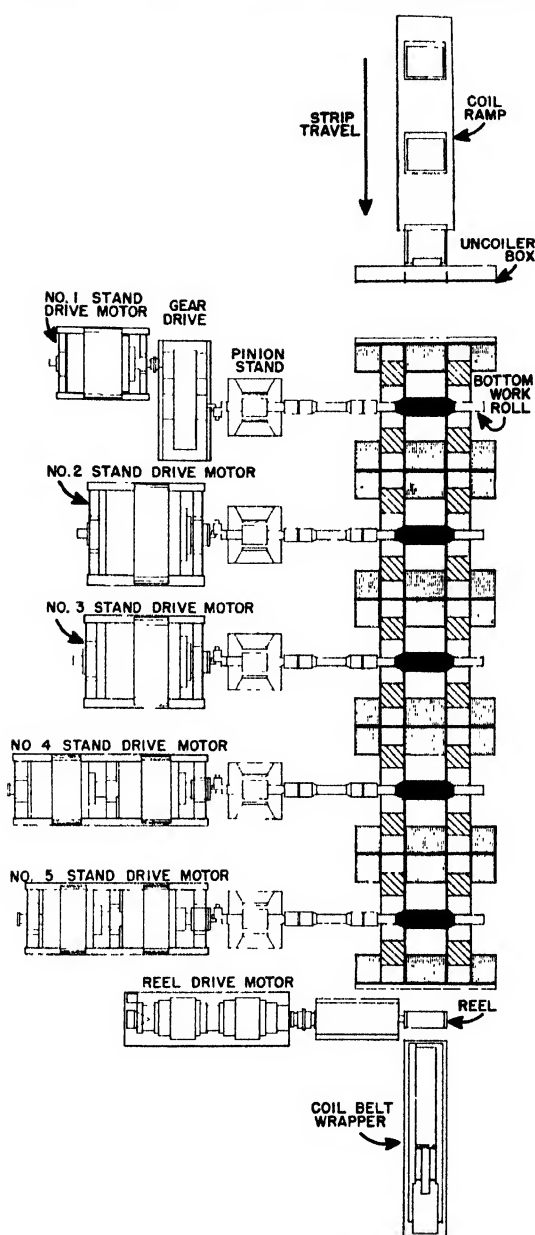

FIG. 34-1. Schematic arrangement of the mill stands and auxiliary equipment comprising a modern five-stand tandem cold-reduction mill. The shaded sections of the drawing represent the mill housings of the five four-high mill stands. Only one work roll of each stand is indicated in black; no other rolls are shown.

temperature generally runs between 150° and 250° F. On high-speed tandem mills, rolling 0.010-inch thick tin plate stock, delivery speeds up to 5000 feet per minute are now being used. The temperature of the steel leaving such high-speed mills may be as high as 400° F.

The proper reduction of thickness which should be made at each pass of a reversing mill or in rolling on each stand of a tandem mill can be expressed only in very general terms. The work load should be distrib-

uted as uniformly as possible at the various stages without falling very much below the maximum capacity of any stage. The maximum is determined in each case by several factors, of which the most important are mill design, power available, steel width and total reduction to be taken, steel lubrication, steel cross-sectional contour, steel hardness, steel tension, steel surface, roll diameter and roll surface. Generally, the lowest percentage of reduction is in the last reduction

FIG. 34-3. A 54-inch, high-speed, four-stand tandem cold-reduction mill. The delivery end of this mill is at the left of the illustration.

FIG. 34-4. A 48-inch, high-speed, five-stand tandem cold-reduction mill. Product being rolled travels through the mill from right to left in this view.

pass to permit better control of the flatness of the finished product. On the conventional wide four-high tandem mills used to cold reduce most sheet and tin plate stock, the individual pass reduction will range generally between 25 and 45 per cent on all stands but

the last, where it will fall between 10 and 30 per cent. The resultant total reduction on these mills from hot-rolled breakdowns in coil form to finished product will usually run 45 to 65 per cent for most sheet gages and 80 to 90 per cent for most tin plate.

SECTION 2

ROLL ARRANGEMENT FOR COLD REDUCTION

In reducing the thickness of steel, the action of a pair of rolls may be visualized as being somewhat similar to that of two very blunt knife edges in cutting partially through a stationary piece across which the knife edges are opposed under pressure. The smaller the roll diameter or the sharper the knife edges, the less pressure is required to do the necessary work. Other factors being equal, the force imposed across a set of work rolls to obtain a given reduction in thickness of steel varies with the square root of the roll diameter. To minimize the power requirements and mill size, it is, therefore, advantageous to use work rolls of as small diameter as possible.

The steel being rolled is necessarily narrower than the length of the work rolls. In a two-high mill, these rolls are supported only at their ends and rolling pressure is applied there. In view of this, it is obvious that rolls of some minimum diameter no longer will be sufficiently rigid to withstand the necessary pressures without bending. In extreme cases, this bending along the length of the roll might be sufficiently great to cause the rolls to touch each other at the ends. The tendency, of course, is for the bending to increase as the mill width (the roll length) becomes greater. Using a "crowned roll," one that is slightly larger in diameter in the middle than at the ends, will compensate partially for the roll deflection just described.

In order to overcome the difficulties arising from bending of work rolls of small diameter without sacrificing the advantage of the small diameter, the modern mill backs up the work rolls with rolls of larger diameter. These more massive rolls resist the bending force of the screw-down pressures applied to their ends, and the pressures are transmitted to the work rolls along their entire length. For example, four-high cold-reduction mills in the 42-inch to 98-inch width range, which produce nearly all cold-rolled sheets and tin plate, will have two work rolls of 16-inch to 21-inch diameter, each backed up by a roll of 42-inch to 56-inch diameter. The driving power is applied at one end of each of the work rolls of such a mill and screwdown pressure at both ends of the backing-up rolls.

While the widespread use of such conventional four-high mills, in single stands or, more commonly, in tandem arrangements, has long ago proved their economic suitability for producing most of the cold-rolled flat steel products, many departures from this type have

been tried to obtain even smaller work-roll diameters. In the four-high Steckel mill, none of the rolls are driven and the steel is pulled back and forth between the 2 to 5-inch diameter work rolls by reversing power-driven reels. The back-up rolls in this case are 24 to 36 inches in diameter. Most Steckel installations are confined to the rolling of narrow strip. Other mills, known as the "six-high" or "cluster" types, use two or more backup rolls for each work roll. The currently most successful of the multiple-roll class is the Sendzimir mill, with two work rolls of 1 to 2½-inch diameter. Each work roll is backed up by two rolls of twice that diameter, each of which in turn is backed up by two segmented rolls of even larger diameter. The intermediate backup rolls are driven and the outer segmented rolls, which are actually rows of bearings on common shafts, provide a caster-like support action and permit the application of screw pressure by rotating these shafts eccentrically. As a result, a light, wholly-enclosed housing is possible and the entire roll system is immersed in lubricant. This mill appears to be well-adapted to taking heavy reductions on steels of the harder grades such as stainless and high-silicon steels.

Even with the rigidity provided by massive backup rolls, work rolls of the common four-high mills will flex or bend somewhat under the rolling pressures used; this tendency is greater in the wider mills. Accordingly, on mills rolling sheets and tin plate, work rolls are "crowned," that is, ground with roll diameters which increase very gradually from end to center. This convexity, which may consist of a diameter differential of 0.010-inch on the widest mills, compensates for normal roll flexure. On mills about 40 inches wide, the crown may be 0.001-inch or less, and on narrow cold-reduction mills it is usually unnecessary. The work rolls themselves are made of forged, hardened steel, surface ground to a high finish on specially-designed precision lathes. Work rolls for the last stand of a tandem mill, especially in a three-stand mill for sheets, generally are roughened slightly by shot-blasting to impress a matte pattern on the sheet as an aid in preventing sticking of stacked sheets in annealing. Work rolls for narrow cold-reduced strip, which requires a much brighter surface than sheets, are highly polished. Backup rolls on wider mills are generally made of cast steel and are always surface ground. They can be shaped "flat," that is, with no crown, or with up to 0.010-inch convexity.

SECTION 3

TYPICAL MILL LAYOUTS

Four-High Tandem Mills—The bulk of the cold-reduced flat steel made in this country is rolled on three-, four- or five-stand four-high tandem mills. Most tin plate falls in the thickness range of 0.008 to 0.014-inch and requires 80 to 90 per cent cold reduction from the thinnest hot-rolled breakdowns in coil form available in the width range of 24 to 36 inches. Tin plate, therefore, usually is rolled on five-stand mills around 42 to 48 inches wide. Most cold-rolled sheets for

automotive bodies, agricultural implements, architectural use, furniture and household equipment are required in thicknesses of 0.025 to 0.065-inch and widths of 30 to 72 inches. Material for these applications, most of which is given 45 to 65 per cent cold reduction, generally is rolled on three-stand mills producing material ranging from 54 to 98 inches in width. Four-stand mills, usually 48 to 56 inches wide, may be used to roll tin plate but are best adapted to produce 0.015 to 0.030-inch

thick, 24 to 47-inch wide sheets for such applications as roofing, signs and containers. Maximum delivered cold-reduced strip speeds on such tandem mills may run as high as 1000 feet per minute on a three-stand, 3000 feet on a four-stand, and 6000 feet on a five-stand mill. The average operating speeds vary greatly throughout the industry.

All such mills have uncoiling reels, cradles, or boxes from which the coil is fed into the actual roll train, coil ends being started either by hand or by pinch rolls. At the discharge end the finished coils are re-coiled on a mandrel, being started by a belt wrapper (a continuous driven fabric belt bearing against the mandrel), which guides the head end of the cold-reduced strip around the mandrel and is withdrawn when the re-coiling has been so started.

Mill housings are massive castings, similar to those on finishing stands of a hot-strip mill. On most tandem mills, both work rolls of each stand are driven through a pinion arrangement by a single motor, up to 5000-horsepower motors being used, although some of the latest mills have individual motors for each work roll on some stands. For the first stand or stands, in which the rolling speed is relatively low, motors are geared down; direct drive may be used for one or more of the remaining stands of such a tandem mill.

The 48-inch five-stand tandem mill at United States Steel Corporation's Irvin Works serves as an example of a unit of this type (Figure 34-4). This mill rolls a pickled, 12,000 or 24,000-pound, hot-rolled breakdown in coil form from approximately 0.085-inch thickness down to an average gage of 0.010 inch at a speed of 3300 feet per minute. The five stands, plus the reel, require a total of 11,000 horsepower for driving. From the moment when the head of the coil has been threaded through all stands until the mill reaches top speed, roughly 40 per cent of the horsepower is used for acceleration; the balance is required for reducing the metal. On this mill, the motors on No. 4 and 5 stands and also on the reel are of the double-armature type. Such motors provide a marked reduction in accelerating time and improved control at high speeds due to their lower inertia. The work roll and backup roll diameters are 21 inches and 53 inches, respectively. All work rolls are equipped with roller bearings while the back-up rolls are equipped with oil-film bearings. On an average, the work rolls in No. 5 stand are changed for redressing the surface after rolling every 150 tons; No. 4 stand, after 250 tons; and the first three stands after rolling somewhat over 1000 tons. Back-up rolls on the 5-stand tandem mill average approximately 20,000 tons between dressings. The cold-reduced strip tension reel at the delivery end is designed to pick up the end of the strip coming from the mill, grip it slowly and put it under tension without sudden or undue stress. The reel also winds the cold-reduced strip under constant tension, slowing down automatically without altering the tension as the coil increases in diameter. Such control is necessary to prevent tearing of the very thin, hard, cold-reduced strip. The reel is of the collapsible type and easily stripped by an air-operated plunger.

Four-High Reversing Mills—A typical four-high re-

versing mill consists of a single stand with reels located on each side of the mill. The mill itself is essentially the same in design and arrangement as the individual stands of a tandem mill. In the reversing mill, the steel must be passed back and forth until the required reduction is obtained. On the entry side of the mill, means are provided for uncoiling and feeding the coil through the mill to the tension reel on the delivery side. After the first pass, the tail end of the coil coming from the uncoiler is gripped by the second tension reel on the entry side of the mill. In each pass, the reel serving as the payoff unit is operated as a generator, providing back-tension to minimize rolling friction and feeding of current into the drive-reel motor. On the last pass, the tail end of the coil is released from the unwinding tension reel, completely wound on the winding reel and stripped in a manner similar to the action on the delivery reel of the tandem mill. For the rolling of tin plate product, a reversing mill usually requires five passes; for relatively heavy sheet product, usually three passes. All passes are considerably slower than the delivery pass of a tandem mill. From this it can be seen that a reversing mill is inherently flexible but cannot compete with a modern tandem mill from a production or cost standpoint where large tonnages are involved. Low installation costs in comparison to tandem mills make reversing mills popular for the production of specialty items that vary widely in dimensions and are ordered in small tonnages for each specification.

Two-High Cold Mills—Two-high cold mills may be used singly or in tandem for reducing narrow coils. Low-carbon steel may be reduced as much as 50 per cent on such mills, usually in four passes. In practice, however, no more cold working is done than is necessary to obtain the finish desired, and it has been found that best surface finishes can usually be obtained in a four-gage reduction; i.e., from 16 to 20 gage. The general practice on two-high cold-rolling mills is to roll coils down to the finished gage but not less than 0.020 inch in thickness for widths up to the diameter of the rolls. For coils under 0.020 inch thick, this relation between width of steel and diameter of rolls decreases, until for a thickness of 0.010 inch, the width of steel is about half the roll diameter. Aside from surface finish and control of hardness, the chief object of cold rolling narrow coils on the two-high mills is to obtain product as free as possible from camber, buckles, ruffles and gage irregularities of the hot-rolled product. These defects are overcome to a high degree by the process of rolling under tension. Unwinding reels with sufficient drag capacity, together with a delivery reel of sufficient power to stretch the steel, are a necessary part of any modern two-high mill installation for the rolling of narrow coils. In addition, most mills rolling narrow coils are equipped with rolls to control the form of the edges of the steel and also to control its width. These edge rolls are relatively light in construction and are grooved to produce the required edge. They revolve on vertical axes and are mounted in housings immediately in front of the horizontal work rolls. Edge rolls may be power driven or the steel may be pulled through idle edge rolls by the horizontal work rolls.

SECTION 4

DISPOSITION OF PRODUCT

Disposition of Strip After Cold Reduction—Disposition of the cold reduced, hard strip depends on prior processing and ultimate use. Much narrow high-finish strip is sold as cold reduced, for "full-hard" applica-

tions, on which heavy cold reductions have been used, or as intermediate tempers, in which the cold-reduced strip has been reduced a predetermined percentage from hot-rolled breakdowns in coil form or inter-

mediate-annealed gage to develop specified mechanical properties.

For sheet products, the coil may be taken to an uncoiling, side-trimming and sheet-shearing line, where it is cut to sheets of accurate size prior to heat treating. When annealing is to be done in coil form, the coil is

either recoiled through a side trimmer or, if side trimming to width has been done on the continuous pickling line before cold reduction, the coil is conveyed directly from the mill to the annealing department. For tin plate, the coil is subjected to an alkaline cleaning process for removal of surface dirt and oil prior to annealing.

SECTION 5

COLD-REDUCED STRIP CLEANING

In order to satisfactorily coat tin and terne plate either by the hot-dip or electrolytic process, it is necessary to clean the cold-reduced steel to remove the lubricant used in cold reduction, since the lubricant film left on the steel will decompose during annealing, and leave undesirable residues of carbonaceous material. Such residues are not removed satisfactorily in the subsequent pickling operations. Without exception, cold-reduced strip cleaners currently employ alkaline detergent solutions to remove the rolling-mill oils or solutions. The most commonly used reagents are caustic soda, sodium orthosilicate and trisodium phosphate; sodium metasilicate and sesquisilicate also have found

some application for certain types of product cleaning.

The type and amount of lubricant to be removed should be evaluated, as this may have a bearing on the required characteristics and operating conditions of the cleaning solution. Electrolytic action, while not universally employed, is believed to have merit. Figure 34-5 shows diagrammatically a continuous cold-reduced-strip cleaning line designed to employ the electrolytic principle. The detergent solution cleans the steel and serves as a conductor of electric current between the electrodes shown and the products being cleaned. Thorough rinsing of the steel after cleaning is essential to completely remove all contamination.

Fig. 34-5. Schematic arrangement of the equipment comprising a typical electrolytic cleaning line for processing cold-reduced steel.

SECTION 6

HEAT TREATMENT OF COLD-REDUCED STEEL

Purposes and Types of Heat Treatment—As is true of other steel products, sheets, strip and tin plate are heat treated primarily to effect changes in mechanical properties which will render the material suitable for the intended purpose. Other heat-treating objectives, involving relatively small tonnages of flat-rolled steel but highly important to the specialized commodities to which they apply, include: solution of chromium carbides to attain maximum corrosion resistance of austenitic stainless steels; development of optimum magnetic properties and establishment of the thin insulating oxide on silicon-bearing electrical sheets; dispersion or spheroidization of carbides to influence later heat-treating characteristics of alloy and high-carbon sheets.

Except for the very small proportion of "full-hard" cold-reduced strip and sheets used in the as-cold-reduced state to take advantage of the high strengths developed by cold reduction, some form of heat treatment is applied as a separate operation to all cold-reduced flat products to restore the ductility lost in cold reduction. In the case of hot-rolled sheets and strip made on a modern continuous hot-strip mill, supplementary heat treatment is usually unnecessary. On such hot-rolled material, rolling practices are used

which include definite finishing, piling and coiling temperatures as the steel leaves the last pass of the mill; the resultant "mill heat treatment" can be varied to provide mechanical properties in the as-rolled state which are satisfactory for most uses. This section will consider only those types of heat treatment conducted as separate operations.

Heat treatment of cold-reduced sheets, strip and tin plate may be divided into (a) "batch" operations—commonly called "box annealing"—in which a large stationary mass of steel is subjected to a long heat-treating cycle by varying the temperature within the furnace which surrounds it; and (b) "continuous" operations—including "continuous annealing," "strand annealing" and "normalizing"—in which a single thickness or a few thicknesses of cold-reduced sheet or strip are passed through a furnace in a relatively short time and receive a heat-treating cycle determined by the temperature distribution in the furnace and the dimensions and rate of travel of the steel.

Virtually all box-annealing practices slowly raise the steel to a temperature level at or below the lower critical point and "soak" it there for several hours. Such a cycle provides full recrystallization for steel in

the severely-deformed cold-reduced state and results in the softest possible finished product; accordingly, box annealing accounts for about 95 per cent of the heat treatment applied to cold-reduced steel and about 90 per cent of the heat treatment applied to all flat-rolled steel in the United States.

Depending on the nature of the steel and the results to be obtained, in continuous heat treatment the steel may be heated quickly to a maximum temperature at or somewhat above the lower critical temperature (continuous, strand or open annealing), or it may be heated slightly above the upper critical temperature (normalizing). In any case, the time at temperature is only a few minutes and the cooling rate is fast as compared to the hours-long cooling cycle of a box-annealed charge. The ferrite and structures resulting from transformation in cooling are fine-grained and the finished steel is generally harder than that produced by box annealing; continuous heat treatment is used, therefore, to attain properties not attainable by box annealing, but usually the product is somewhat harder.

While the great bulk of flat-rolled steel products can be heat treated adequately at temperatures around

1250° F, a few, because of their sluggish recrystallization tendencies after cold reduction, or their need for relatively quick cooling from the austenitic state to attain optimum properties, must be heated to temperatures ranging from 1400° to 2200° F. In such cases, continuous heat treatment is the most convenient method, as it avoids the hazard of pressure welding ("sticking") inherent in large masses of cold-reduced products held for hours at such temperatures. Continuous heat treatment is the only way to attain the quick cooling necessary to hold chromium carbides in solution in austenitic steels such as AISI Type 304 or to develop high strength levels in alloy sheets of the AISI 4130 type. It permits maximum reaction between a decarburizing atmosphere and the steel being treated (in single thicknesses) for such products as silicon-bearing sheets, whose magnetic properties require very low carbon contents. The controlled recrystallization possible in continuous heat treatment makes a fine-grained microstructure easy to obtain when such is desired, and minimizes the tendency for retention of directional properties of rolled steel which may be responsible for undesired irregular shapes in attempting to produce cylindrical stampings.

SECTION 7

EFFECTS OF HEAT TREATMENTS ON MICROSTRUCTURE

Box Annealing—Prior to cold reduction, low-carbon rimmed steel in the form of hot-rolled breakdowns has more or less equi-axed ferritic microstructure, with the carbides visible as pearlite or cementite (depending on whether the product was coiled cold or hot); it is relatively free of internal stresses, particularly if coiled hot and so "self-annealed." Cold reduction, however, elongates the grains from one- to ten-fold, greatly distorts the crystal lattice, and induces heavy internal stresses; the resultant product is very hard, with little ductility. This high degree of plastic deformation, however, renders the steel capable of returning to microstructural "equilibrium" by recrystallizing during heat treatment at temperatures well below those representing the thermal zone of conventional phase transformations. If such recrystallization is allowed to continue to completion by holding the steel at the proper temperature for sufficient time, the resultant structure again will consist of clearly-defined equi-axed ferrite grains with undistorted lattices and the steel again will be soft and ductile. In whatever state they were in the hot-rolled product, the carbides will have formed cementite, either small scattered spheroids (from hot-rolled breakdowns coiled cold) or massive agglomerates (from hot-rolled breakdowns coiled hot or from annealing slightly above the lower critical temperature).

Assuming sufficient time at the annealing temperature, steel given a heavy cold reduction will begin to crystallize at a lower temperature, will complete recrystallization more quickly, and finish with a finer ferrite grain, than steel given a light cold reduction. This is because the former material is more distorted before annealing and so has more centers of nucleation and higher localized stresses to induce the crystalline realignment. Similarly, those variations in practice during the hot-rolling of breakdowns which affect grain size of the product will affect similarly the microstructure of the cold-reduced, box-annealed steel, within the limits determined by steel grade, degree of cold reduction and annealing practice.

Recrystallization begins at each nucleation center with a return from distorted to "normal" atom alignment and is propagated by absorption of the surround-

ing distorted material into that alignment until the growth stops, establishing a single ferrite grain. Grain formation generally is stopped by the advancing fronts of differently-oriented adjacent grains. Within the practical range of recrystallization temperatures, however, the tendency of adjacent grains to assume the same lattice alignment, and to merge to form a larger grain, increases with increasing temperature. The maximum annealing temperature at which the steel is held for a significant time, therefore, determines the finished grain size for a given steel grade, hot-rolling practice and degree of cold reduction.

Beyond the period permitting full recrystallization—one to four hours at maximum temperature is sufficient for common steel grades and mill practices—time at subcritical temperature has relatively little effect on the grain size of the common steels. Extended "soaking" times do, however, lower the hardness for a given grain size, so that the annealing cycles applied generally hold the steel at temperature two to four times as long as is necessary for recrystallization.

A box-annealing practice developed to attain a given end result in grain size and physical properties, therefore, must balance several factors, some of them outside the annealing operation itself and invariable to any effective degree. Fortunately, minor variations in annealing practice have little effect on results and effective variations aimed at attaining lowest steel hardness values are not difficult to make or control.

Box-annealing equipment consists of annealing bases on which to place the steel charge, furnaces to apply the heat, and, generally, inner covers which fit over the charge in the furnace and contain the protective atmosphere which prevents oxidation of the steel (Figure 34-6). Each of these basic units may vary considerably in design, with little or much auxiliary equipment; in any steel plant several sets of units are grouped together into an annealing department, which is serviced as a whole by tracks, cars, tractors, cranes and atmosphere preparation equipment.

In most modern equipment, the bases are stationary and the portable furnaces are lowered by crane onto the loaded base and attached to fuel and control con-

FIG. 34-6. A 500-ton capacity annealing furnace for coils. The furnace is being lowered by crane over the base loaded with eight stacks of coils. The burner tubes may be seen extending across the interior of the furnace. Note guide posts at the corners of the base.

nections for the annealing operation. To attain maximum furnace utilization, two, three, or four bases and an equivalent number of inner covers are provided for each furnace. Thus, no furnace time is wasted while the bases are being loaded or cooled to handling temperature. Some plants use stationary "in-and-out" furnaces with doors at one end; the loaded bases, with inner covers in place over the charge, are pushed into and withdrawn from the furnaces on tracked rollers.

Annealing bases are usually rectangular, although circular bases (and furnaces) are not uncommonly used for coil annealing of cold-reduced products. A base consists of a shallow tray of cast iron or, more commonly, refractory-lined steel. For sealing the open down-end of the inner cover, the bottom of the base may be covered with a layer of sand or the sand may be contained in a trough around the periphery of the base. Where expensive protective atmospheres are used, such as cracked ammonia (to protect high-carbon steel against decarburization), the trough into which the edge of the inner cover fits is filled with oil or low-melting alloy for perfect sealing.

Annealing bases for cut-sheet charges generally have a steel plate, set on the sand or raised on rails or piers, on which the piles of sheets rest to permit circulation of the contained atmosphere. For annealing coils, rectangular bases have two to eight raised "stools," each capped with an annular plate and generally containing a motor-driven fan for atmosphere circulation and better heat transfer. In addition, most bases are fitted with thermocouple inlets and atmosphere inlets and outlets.

The dimensions of a base are, of course, determined by the length and width of the furnace used on it. In the United States, they vary between 5 feet and 18 feet in width, 8 feet and 35 feet in length.

Inner covers are commonly open-bottomed thin-walled steel boxes or cylinders to fit, respectively, rectangular charges of cut sheets or cylindrical charges of stacked coils. These shells commonly are formed and welded either from $\frac{3}{16}$ to $\frac{1}{4}$ -inch thick low-carbon steel, or $\frac{3}{32}$ to $\frac{1}{8}$ -inch thick 18-8 columbium-bearing or 25-12 stainless-steel sheets. They may be strengthened by beading or corrugating the walls and the carbon-steel covers may be coated with aluminum oxide, sodium silicate or other protective compounds to reduce their oxidation rate.

The older in-and-out furnaces use thicker cast-iron covers to withstand the more severe oxidation conditions typical of open-flame firing.

Two innovations in inner covers are receiving some attention. In one design, the radiant tubes in which the fuel is burned are contained in the cover rather than in the furnace as in conventional equipment, and the "furnace" is simply a heat-insulating unit. This arrangement is intended to effect fuel economy and faster heating. Another new type of cylindrical cover has an inner shell to force the protective atmosphere being circulated by fans into better contact with the inner surface of the cover proper, and so effect better heat transfer and distribution.

Box-annealing furnaces are stationary or, more commonly, portable. Stationary furnaces, rectangular in shape, may be built singly or in batteries of two or four. Each furnace consists of a rectangular steel frame lined with 10 to 14 inches of fire-brick. Overall dimensions vary from 7 to 15 feet in width, 7 to 10 feet in height and 15 to 27 feet in length. Charging ends are fitted with hinged or counter-balanced doors, the latter traveling in vertical tracks. Floor tracks extend from the loading area into the furnace hearth and one or two charged bases are pushed into the furnace on cast-iron

balls or carried in on a charging machine. Such furnaces may be fired with coal, oil, or gas.

Stationary furnaces are seldom used for annealing coils. Most of them employ heavy cast-iron inner covers and cast-iron bottoms, which together weigh as much as the 15 to 25 tons of sheets being annealed. The resultant fuel consumption of 2 to 4 million Btu per ton of sheets annealed represents very low efficiency. More modern in-and-out furnaces, with light steel inner covers over the charge, can anneal up to 150 tons per charge with a fuel consumption of 1.2 to 1.6 million Btu per ton of sheets.

Portable annealing furnaces consist of a structural-steel frame covered with steel plate and lined with 6 to 12 inches of refractory insulating brick. The rectangular furnace generally used varies greatly in size and in annealing load weight, depending on mill requirements, handling facilities and effectiveness of design in providing temperature uniformity. Dimensions of furnaces now in use range from 5 to 16 feet in width, 6 to 14 feet in height and 8 to 33 feet in length. Loads of sheared sheets vary from 25 to 150 tons and of coils from 50 to 500 tons; fuel consumption ranges between 0.8 and 1.5 million Btu per annealed ton and annealing rate from 1 to 10 tons of steel per furnace hour.

Such furnaces commonly are gas-fired, although any fluid fuel may be used and electrical resistance heating has been tried. Burners usually fire into "radiant tubes" of 25-12 stainless steel. These tubes are 3 to 6 inches in diameter and as long as the furnace size and desired temperature distribution dictate. They may run vertically or horizontally along the inner walls of the furnace or, in large furnaces for annealing coils, may span the distance between the walls for better temperature distribution. The tubes vent the products of combustion on the outside of the furnace.

Heating of the inner cover thus occurs by radiation. Proper tube location and the flexibility possible in having each tube served by an individual burner permit the necessary uniformity of heating of the large masses of steel contained in one annealing charge. For minor adjustments, burners can be controlled individually. They are manifolded together, however, and the fuel flow to the individual burners of one furnace is usually determined by the main fuel valve of the furnace which is controlled automatically by predetermined tube-temperature control settings and by charge-temperature controls.

Some use is made of tubeless furnaces, with the burner discharging into a refractory baffle which prevents flame impingement on the inner cover but permits circulation of the hot combustion gases between the furnace wall and the inner cover. Convection plays an important part in heating the inner cover in this design. The decision to use a tubeless furnace will be influenced by the relative importance of its possible fuel economy, freedom from radiant tube costs, higher inner-cover costs and different temperature-distribution characteristics.

Box Annealing Practices—To begin an annealing operation in portable furnace equipment, sheared sheets are loaded on the base in piles 3 to 5 feet high and coils on the base stools in stacks 8 to 12 feet high; loading is done by traveling overhead cranes equipped with hooks, slings, retractable racks or magnets. Thermocouples are inserted in standard locations in the charge. One rectangular inner cover is lowered over the entire sheet charge or an individual cylindrical "ash can" inner cover is lowered over each stack of coils and settled in the sand seal. The furnace is then lowered onto the base, fuel line and thermocouple connections

are made, the flow of deoxidizing gas to purge the air from the space under the inner cover is begun, and the burners are ignited. Base fans, if available, are turned on to effect high-speed circulation of the atmosphere in the inner cover.

The subject of deoxidizing gas protective atmospheres is treated more fully elsewhere in this volume (see Index). It is sufficient to say here that it generally consists of the products of partial combustion of a fuel gas in a limited volume of air, these products then being treated to remove most of the resultant water vapor, dirt and carbon particles, and in some cases further treated to remove sulphur dioxide and carbon dioxide. The resultant mixture of 75 to 85 per cent nitrogen plus varying percentages of hydrogen, carbon monoxide, carbon dioxide and methane protects the bright steel surface from visible oxidation throughout the annealing cycle. Other effective atmospheres include dissociated ammonia and high-purity nitrogen.

During the heating-up period, fuel consumption is maintained at a constant rate until "tube" or "furnace" temperature, determined by a thermocouple connected to a recording-controlling instrument, reaches a predetermined level chosen to protect the equipment from damage. Fuel feed then is controlled automatically or manually so that this temperature is not exceeded. The next control point is reached when the thermocouple located in the hottest part of the load reaches a temperature preset to avoid overannealing or welding of the charge. Finally, the soak is begun when the "control couple" (either at the coldest spot in the charge or, if this is inaccessible, in a location bearing a known temperature relationship to the coldest spot) reaches the specified soaking temperature. Another fuel cutback takes place here, and the control-couple temperature curve flattens out through the specified duration of the soaking period. At the end of the soaking period, the fuel is shut off, the furnace is removed to begin a cycle on another base, and the charge is allowed to cool (still in a protective atmosphere under the inner cover) to about 300° F, when it can be exposed to air without oxidizing. The cooling period takes at least as long as the combined total time of heating and soaking.

The temperatures and times specified for annealing practices vary greatly from plant to plant, even in the manufacture of the universally similar dead-soft low-carbon sheet. This is true because of inherent differences in the cold-reduced steel to be annealed and differences in furnace size and design, load size and piling pattern, and thermocouple locations. As an example of the effect of one of these factors, heat conductivity through a load of sheets parallel to the sheet plane is somewhat less than through a solid mass of steel, but four to seven times greater than heat conductivity perpendicular to the sheet plane. A stack of coils consists of a hollow cylinder with a 16-inch to 30-inch inside diameter and a 36-inch to 84-inch outer diameter, receiving inner-cover radiant heat perpendicular to the curved planes of the layers of steel comprising the coils. This handicap can be overcome in part by blowing the atmosphere at high speed through the spaces inside and outside the coil stack, and so transferring some of the heat from the inner cover to the inner diameter of the coils. Another means is to separate each pair of coils in a stack with "convector plates," resembling flattened doughnuts with passages for the hot circulating atmosphere between top and bottom surfaces. Thus, some heat is transmitted to the ends of each coil, from which it has an easier path to follow.

Regardless of the wide differences necessary in specified control cycles, the coldest spot of an annealing

charge, whether or not actually accessible to a thermocouple under production conditions, will be found to have been annealed for 10 to 20 hours at a temperature in the range of 1225 to 1275° F in virtually all plants making deep-drawing rimmed-steel sheets, with the proper formula within these limits being determined by the prior history of the cold-reduced steel. Depending on furnace and load characteristics, the hottest part of the charge will have been at 1275° to 1350° F for 20 to 50 hours, and the furnace will have been under fire for 30 to 90 hours. When no steel decarburization occurs (as is the case with adequate prepared-atmosphere protection), the gross differences in time at temperature throughout an annealing load have little effect on sheet properties if the cold portion has been adequately annealed and so approaches the inherent limit of grain growth and steel softening.

Such temperature differences are more critical in annealing tin plate, where definite higher hardness levels are wanted. Partial protection against over-annealing exists in this case because the heavy cold reductions used limit the grain size to a relatively fine, and therefore relatively hard, structure, regardless of any annealing temperature employed below the transformation-temperature range. Such heavy cold reduction also induces full recrystallization at a lower temperature than is necessary on steel thicknesses given less cold reduction, and tin plate can be annealed fully in the slightly lower temperature range necessary to attain proper hardness.

For products other than low-carbon cold-reduced sheets, strip or tin plate, annealing practices can vary considerably from the outline given. Box-annealing furnaces are used occasionally at temperatures as low as 1000° F to stress relieve, rather than recrystallize, certain specialty steels, and temperatures up to 2000° F have been employed on other specialties.

Normalizing—The most common type of continuous heat treating employed at this time is normalizing, in which the sheet is heated above its upper critical temperature, around 1800° F for low-carbon steel, and cooled at a rate which permits the formation of the proper ferrite grain size. Normalizing is used only where box annealing is inadequate; typical applications include the heat treatment of alloy sheets to attain a fine pearlitic structure or the heat treatment of cold-reduced "pure iron" which recrystallizes sluggishly in conventional box annealing.

Normalizing furnaces are designed to heat and cool the sheets singly or in thin packs of two, three, or four sheets. Therefore, they are built in the form of long low chambers, usually in three sections, known as the preheating zone (12 to 20 per cent of the total length), the heating, or soaking, zone (about 33 per cent of the total length), and the cooling zone, which occupies the remaining 40 to 50 per cent of the length. In modern furnaces of the conveyor type, the only type adaptable for treating short lengths, the sheets are carried successively through each of these zones upon disc rollers made of heat-resistant alloys with polished surfaces to avoid scratching the sheets, and with the discs staggered to assure uniform heating of the sheets. The discs are mounted upon water-cooled shafts, which are driven by variable-speed motors through chains and sprockets or shafts and gears. These furnaces are built up to 100 inches in width and vary from 120 to 200 feet in length; fuel consumption is 2.0 to 4.5 million Btu per ton and production rates vary from 3 to 12 tons per hour. A typical furnace of this type was illustrated in Chapter 21. Normalizing furnaces usually are heated with gas or oil and do not employ protective

atmospheres. The sheets are, therefore, scaled during the heat treatment. Burners are arranged, along each side of the heating zone, usually above the conveyor rolls, but occasionally both above and below the conveyor. The roof, which is higher over the preheating and soaking zones than over the cooling zone, usually is built in sections. In most types, both the preheating and cooling zones are heated by the hot gases from the heating zone. This distribution of heat and gases within the furnace is obtained through two stacks, one being located at the entering end to draw the gases through the preheating zone and the other near the exit end to maintain a neutral atmosphere in the cooling zone. However, both the preheating and the cooling zones may be equipped with burners, the better to control their temperatures. Air is excluded by regulating the draft to maintain a slight pressure within all the zones. Heat losses are overcome by the generous use of heat-insulating materials. Furnaces designed to normalize sheared sheets are equipped with roller tables, one at each end, for charging and receiving the sheets.

The free-loop or catenary type of furnace is designed to normalize continuously cold-reduced steel unwound from coils, and neither rolls nor any other type of conveyor support material passing through the heating zone. The heating zones of these furnaces vary from 20 to 50 feet in length, and the preheating and cooling zones are usually shorter than in the conveyor type and may be omitted for some kinds of work. Such furnaces may have pickling or other descaling equipment at the exit end to remove, in the same operation, the surface oxides formed on the steel during normalizing. Catenary furnaces so equipped, but without a cooling zone, are widely used for the heat treatment of stainless steel, as the temperatures of 1900° to 2200° F used on the austenitic grades would result in short life for rollers used in the furnace. Steam or water quenching facilities are usually provided at the exit end of furnaces for heat treating stainless steel in this manner.

Assuming that the normalizing is to be done in a three-zone conveyor-type furnace, equipped with pyrometric controls, the operations appear extremely simple. If it is necessary to avoid all danger of scratching the sheets, they are brought to the charging table, and laid one or more at a time by hand upon a rider, or conveyor, sheet. The heaviest sheets (length, width and gage considered) are normalized singly, but lighter sheets may be laid two or more in a pile. Sometimes single sheets are laid upon a rider sheet and covered with another, called a cover sheet, to control heating and retard scaling. The sheets are carried by rolls into the preheating zone, where they at first absorb heat very rapidly because of the great temperature differential between them and the furnace interior. As the sheets become heated and this difference grows less, the absorption of heat becomes slower, so that after traveling 15 to 20 feet, the sheets enter the soaking zone several degrees below the normalizing temperature. Heating is completed in the soaking zone, which is maintained at a constant temperature, and sheets are at the necessary temperature for a time sufficient to convert the microstructure to austenite before they pass into the cooling zone. The sheet or sheets emerge from the cooling zone at a temperature which can be varied between 300° and 1000° F, and are conveyed for a short distance upon the run-out table, where they are cooled rapidly in contact with the air and carefully removed from the rider sheet. The trip through such a furnace is carried out at a uniform speed of 5 to 20 feet per minute and requires 5 to 20 minutes to complete.

Roller-hearth sheet-normalizing furnaces are some-

FIG. 34-7. Two tower-type continuous annealing furnaces for processing silicon steel.

times modified by removing the cooling zone and substituting air, steam, oil or water quenching facilities, the latter two as sprays or tanks. Such facilities are utilized to retain the austenitic structure developed in the heating zone on sheared sheets of stainless or Hadfield manganese steels, and to develop a martensitic structure (for subsequent tempering) in the higher-carbon alloy steels of the AISI 41xx or 86xx types.

Continuous Annealing—Continuous annealing of light-gage cold-reduced steel in a deoxidizing atmosphere has received increasing study since the modern cold-reduction process has provided single lengths of material thousands of feet long; its potentialities for tin plate, which generally requires higher hardnesses than sheets, are very attractive. In this treatment, a single strand of steel, cold reduced to the thin section used for tin plate, travels at high speed through a heating zone having a controlled atmosphere, where it is brought to a temperature just above the lower critical in a very short time, recrystallizes almost instantaneously, passes through a cooling zone and emerges into the air cold enough to avoid oxidation.

Such an operation provides fully-recrystallized steel, ductile in spite of its relative hardness and nearly free of directionality in physical properties. The extremely short time at temperature is effective because recrystallization has been suppressed by the rapid temperature

rise; the resultant increase in energy level at all potential nucleation centers causes the microstructure to "flash over" once recrystallization begins. From an engineering standpoint, the operation is made practical by building the heating and cooling zones as towers and increasing their effective length by threading the steel back and forth around rolls at the top and bottom of the towers.

A furnace of this sort for full-width tin plate is shown in Figure 21-21 of Chapter 21. In the direction of strip travel, the unit consists of a double pay-off reel; a welding unit; an alkaline electrolytic cleaner with a brush scrubber, water rinse, and drying unit; and a looping tower from which strip is taken to maintain constant line speed when a weld is being made. The furnace proper consists of a gas-fired "heating zone" wherein the strip makes six passes; an electrically-heated "holding zone" of six passes; an electrically-heated "slow-cooling zone" of two passes; a water-jacketed "fast-cooling zone" of twenty passes; a final cooling zone of two passes; another looping tower and two recoilers. Each pass consists of 55 feet of strip and all passes are vertical. The strip is heated to approximately 1200° F in the heating zone and maintained at this temperature in the holding zone. Upon leaving the holding zone the strip is cooled to about 1000° F in the slow-cooling zone and thence to about 240° F in the

fast-cooling zone. During this period, the strip is protected from oxidation by a gas atmosphere consisting of 95 per cent nitrogen and 5 per cent hydrogen. Subsequent cooling is done in air. At an operating speed of 900 feet per minute, only two minutes elapse from the time a given section of strip enters the heating zone to the time it leaves the fast-cooling zone.

Two continuous furnaces of somewhat different design were put into operation in 1949 at the Vandergrift plant of United States Steel Corporation (Figure 34—7). These units were built for heat treating high-silicon electrical steels, which require precise recrystallization control at higher temperatures and very low carbon contents to attain optimum electrical properties. With a floor length of 175 feet, the furnaces utilize the tower principle to permit several hundred feet of steel to be treated at temperatures up to 1900° F for controlled lengths of time, and under atmospheres of varying de-

carburizing power, as determined by the desired magnetic properties of the product. Speeds up to 240 feet per minute and production rates up to 10 tons per hour are possible.

Chapter 35

THEORY OF CORROSION

SECTION 1

CAUSES OF CORROSION

The Mechanism of Corrosion—The corrosion of the common metals in usual environments is an electrochemical phenomenon. That is, it is associated with the flow of electric currents over finite distances. Electric currents associated with corrosion have been detected in numerous cases, and in a limited number of instances the amount of corrosion occurring has been accounted for quantitatively by the amount of electric current which passed.

Knowledge that corrosion is electrochemical is important, since it assists in the development of methods for combating corrosion. For instance, it is obvious that, in order for electrochemical corrosion to occur, there must be differences in potential between different areas of the corroding structure. Such differences can be caused by the use of dissimilar metals or alloys in contact with each other. However, differences in potential can be caused by heterogeneities of any kind in the metal surface or in the environment contacting the metal. Some of the most important of these heterogeneities will be discussed below.

FACTORS WHICH AFFECT CORROSION RATE

The fundamental reason why metals corrode is that the corrosion products are more stable than the metals themselves. Thermodynamically speaking, in order for metals to corrode there must be a decrease in free energy associated with the formation of the appropriate corrosion product from the metal. This free energy decrease is the **driving force** of the corrosion reaction. However, the magnitude of this driving force gives little information regarding the rate at which corrosion will occur. The rate of corrosion is determined by other factors which will be described later in this chapter.

An **electrolytic cell**, in its simplest elements, consists of an **anode** and a **cathode** in a conducting solution (electrolyte). **Polarization** consists of a behavior at an electrode and results in what might be defined as a "back e.m.f.," which has the effect of opposing the flow of current in the electrolytic cell. Polarization thus is a phenomenon analogous to mechanical friction. **Hydrogen overvoltage** is one of the components of the total effect of polarization, and results from the deposition of hydrogen on the surface of one of the electrodes (anode or cathode). It will be recognized that polarization (and hydrogen overvoltage) always retard current flow and tend to lower rates of corrosion. Conversely, any factors that reduce polarization tend to accelerate corrosion.

Moisture—The presence of liquid or gaseous water is the factor of most importance in stimulating normal types of corrosion (although in special cases the presence of some moisture may retard corrosion). The reason for the customary stimulation in corrosion rate

caused by the presence of moisture is that moisture generally increases the electrical conductivity of the environment contacting the metal surface. Since corrosion is commonly electrochemical in nature, an increase in electrical conductivity of the environment will permit flow of larger electrical currents and, therefore, result in higher corrosion rates for given potential differences from point to point on the metal surface. Examples of the effect of moisture in stimulating corrosion are so well known that it is hardly necessary to elaborate greatly on this point. It has been established that even unalloyed steels will remain uncorroded if they are exposed to air with a relative humidity less than about 30 per cent. At higher humidities appreciable rusting will occur. Similarly, contact between steel and dry cloth or paper causes no serious attack of the steel, whereas, contact with damp cloth or paper may.

Salts—Neutral salts may stimulate corrosion in the presence of moisture by either or both of two mechanisms. They increase the electrical conductivity of the solution and thus increase corrosion currents. In addition, certain salts may form complexes with the metal corrosion products, thus increasing the solubility of the metal ion. This also stimulates corrosion. Local differences in salt concentration in a liquid which contacts a metal surface can cause severe localized attack as a result of the formation of concentration cells. These will be discussed in greater detail later.

Acids—There are two broad classes of acids:—(1) oxidizing acids such as concentrated nitric acid and (2) the non-oxidizing acids such as hydrochloric acid. The non-oxidizing acids stimulate corrosion by permitting the more rapid evolution of hydrogen as a result of reduction of the hydrogen overvoltage. Oxidizing acids may or may not be corrosive, depending on whether they form thin protective films on the metal surface. The so-called **passivity** of steel in concentrated nitric acid is the result of the formation of a thin, insoluble film on the steel surface upon contact with nitric acid above a certain concentration. Very concentrated sulphuric acid also forms a protective film upon contact with steel. Under usual service conditions, an increase in the acidity of a solution generally tends to increase its corrosivity.

Alkalis—For most ferrous materials, an increase in the alkalinity of a solution generally will tend to reduce the total amount of corrosion, although it may increase the intensity of attack at local areas. Very strong caustic solutions, particularly at elevated temperatures, or molten caustic materials also may be corrosive to a serious extent on account of the amphoteric nature of iron.

Oxygen and Oxidizing Compounds—Free oxygen and many oxidizing compounds have a complex effect on

the corrosion of steel. In aqueous solutions, they stimulate the total amount of corrosion but tend to restrict the area which is attacked. On the other hand, if sufficient oxygen or oxidizing compound is present in the solution, attack may be prevented entirely. This inhibiting action of oxygen and oxidizing compounds is of most importance in the case of stainless steels, while the accelerating action of dissolved oxygen is of great importance in the corrosion of unalloyed steels by natural waters and many chemical solutions.

The behavior of free oxygen and oxidizing compounds in general can be described in electrochemical terms. These materials stimulate the cathodic reaction by depolarization, but they tend to retard the anodic reaction by forming films on the surface of the anode. Thus, their behavior is complex.

In gaseous exposures at elevated temperatures, the presence of oxygen in the atmosphere generally results in increased rates of scaling or oxidation.

Sulphur Compounds—Sulphur compounds, either in solutions or in gas atmospheres, generally accelerate the corrosion of ferrous materials. Practically, such compounds give the most trouble in gaseous exposures at elevated temperatures. In the petroleum industry alone, corrosion of ferrous materials resulting from the presence of sulphur compounds in the products being handled, annually causes millions of dollars worth of damage. Apparently the sulphur compounds render the scale less protective, thus permitting increased rates of attack.

High Temperatures—In general, the higher the temperature of the exposure, the faster corrosion will proceed. There are many exceptions, since change in temperature can affect simultaneously several factors which all may influence corrosion rates. For example, raising the temperature of an aqueous solution exposed to air may either increase or decrease the rate of attack on metallic surfaces contacting the solution. Some of the effects of raising the temperature of a solution can be described in electrochemical terms. Increase in temperature increases the conductivity of the solution and also tends to decrease cathodic polarization. Both of these factors tend to stimulate corrosion. However, raising the temperature may decrease the concentration of oxygen dissolved in the solution but may cause more continuous films to be formed on anodic areas. Both of these factors tend to reduce corrosion rates. In practice, increase in the temperature of solutions freely exposed to the air usually results first in increasing the corrosion rate, but as temperatures above about 180° F are exceeded, the corrosion rate may decrease until the boiling point is reached.

Increase in temperature generally increases corrosion by gases, although here also special effects may come into play so that for some regions of temperature variation, relatively small increases in temperature may actually reduce corrosion rates. One of the most obvious examples of this is where the gas contains water vapor. At temperatures below the dew point, liquid water condenses from the gas and corrosion may be rapid. At somewhat more elevated temperatures, the humidity is less than 100 per cent, so liquid water does not form and the corrosion rate is much lower.

Galvanic Action—When dissimilar metals are placed in electrical contact and exposed to a conducting solution, generally corrosion of one member of the combination is accelerated while that of the other member is retarded. The metal of the combination which has the most active solution potential under the particular conditions of exposure is anodic and sends electric current through the solution to the cathodic metal. The

direction of the current flow determines the member of the couple which will suffer accelerated or **galvanic corrosion**. The magnitude of the current determines the corrosion rate. The electromotive force series indicates roughly which metal of the combination will be anodic and thus suffer special attack. However, since the potentials of the different metals vary with respect to different solutions, the electromotive force series is only a very rough guide.

For example, in sea water, steel is anodic to tin. Thus, contact with tin will accelerate corrosion of steel in sea water. However, when exposed to fruit juices under food container conditions, tin is anodic to steel and will tend to protect steel when in electrical contact with it.

The solution potentials of different alloys of the same base metal may be quite different in specific exposures. Thus, galvanic corrosion can be caused by contact between two different alloys of the same metal. In general, contact between any two metals or any two alloys in any conducting solutions should be suspected of resulting in galvanic corrosion unless there is definite evidence to the contrary.

In some cases, different metallurgical structures of the same metal or alloy have different solution potentials. Thus, corrosion cells are set up. This cause of corrosion should be suspected in welded structures unless they have been heat treated after welding.

Stray Currents—Stray direct-current electricity is a common cause of corrosion of underground steel pipe lines and other buried steel structures. It is also encountered in harbor structures of steel, steel-hulled vessels while tied up at docks, and in lake or river structures. In some cases, it has caused severe corrosion in chemical plants or other plants where large amounts of electrically conducting liquids are handled. Stray current causes more rapid attack than almost any other commonly encountered cause of corrosion. In fact, wherever very rapid attack of a metallic structure buried in the ground, immersed in water or exposed to conducting liquids is encountered, stray currents should be investigated as one of the most likely causes.

Alternating current electricity is much less likely to cause severe corrosion of ferrous structures unless it is of very low frequency (say one cycle per second).

Concentration Cells—When one portion of a metal surface is exposed to an electrolytically conducting medium which differs in any way from the electrolytically conducting medium which contacts another portion of the same metal surface, selective corrosion of the portion of the surface contacting one of the two types of media is likely to occur.* For example, suppose a steel tank is partially filled with a salt solution. If, for any reason, the concentration of salt is different in the layers of solution near the bottom of the tank than it is toward the top of the tank, comparatively more severe corrosion of the steel contacting either the more dilute or the more concentrated solution is likely to occur. This is true even though no corrosion would occur if the tank were full of solution having a uniform concentration from top to bottom. Corrosion in this case is caused by **concentration cell action**.

A special type of concentration cell action is caused by local differences in oxygen concentration of the liquid. For example, let us suppose that liquid saturated with oxygen is circulating freely in contact with most of the inside surfaces of a steel vessel. However, there is a narrow channel or fissure in some part of the surface where stagnant liquid is trapped. The oxygen content of this stagnant liquid will generally be less than that of the freely circulating liquid in contact with it.

* References are at end of chapter.

Thus, an oxygen concentration cell is set up which causes more severe corrosion of the metal surface in contact with the portion of the liquid having the lower oxygen content.

Oxygen concentration cells are a very common cause of corrosion under service conditions. The severe localized corrosion at joints and crevices, and on surfaces in contact with wet insulating materials, is largely the result of oxygen concentration cells.

Stress—Applied or residual stresses, either static or dynamic, can greatly accelerate corrosion.¹ Generally speaking, the acceleration of corrosion by static stress is greatest in environments which do not cause appreciable general corrosion. In fact, stress corrosion often occurs under conditions which would cause almost negligible attack in the absence of stress. A particularly dangerous form of stress corrosion is **stress corrosion cracking**. Under some specific sets of conditions, a stressed part of almost any metal or alloy may suddenly crack, although there may have been no appreciable corrosive attack evident prior to the sudden development of the stress corrosion crack. Stress corrosion cracks rarely occur when metallic parts are stressed appreciably below the yield strength. Since design stresses for most stressed assemblies are normally kept well below the yield strength, it is normally not the stresses for which the structure was designed which cause stress corrosion cracking. Instead, it is normally the residual or so called "internal" stresses which cause this type of failure. These residual stresses are induced during the fabrication of the structure, by bending, welding and other fabricating procedures. The magnitudes of such stresses are frequently not known to the design engineer and are consequently not considered by him in designing the structure.

Cyclic stresses also frequently accelerate corrosion. In cases where the frequency of the alternation in cyclic stresses is high, failures accompanied by corrosion are said to be caused by **corrosion fatigue**. Cyclic stresses, especially if of high frequency, normally cause more rapid failures when accompanied by corrosion than do static stresses of the same magnitude.

Abrasion, Erosion and Cavitation—Surface effects such as abrasion or wear, erosion, impingement of

liquid at high velocity, or cavitation effects caused by the collapse of gas or vapor bubbles at the metal surface can all contribute to intensified corrosion damage in specific cases.

Other Surface Effects—Practically any local difference at the metal surface can cause corrosion under suitable conditions. Thus, a scratch in the metal surface can form a weak point at which localized attack may occur. Local differences in temperature, velocity of liquid flow, degree of surface roughness and even amount of illumination can all cause localized corrosion in specific cases. In fact, any heterogeneity in environment, metal surface or, as will be indicated subsequently, in the metal itself, can cause localized attack.

Metallurgical Factors—As mentioned just above, any heterogeneities in the metal or alloy itself can give rise to localized corrosion. For most commercial metals or alloys these "internal" effects are normally a minor factor in influencing corrosion under service conditions. Generally, environmental factors are of much greater importance. This is very fortunate since it is impossible to avoid internal heterogeneities in commercial metals and alloys. All such commercial materials contain inclusions or minor segregations. Whenever localized attack develops in service, it is common practice to put the blame on these small particles of different phases. Actually, as has been shown by the work of Homer², Mears³ and others, very careful control of the uniformity of the corroding environment and of the metal surface is normally required to reveal the effect of inclusions on corrosion. In special cases, with specific metals or alloys, metallurgical factors may be important. For example, in the case of 18 per cent chromium-8 per cent nickel stainless steels, it is well known that slow cooling from the austenitizing temperature or reheating in a critical temperature zone for an appropriate time can cause the precipitation of carbides at grain boundaries, thus sensitizing the alloy to intergranular attack by certain media. In this case, the metallurgical condition is of great importance in controlling corrosion behavior. However, the fact remains that, in general, the metallurgical condition of most commercial materials is not of great importance in affecting corrosion rates.

SECTION 2

METHODS OF PREVENTING CORROSION

A knowledge of the factors which accelerate corrosion is of value to most people only as it aids them to understand and to guard against corrosion failures in service. A knowledge of appropriate methods of preventing corrosion is important for the same reason.

Material Selection—The most obvious method of preventing corrosion is to build the structure of a material which is unaffected by the service. Unfortunately, it is not always feasible to do this. The most inert materials may be too expensive or otherwise unsuited for the article to be built. Generally, the engineer must make a compromise. He cannot afford to use the most corrosion-resistant material but instead must compromise on a material which has the lowest combined initial cost plus maintenance costs for some selected period of time. The more accurately the engineer knows the corrosion behavior of the various competitive materials under the desired service conditions, the more accurately can he select the most economical material to use. As a guide to proper selection, nothing has yet replaced previous service use. Since small variations in service conditions can sometimes affect corrosion rates

greatly, even previous service use is not infallible. Nevertheless, it is the most trustworthy criterion available.

If it is desired to select material for equipment required for some new process or chemical, there will be no previous background of experience. In such a case, the engineer must be guided by knowledge of the behavior of various materials when used as equipment for similar processes. Better yet, a pilot plant or small-scale service test can be made using a material or materials of construction deemed likely to be satisfactory. The selection of materials for these small-scale tests can be based on laboratory tests or published information. In conducting the laboratory tests, it should be kept in mind that the closer these tests can be designed to simulate actual practice, the more accurately can the results be used to predict satisfactory service performance.

Selection of a suitable material of construction may eliminate the need of using any other form of corrosion prevention. However, it is frequently more economical to use some less resistant but cheaper material and to

employ one or even several protective measures. In most cases it is not economical to use the most resistant material of construction, but instead to use the cheapest material which will do a satisfactory job.

Appropriate Design—It is frequently overlooked that small changes in design may make it possible to use cheaper materials of construction.⁹ For instance, it might be feasible to use carbon-steel pipe as a vapor line for handling gaseous chemicals if the line were insulated to prevent condensation. If the insulation is omitted, such severe corrosion of the steel might occur that it would be necessary to employ stainless steel or non-ferrous pipe in order to reduce corrosion to a tolerable value.⁴

Similarly, the design of a processing tank might be such that liquids could lodge in crevices, pockets, joints or other dead spaces. Severe corrosion is likely to occur in such areas as a result of concentration cell formation. By altering the design to eliminate these regions, the same material of construction can be used with greatly reduced corrosion damage. In the case of tanks or processing vessels for chemicals, the most severe corrosion often occurs on the *outside* of the vessel, not on the inside as might be anticipated. Such equipment should be designed so that moisture will not be trapped in external joints between the vessel wall and the supporting members, between the bottom of the vessel and the supporting wood or concrete base, or in absorptive thermal insulation which contacts the external surfaces of the vessel. Moisture in these locations, even condensed moisture or tap water, can cause severe corrosion. To prevent corrosion, the design may be as important as the selection of the material of construction.

Protective Coatings⁸—Protective coatings are discussed in greater detail in Chapters 36 to 39, inclusive. There are a large number of different types of protective coatings. They can be classified in various ways. Based on their means of preventing corrosion, it is convenient to classify them as:

1. Anodic coatings
2. Cathodic coatings
3. Inert coatings
4. Inhibitive coatings

When a coated metal article is exposed to an electrolyte, if there are discontinuities in the coating, several possibilities present themselves. A positive electric current may flow from the coating through the solution (electrolyte) to the base metal. If this happens, the coating is anodic to the base metal. Furthermore, if the current density at the exposed area (or areas) of the base metal is of the correct magnitude, corrosion of the base metal will be prevented. Thus, anodic coatings tend to prevent corrosion of exposed areas of the base metal by sending electric current to them through any contacting film or layer of an electrolytically conducting medium.

In contrast to this, cathodic coatings tend to stimulate corrosion at exposed areas of the base metal under similar conditions of exposure.

Coatings showing the most pronounced anodic or cathodic behavior are the metallic coatings. Non-metallic coatings, especially oxide or sulphide coatings under some conditions of exposure, act as cathodic coatings. However, there is no definite evidence of non-metallic coatings acting as anodic coatings. It should also be pointed out that the same metallic coating on the same base metal can behave as an anodic coating under one set of exposure conditions, as a cathodic coating under other conditions, and as an inert coat-

ing or even as an inhibitive coating under still different conditions.

Tin coatings on steel form a good example of this variation in behavior under different environmental conditions. When exposed outdoors, in sea water, in most natural water, or even to many food products in the presence of air, tin is cathodic to exposed areas of the steel base. However, when exposed to nearly air-free food products, tin is generally definitely anodic to steel. Presumably, if the exposure were to food products containing some critical amount of oxygen, tin would be neither anodic nor cathodic to steel. That is, it might then be classed as an inert coating. Again under different conditions, the accumulation of dissolved tin compounds from the coating in the food product might reduce greatly the corrosiveness of the product to steel. In this last case, the tin compounds would be serving as corrosion inhibitors; therefore, the tin coating could be classed as an inhibitive coating.

It should also be pointed out that, although cathodic coatings tend to stimulate corrosion of exposed areas of the base metal, this does not always mean that increased attack of these areas will in fact occur. For example, if the cathodic coating is thick and if the exposed areas of base metal are small, attack may be stifled by plugging of the small pores in the coating with corrosion products from the base metal.

Inorganic coatings are sometimes inert, sometimes cathodic and sometimes inhibitive. Organic coatings are generally either inert or inhibitive. Either inorganic or organic coatings which contain water-soluble chromates generally function as inhibitive coatings in most natural environments. It is obvious that the inhibitive value of such coatings is greatest when there is only limited opportunity for leaching of the soluble inhibitor to occur. For example, it would be expected that the inhibitive action of a coating containing a soluble chromate would be more in evidence if the coating were on the interior of a tank which contained only a small amount of stagnant water than if it were on the interior of a pipe through which unrecirculated water was passing continually.

Organic coatings can also function in a manner which does not permit their classification in one of the four simple groups mentioned above. For example, in special cases, organic coatings when exposed to liquid media can serve as semipermeable membranes. Then, by osmosis, dialysis or electro-dialysis, liquid can be transferred through the organic coating to the metal-coating interface. The composition of the liquid which collects at the interface may differ markedly from that of the liquid on the outside of the coating. It may be either more or less corrosive to the base metal than the parent liquid. This behavior is still obscure but it is known to exist.

Treatment of Environment—Corrosion can sometimes be prevented either by adding something to the corrosive medium or by removing some corrosive agent from the medium.^{8, 10} For example, a certain tap water may be highly corrosive to the steel tank in which it is stored. By adding a corrosive inhibitor, such as sodium chromate, to the water the attack may be prevented. Alternatively, by removing dissolved oxygen from the water, the corrosion rate may be greatly reduced.

Corrosion prevention by treating the environment is normally employed when there is only a limited amount of the corrosive material. Thus, it is more widely used for waters which are recirculated than for waters which are flowing continuously from the source without recirculation.

Chromates are by far the most versatile corrosion in-

hibitors, although phosphates, silicates and various complex organic compounds are also used. The mechanism of inhibitor action differs for the various inhibitors and types of uses. In some cases, inhibitors function simply by forming a protective film or layer on the metal surface. In others, they retard one or more of the electrolytic processes necessary for corrosion to occur.

Inhibitors can be classified according to their behavior as "safe" or "dangerous." A safe inhibitor is one which will not cause intensified attack at local areas, even when added in insufficient amounts to prevent attack completely. A dangerous inhibitor will stimulate attack at a few local areas while reducing attack at most of the exposed areas. Unfortunately, most of the inhibitors at present used in other than mineral acid media are dangerous.

Inhibitors can also be classified as "expansive" or "contractive." As the terms imply, expansive inhibitors increase the area of the metal which is attacked, while contractive inhibitors reduce the attacked area.

Thus, a specific inhibitor may be classified as "safe, expansive," "dangerous, contractive" or "safe, contractive."

Cathodic Protection¹—It has already been mentioned that some coatings have the property of sending an electric current through an electrolyte to exposed areas of the base metal. This current flow tends to prevent corrosion of the base metal. Protection in this manner by current flow from any source is termed **cathodic protection**, since the metal being protected is made the cathode of an electrolytic cell.

Sometimes it is not convenient to use a coating metal to provide cathodic protection. Cathodic current from pieces of an anodic metal in electrical contact with the article to be protected and also exposed to the electrolyte can be used. These are termed "galvanic anodes." Alternatively, direct current from a storage battery or from a generator, or rectified alternating current from a power line, can be used. The only essential is that a sufficient cathodic current density must be maintained at all areas of the protected article which contact the corrosive solution.

Determining the magnitude of the current density just sufficient to prevent corrosion under various types of service conditions is a difficult problem. Fortunately, for most ferrous structures, it is not necessary to know the limiting current density with great accuracy. Any cathodic current density which is applied to a given area will reduce corrosion. Furthermore, if the limiting current density is exceeded, no harm is done to the structure. This means, simply, that protection is costing more than necessary because some of the current is being wasted.

Cathodic protection is a very effective way of preventing corrosion by most types of electrically conducting media. Also it is relatively safe, since as long as all the current flows to the structure, corrosion will be reduced even if protection is not complete. It is relatively easy to apply cathodic protection to small, geometrically simple structures. However, skilled electrochemical engineers are required to develop efficient cathodic protection for large or geometrically complicated structures.

At the present time, cathodic protection is applied widely to the steel hulls of marine vessels, to the interiors of small and large steel water tanks, to the ex-

teriors of buried steel pipe lines and to a variety of types of chemical equipment. It should also be mentioned again that the usefulness of tin plate for food containers and of galvanized sheet for roofing, siding and the like depends upon cathodic protection of the steel base by the coating metal.

Periodic Cleaning—It is frequently overlooked that periodic cleaning may greatly reduce corrosion damage. The fundamental reason why cleaning is beneficial is that it removes moist layers of solid matter from the metal surface. Corrosion products may be hygroscopic and generally are water sorptive. Thus, a metal surface coated with a heavy layer of corrosion products and exposed to the atmosphere will be wet for a considerably greater proportion of the time than will a similar clean surface. In like manner, layers of dust or soot of many types stimulate corrosion. Some materials hold moisture, others contain soluble products which in themselves are highly corrosive. It is only rarely that clinging debris is protective.

Chapter 36

PROTECTIVE COATINGS FOR STEEL

SECTION 1

PURPOSE OF PROTECTIVE COATINGS

Functional Coatings—All metals, when exposed to certain media, will corrode, the extent of corrosion depending on the nature of the metals and the environment to which they are exposed. It is common knowledge that all steels, except the more expensive, high-alloy, corrosion-resistant and heat-resistant steels, commonly called "stainless steels," will rust or corrode eventually, if unprotected by a coating. The rate of corrosion will, however, vary when steels are exposed to weathering, underground or underwater conditions. The action of oxygen and moisture in air and of oxygen in water to produce rust is greatly accelerated by chemical contaminants in the environment. Some of the most noteworthy of these are acids, and certain salts of mineral acids, such as ferric sulphate and sulphur-dioxide gas which are present in many industrial atmospheres. The corrosion resistance of an unprotected steel varies greatly depending on composition and environment. In the atmosphere, it has been conclusively proven that the nature of the rust formed affects greatly the subsequent corrosion rate. Some rusts are tight and non-porous and are more protective. Steels containing a small percentage of copper (0.20 per cent), on exposure to atmosphere, form a tighter rust than steel containing little or no copper. Likewise the rust on many high-

strength, low-alloy steels is more adherent than that formed on the copper-bearing steels (see Figure 36—1).

To prevent or inhibit the formation of rust, however, in any environment a protective coating of some sort is required. These coatings are of many kinds, and the methods by which they are applied to the surfaces to be protected, must be adapted to the nature of the coating material. Coatings may generally be classified as metallic or non-metallic, the latter often comprising mixtures of various substances of organic or of both organic and inorganic nature. Many coatings do not adhere well to steel. Some are porous, not being wholly impermeable to the gases and liquids which may attack the steel base. To improve adhesion, pretreatments of the steel base are often used. Porosity may be lessened by the application of heavy coatings or of several coats of the same or of varied compositions if the purpose for which the product is to be used will permit such a practice.

Although coatings are applied mainly for lasting or long time protection, sometimes it is merely necessary that they afford temporary protection, to prevent rust in transit or storage, in which case it may be required that they be removed easily or possess properties that permit the steel to be used without their removal. In some cases the coating may have to be a good primer and

FIG. 36—1. Typical sheet samples of uncleaned high-strength, low-alloy steel (U.S.S. Cor-Ten) at left, copper steel at center, and low copper steel at right, after exposure to an industrial atmosphere for 3.6 years. The hard smooth adherent oxide on the high-strength, low-alloy steel is characteristic. The actual size of each of these three panels is approximately 4 inches by 6 inches.

compatible with coatings applied to the finished article or serve as a drawing compound to aid in the forming of the final product.

Coatings Combining Decorative and Protective Properties—Coatings may be not only protective but also decorative and, in fact, more often than not the feature of appearance is of prime importance. For example, galvanized sheets have often been required to exhibit a pleasing spangled surface. The presence of this spangle

or bright appearance has been associated with the highest quality product although tests have shown no longer actual service life than that of galvanized sheets of duller lustre with equivalent weight of coating. Thus, dependent on the required appearance of the ultimate product, a variety of bright or dull coatings may be manufactured. In the field of organic coatings, a variety of hues may be obtained by a variation of the pigments or stains used in the coating mixture

SECTION 2

PREPARATION OF STEEL FOR APPLICATION OF COATINGS

Importance of Clean Surface—Before application of any protective coating, it is imperative that the surface of the steel be thoroughly cleaned. This feature is neglected more often than any other by those unskilled in the application of a protective film and is often the cause of coatings of poor quality even when applied by those with experience. Scale from hot rolling or annealing should be removed from the steel by shot or sand blasting, by pickling in acid, or by flame descaling with an oxygen-acetylene torch, after which any loose dirt or acid should be removed by brushing or rinsing. This cleaning is important for the application of all types of coatings. Tight scale frequently is not removed on heavy steel sections prior to the application of priming paint, for economical reasons; in such cases the use of special inhibitive primers may result in satisfactory service. Nevertheless, experience has shown repeatedly that superior protection is obtained if all the scale has been removed. Removal of temporary protective coatings, drawing compounds, oil, grease, or dirt from shop operations is absolutely necessary. This may be done by solvents, by vapor degreasing, or by alkali cleaning. Rinses are used to insure thorough removal of cleaner from the metal surface.

Pickling—In large-scale operations, pickling in hot sulphuric acid (H_2SO_4) is a common practice to remove mill scale or rust. The time, concentration, and temperature will vary depending on the type of scale to be removed or the type of steel to be pickled. In continuous strip operations or where size and shape do not vary greatly, electrolytic pickling may be employed at room temperature. The article to be pickled is made the anode, if some actual solution of the steel is required, or the cathode where only cleansing by the blast of hydrogen evolved at the cathode is necessary. Cold muriatic acid (HCl) often is used in small shops to pickle steel and does so very efficiently, although this acid is more expensive than sulphuric acid. Other acids are not used as commonly, although phosphoric acid (H_3PO_4) is find-

ing wider usage where a phosphate coating is desired adjacent to the steel base.

Shot or Sand Blasting—The impingement of steel shot or sharp sand by a blast of air on the scaled or rusted steel surface imparts a very desirable surface texture. The surface finish created is usually quite rough and the roughness of surface is regulated to some extent by particle size of the shot or sand. This type of surface is desirable in that it promotes adherence of some coatings. A rough or eggshell finish may be imparted to steel sheets by the working rolls of a cold mill, which have been shot blasted. This produces a finish to which many protective and decorative coatings can be applied readily. Such sheets commonly are supplied to auto body makers.

Alkaline Cleaning—This method is used where mineral and animal fats and oils must be removed. Mere dipping in solutions of various compositions, concentrations and temperatures are often satisfactory. The use of electrolytic cleaning may be advisable for large-scale production or where this method yields a cleaner product. Caustic soda, soda ash, alkaline silicates and phosphates are common cleaning agents. Sometimes the addition of wetting agents to the cleaning bath will facilitate cleaning.

Solvent Degreasing—This treatment consists of cleaning steel by dipping in a commercial solvent, such as naphtha, trichlorethylene or carbon tetrachloride and rinsing in a clean solution of the same solvent or simply hand cleaning with rags wet with the appropriate solvent. Since the use of volatile solvents in the open constitutes a fire hazard, the less inflammable compounds are favored. Since the vapors of most solvents are toxic in nature adequate ventilation is necessary. Vapor degreasing, usually done in specially built machinery, is a similar process except that solvent vapor is the cleaning agent.

These methods are usually employed where organic coatings are to be applied.

SECTION 3

METALLIC PROTECTIVE COATINGS

The most commonly used metallic coatings include tin, zinc,terne metal (lead + tin), nickel, chromium, cadmium, copper, aluminum, bronze, brass, silver, gold, lead, iron and steel, and sometimes other alloy combinations of the above mentioned metals. A metallic coating may be anodic or cathodic to the metal to which it is applied for protection. If anodic it is "sacrificial" or less noble than the base. If cathodic, it is more noble and its protective value is due to its own relative chemical inactivity in the environment to which it is exposed.

A rough indication of the activity of the metals may be obtained from the "electrochemical" or "electromotive"

series, a classification of metals in the order of electrode potential referred to the standard hydrogen electrode at a temperature of 25°C (see Table 36-I). This table is often used mistakenly as if the order of metals were invariable, each metal displacing from solution or protecting from corrosion those below it. That this is often not true is shown in the second column of the table, where the values of potential in a normal salt solution are given. From the "electrochemical" series it would be anticipated that the corrosion of zinc would be retarded by contact with aluminum, while the potential measurements in salt solution indi-

cate that the zinc should protect aluminum. In sea water and many natural waters, this protection of aluminum by zinc actually occurs. The electrochemical series is useful since metals near the top are generally protective to those near the bottom of the table. When, however, two metals differ little in potential, i.e., are close together in the first column of Table 36—I, one cannot predict which will protect the other, without actual tests. In many instances, the results of potential measurements in a salt solution (second column of Table 36—I) are a better guide as to the ability of one metal to protect the other

under natural conditions of exposure than is the electromotive series. Many factors, such as the environment to which exposed, the magnitude of current generated, the relative area of metals exposed, the texture of metal surface and the inherent tendency of the metal to form an insoluble protective film notably affect the corrosion of metals themselves or their corrosion rate when used as coatings for steel.

Table 36—II illustrates the variable effect of environment or exposure conditions on the solution potentials of several common metals. It will be noted that the relative potentials of these metals vary when they are exposed to different solutions. Thus, no one table of solution potential values can indicate the electrochemical behavior of the different metals under all conditions of use. Actual tests under conditions similar to those of service are required before it is possible to make accurate predictions. The electrochemical behavior of metallic coatings on steel under conditions of atmospheric corrosion is now fairly well established. Zinc is anodic to steel under most exposure conditions and will prevent corrosion even at small discontinuities in the coating. The behavior of aluminum coatings is more complex. In some environments, they tend to protect exposed steel areas but in others there is no evidence of electrochemical protection. Tin, terne metal, nickel, copper, silver, gold and lead are all cathodic to steel under most conditions of atmospheric exposure and, if used as coatings for steel, will tend to accelerate corrosion at pores, scratches, and pinholes. In some cases, the corrosion products formed in the areas where steel is exposed, will stifle corrosion. This is particularly true for heavy coatings of lead, tin, terne metal and aluminum.

From the above it will be concluded that protection against corrosion is not a simple problem, but an extremely complex one.

METHODS OF APPLYING METALLIC COATINGS

Metallic coatings are applied to steel surfaces by the following methods:

Hot Dip Processes—The steel article to be coated is immersed, after thorough cleaning, in a molten bath of the metal forming the coating. Zinc, tin, terne metal, aluminum, and lead are applied commercially in this manner and are discussed fully elsewhere in this book (see especially Chapters 37, 38 and 39).

Metal Spraying—This method, introduced about 1910, may be used with most of the common metals including aluminum, copper, lead, nickel, tin and zinc and alloys such as brass, bronze, babbitt metal, monel metal and stainless steel. The coating metal usually is drawn into wire and fed into a specially constructed spray gun. This gun is operated with compressed air and a fuel gas. It is small and compact although it contains an air-gas mixing chamber, a special nozzle for burning the mixture and melting the wire, an outer compressed-air nozzle concentric with the inner nozzle, and an air turbine driving knurled rolls which draw the wire from its spool and feed it through the inner nozzle. The gases at the nozzle are ignited, the wire is melted as it is fed to the nozzle and is projected against the surface to be coated at a speed of over 500 feet per second. Although the particles of molten metal are cooled instantly to a temperature of about 80° F, the impact causes them to adhere firmly to the steel surface, provided it has been cleaned thoroughly, as by machining or by sand or shot blasting. Metal spraying is used for building up surfaces and sometimes for the application of thin coatings as a protection against corrosion.

Metal Cementation—The metals zinc, chromium, aluminum and silicon are successfully applied in this man-

ner, in which the protecting metal is alloyed into the surface layers of the steel.

In *sherardizing*, practiced since about 1900, the parts to be coated, usually small articles such as nails, are thoroughly cleaned by pickling or sand blasting; packed in metal drums with fine zinc dust, usually containing 5 to 8 per cent of zinc oxide; and heated for several hours at between 650° and 750° F, the drums being slowly rotated in the furnace during the heating. The coating is thin and consists of intermetallic compounds of iron and zinc, ranging from an iron-rich alloy next to the steel base to almost pure zinc at the surface, but it affords good protection against atmospheric corrosion. The process was invented by Sherard Cowper-Coles.

Chromizing is a cementation process analogous to sherardizing. The parts to be treated are packed in a container with a mixture of 55 parts of chromium or ferrochromium powder and 45 parts of alumina by weight. They are then heated "in vacuo" or in a protective atmosphere (preferably hydrogen) at 2370° to 2560° F for three or four hours, although a shorter time and lower temperature may be used when less penetration is desired. Although producing a high-quality corrosion-resistant product, the process has been superseded largely by chromium plating or by the use of corrosion-resistant alloy steels.

In *calorizing*, developed by General Electric Company about 1925 to 1930, the thoroughly cleaned steel articles are packed in steel drums containing a mixture of aluminum and aluminum oxide. A reducing gas is passed into the drum, which is rotated in the furnace and heated for about 5 hours at between 1730° and 1750° F. The resulting coating is said to be a solid solution of aluminum in iron, richest in aluminum at the outer surface, and is used principally to protect the steel from oxidation at elevated temperatures, as in pyrometer tubes, superheater tubes and oil-refinery equipment.

Thirigizing is a special type of siliconizing, or impregnation of the surface of low-carbon steels with silicon. In this process, the surface of low-carbon steel, freed of sand and heavy scale, is packed with silicon carbide or ferrosilicon mixed with mill scale (iron oxide), heated to a temperature of 1300° F or higher and exposed to the action of chlorine for two hours or more depending on the temperature used and depth of case desired. At this temperature the chlorine reacts with the carbon or the iron of the silicon-bearing substance, leaving the silicon in nascent form to combine with the iron in the steel. The siliconized layer, usually 0.005 to 0.1 inch thick as desired, is very hard and resistant to corrosion by non-oxidizing acids, such as hydrochloric and sulphuric acids, and to wear and oxidation at temperatures up to 1600° F, and is capable of absorbing and retaining substantial amounts of oil. In usual practice, the silicon content of the case remains practically constant for the first 0.040 inch, varying from about 14 per cent at the surface to 12 per cent at 0.050 inch below, then decreases gradually in the next 0.020 to 0.025 inch to the silicon content of the core. The process was developed in 1935-1938 by H. K. Ihrig (U. S. Patent Reissue 20719).

In *corronizing*, developed about 1938 by Standard Steel Spring Company of Coraopolis, Pennsylvania, the steel is electroplated with nickel and subsequently with zinc or nickel-zinc alloy (U. S. Patent No. 2,419,231). The plated steel may be heated to about 750° F to form a nickel-zinc alloy, if zinc alone is the final coating.

Metal Cladding—*Copper cladding* processes give bi-metal products. Usually those containing steel consist of an inner steel core covered with a heavy layer of copper. In the usual process, the steel core, with a clean surface, is mounted in a covered mold and heated out

of contact with air to a temperature slightly above the melting point of the copper, which then is cast about it. Other methods consist of dipping the solid steel core into a bath of molten copper, or of depositing the copper electrolytically. Starting material for copper-clad steel wire is made by forcing a steel rod into a closely fitting copper tube. Semi-finished products prepared by any of these methods may be heated to around 1700° F and hot rolled, then finished by cold rolling or drawing, as in forming copper-clad wire. The wire is used widely for electrical conductors, combining the strength of steel with the high conductivity of copper. Bundy-weld steel tubing is hydrogen-welded, copper-coated, rolled steel tubing. It is used for gasoline and oil lines in automobiles and for refrigerator coils. Copper-clad sheet steel was produced during World War II for the fabrication of copper-jacketed bullets.

Aluminum cladding is accomplished best by rolling flat steel almost to gage, cleaning it thoroughly and either placing it between two sheets of aluminum and cold rolling, or heating to between 600° and 750° and rolling. The latter method results in a better bonding of the aluminum with the steel. Subsequent annealing above 1000° F causes the aluminum to unite with the iron forming the very brittle FeAl. With basic Bessemer steel or open-hearth steel containing above 0.25 per cent silicon, the temperature of this reaction is raised above that for regular open-hearth steel so that the coated strip or sheet may be annealed at a somewhat higher temperature after cold rolling without becoming brittle.

Stainless cladding may be accomplished by (1) electro-welding stainless steel onto the carbon steel (2) casting the stainless steel around a solid carbon-steel slab or (3) placing a slab of carbon steel between two plates of stainless steel, and hot rolling them. In the last mentioned method, fluxes or metals have been used to facilitate bonding but are not necessary if both steels are cleaned thoroughly before making the "sandwich." Welding is usually done around the perimeter of the slab. Considerable care is necessary in the preparation of such duplex material to avoid formation of blisters.

Fusion Welding of Coatings may be accomplished in different ways, as by depositing weld metal under a slag covering by the electric-arc method, or by fusing the surfaces of two bodies of metal in contact by passing a current of sufficiently high density. These initial steps are followed by heating and forming operations carried out in the usual manner, as by rolling. Similarly, weld metal may be deposited upon metal of another kind to afford greater resistance to abrasion, such as manganese-nickel steel welding rod used to face excavating and similar tools.

Electroplating—This process is an old art, practiced not only to protect the base metal from corrosion but also for decorative purposes and, more recently, to protect the base metal from wear by friction or abrasion. Metals used for coatings include cadmium, chromium, copper, gold, tin, lead, nickel, silver and zinc, and alloys such as brass, bronze and lead-tin as well as cobalt-tungsten, tungsten-nickel and cadmium-tin alloys. It will be noted that with the exception of zinc, which is anodic to steel, i.e., protects by sacrificing itself, nearly all electroplated coatings are cathodic to steel and provide protection through surface coverage. The decorative coatings commonly used vary in thickness, according to the life required. Durability usually depends upon the properties of the coating, especially adhesion and porosity. The severity of conditions of exposure, particularly with reference to acidic gases in the atmosphere, also affect the service life. In plating, the preparation of the base metal is very important, not only in that a clean

surface is necessary to obtain good adherence but also because surface preparation has much to do with the final appearance, since the intermediate or final coating is frequently buffed to a high lustre. Therefore, the base metal should be smooth if polishing and buffing costs are to be kept to a minimum. The decorative coatings most commonly applied are nickel, cadmium, nickel followed by chromium, or copper followed by nickel or by nickel and chromium. To protect hard steel and iron surfaces from wear or abrasion, coatings of chromium or alloy coatings of tungsten and cobalt or nickel and tungsten are sometimes used although some of these may not always be applied by electroplating. A few typical plating baths with operating data as commonly used by job platers are shown in Table 36—III.

Miscellaneous Metallic Coatings—(1) Cathode Sputtering. When a relatively high voltage is applied between

two electrodes in a partial vacuum, inducing a glow discharge, the cathode disintegrates and the metal thus removed can be deposited in a thin film on near-by objects within the chamber. In suitably designed chambers, objects may be arranged with respect to the cathode so that they will receive a uniform, thin coating of metal. The process is particularly suitable for the metallization of electrically non-conducting materials such as fabrics and phonographic recording waxes.

(2) *Evaporation or Condensation.* This process, closely related to cathode sputtering, is of more recent origin in practical application. The metal vapor is produced by thermal instead of electrical means. A coiled filament of platinum or tungsten in a higher vacuum than for cathode sputtering is a convenient heat source. The process is usually confined to the deposition of pure metals.

SECTION 4

SURFACE CONVERSION COATING

Steel is often treated in various ways by heating to form a uniform blue or black coating of oxide which, although not thoroughly protective, is pleasing in appearance and, especially if coated with oil, wax or other clear protective coating, is much more resistant to corrosion than steel not so treated. "**Blue-annealed**" plate now produced on continuous plate mills is one example of this finish. **Steam-blued** and **air-blued** finish on thin sheets used for common stove-pipe stock are others and the **gun metal** finish applied to gun barrels is another. Strip steel is satisfactorily colored by passing through heated sand. From three to ten minutes treatment at 650° F will produce a rich blue color. Highly polished steel may be blued by placing it in a bed of hot charcoal about two feet deep. The lower part of the charcoal is in a state of incandescence whereas the upper layers are lower in temperature and suitable for the development of oxide colors. After development of the desired shade of blue, the article is rubbed vigorously with waste or cloth dipped in raw sperm oil.

The **gun-metal** or **carbonia** finish used on rifles, shot-guns and revolvers, as well as on many other metal parts, is obtained by placing the steel loosely in a retort with a small amount of charred bone and heating to 700 to 800° F. After the articles are thoroughly oxidized, the temperature is dropped to about 650° F and a mixture

of bone and carbonia oil are added, after which heating is continued for several hours. On removal, the articles are dipped in sperm oil or tumbled in oily cork to develop a uniform, black finish. If a lower temperature is necessary to prevent excessive softening of the steel, a longer time is usually required and the color obtained is less permanent than at the higher temperatures. Articles which have been first nitrided, when treated by the **gun-metal** or **carbonia** process, take a pleasing, rust-resistant finish and retain their surface hardness since coloring temperatures do not temper nitrided articles.

Barfing is a process somewhat analogous to steam bluing of sheets and black plate. The steel articles are cleaned, placed in air-tight ovens and they then are heated to a dull red heat. Super-heated steam at 60 to 100 lb. per sq. in. pressure is introduced and a slate-blue coating is obtained consisting largely of magnetic oxide of iron. The coating is of considerable depth and is quite durable especially when oil or wax coatings are used as the final application. The **Bower-Barff process** is similar except that, after the steam treatment, the steel articles are cooled to 300° F, dipped in hot linseed oil and kept at 300° F until the oil becomes oxidized. Later, the process was modified by introducing benzene with the steam, thus shortening the treatment and producing a heavier coating.

SECTION 5

CHEMICAL TREATMENT OF STEEL SURFACES

Black, blue or brown finishes on steel also may be produced in various shades by a wide variety of chemical treatments. Molten-salt baths produce effective colors on clean, polished steel, but often the temperature is so high that a change in hardness and other mechanical properties may result. The method may be high in cost because of drag-out salt adhering to the metal on removal from the molten-salt bath.

Niter Baths—Molten mixtures of sodium and potassium nitrates are effective bluing agents in the absence of rust. Manganese dioxide is generally added to the extent of about 2 per cent by volume and seems to aid in the production of good colors. Potassium nitrate is used when a bath operating at low temperature is employed, although the sodium nitrate alone may be used without

affecting the quality of the work. The temperatures used vary from 600° to 1000° F. If a lower temperature is necessary, a black color may be obtained by using a 40 per cent aqueous solution of sodium hydroxide to which about 5 per cent each of sodium and potassium nitrates are added. This solution operates at 250 to 285° F. The colored articles are usually finished by immersing in hot oil followed by wiping and polishing.

Polished steel is **oil blackened** by packing in a carburizing box with spent carburizing compound, excluding air, and heating to 1200° F for about one and one-half hours, and then quenching in oil. Variations of this process at lower temperatures may be effected by heating the articles rapidly to 1000° to 1200° F in air, and quenching in oil. Small parts are colored by introducing

them into a rotary furnace retort operating at about 750° F. A small amount of linseed or fish oil is added to the charge and the parts rotated for three to ten minutes after this addition, after which parts are cooled in air and dipped in a rust-retarding oil.

Articles which have been quenched in oil may be placed, without removal of oil, in a rotary, unperforated-drum retort and heated to 500° to 650° F, maintained for proper tempering time according to color desired. The longer the time the deeper and more desirable will the black color be. The retort is allowed to cool to 500° F, then articles are removed and tumbled in slightly-oiled granular cork to brighten. This method gives a combination tempering and oil-blackening treatment.

Browning of steel is accomplished by a wide variety of processes. The thoroughly cleaned steel is coated by spraying, brushing or dipping with two coats of a browning solution which generally consists of a mixture of metallic salts, acids, alcohol or water. The coating is allowed to dry, heated to 140° to 175° F, and then placed in a humidity room or chamber at the same temperature as that used for preheating, where it is allowed to rust. It is then washed in boiling water for 15 minutes, dried and cleaned with a wire brush or fiber wheel to remove loose particles of rust. Three more rustings with intermediate cleanings are applied after which the browned surfaces are coated with a rust-preventive oil.

Solutions for the coloring of steel by chemicals are very numerous and often contain lead, iron, mercury, antimony or copper salts in combination with sulphur or selenium compounds. Usually the colors obtained by the relatively-cold chemical methods are not as brilliant as those from heat tinting in air or steam, or the product

from salt baths. Nevertheless, certain new chemical treatments have been widely adopted, not because of their superior appearance, but because they are beneficial in bonding paints and lacquers, especially when these are baked. Such coatings have a very durable, final finish and one in which corrosion due to porosity or imperfections in the paint film is minimized. Among these are Coslettizing in which the cleaned and polished steel articles are boiled for about two hours in a solution of phosphoric acid and ferrous sulphate or zinc sulphate, thus forming a basic iron or zinc phosphate which is very adherent. Parkerizing consists essentially of treating the clean surface with manganese dihydrogen phosphate. Later the Parkerizing process was shortened by incorporating a copper salt in the bath to which the name "Bonderizing" was given. Still further improvements have recently been made in the direction of time reduction and spray application. Some of these improved solutions contain zinc phosphate along with alkali nitrates or nitrites.

The Laxal treatment substituted oxalic acid for phosphoric acid and was satisfactory when the enamel- or lacquer-baking temperature could be maintained under 300° F.

Chromodizing makes use of a solution of chromic acid and sodium chloride which is sprayed upon clean sheets at a temperature of about 180° F.

There are a number of other proprietary or commercial coatings which depend upon surface conversion. They usually employ treatment with phosphoric-acid, phosphate, chromic-acid, chromate or strong alkali solutions. In some instances the application of an electrolytic treatment is employed.

SECTION 6

CHEMICAL TREATMENT OF METALLIC COATINGS

Metallic coatings such as zinc, tin and aluminum may be subjected to chemical treatments to increase their durability or facilitate the application and adherence of enamels, paints and the like.

Parkerizing or **Bonderite** solutions, somewhat different from those used on steel but essentially phosphate in composition, are used on galvanized or zinc coatings to increase the adherence of the lacquer or enamel. Patents are owned by the Parker Rustproof Company, Detroit, Michigan.

The "Cronak" treatment likewise is used on zinc and consists essentially of sodium-dichromate solutions acidified with dilute sulphuric acid. The process was developed by The New Jersey Zinc Company, New York City.

The **Iridite** treatment consists of immersion in chromium-salt solutions compounded to yield coatings of various shades. These give a reasonable amount of resistance to wear and corrosion. They may be applied in 10 to 20 seconds to freshly-plated zinc or cadmium coatings and are followed by a cold and a hot water rinse (see "Iron Age," May 24, 1945; pages 34-40).

Anozinc is an electrolytic treatment for zinc coatings and zinc die castings presumably consisting of a chromium-salt mixture which, with suitable variation, results in several shades or colors. The zinc-plated article is made the anode and treated at a current density of 5 to 50 amperes per square foot for 1 to 5 minutes. This process was developed by United Chromium, Incorporated, Detroit, Mich.

Banox consists of the application of an amorphous or

vitreous phosphate generally applied to zinc coatings, although it is modified to apply also to uncoated steel. It affords temporary protection and serves as a bonding agent for paints, enamels and the like (see "Steel," June 17, 1946; pages 122-129).

Other proprietary or commercial coatings have been used more or less successfully as a treatment for metallic coatings. Also numerous formulae, given in handbooks, are adaptable to coloring metallic coatings either for protective or decorative purposes. Typical are two given for blackening electroplated articles in either of the following solutions heated to 120° F:

Antimony black

Water	1 gallon
Sodium hydroxide	4 ounces
Antimony oxide	¼ ounce

Nickel black

Water	1 gallon
Nickel chloride	4 ounces
Ammonium chloride	6 ounces
Sodium sulphocyanide	2 ounces
Zinc chloride	½ ounce
Copper carbonate	¼ ounce

After the black coatings are developed, the articles are rinsed in cold water, then in boiling water, dried at 200° F and oiled or lacquered.

SECTION 7

VITREOUS-ENAMEL COATINGS

These coatings consist of a layer of glass fused to the properly prepared steel base and thus are quite different from enamels of organic origin which will be discussed later. To adjust the properties of the finished articles to the ultimate uses, wide variations in the composition of this glass are required but, in general, it must adhere well to the steel base and possess a coefficient of expansion adjusted to that of the base metal. Good adherence is achieved by incorporating in the enamel certain oxides, usually cobalt oxide. Adjustment of coefficient of expansion is accomplished by a variety of compositions which are compounded by fusing together quartz and feldspar, with fluxes such as borax, fluorspar, cryolite, soda ash, sodium nitrate and litharge. Opacifiers such as oxides of tin, zirconium, or antimony are usually added when the glass is ground to a fine powder. This is generally accomplished in a pebble or ball mill.

Ground coat application is made to the thoroughly cleaned sheet steel (or cast iron) article by immersing in a water suspension or "slip" of pulverized enamel ingredients. The prior cleaning may consist of degreasing, pickling in acid, rinsing in a neutralizing bath, sometimes followed by a nickel-solution dip to improve enamel adherence and behavior during firing, after which the articles are washed and dried. Cast-iron articles are frequently cleaned by sand or shot blasting. After application, the slip is allowed to drain, dried, heated (fired or burned) at as high a temperature as 1500° to 1600° F for 1 to 4 minutes and cooled to room temperature. This fired ground coat offers sufficient pro-

tection to the steel base and may be used alone. However, since the "slip" usually contains cobalt oxide, the resulting coating is dark blue and may not be suitable for all purposes, so that a finish coat may be applied.

Finish Coats are applied when a light color or additional protection such as acid resistance is desired. The fired ground-coated article is sprayed with a slip of the required finish-coat composition, dried, fired for 1 to 3 minutes and cooled. The operation may be repeated several times using the same or different slips and many attractive color combinations can be obtained if desired.

Single-Finish Coats—Much experimental work has been directed toward obtaining a white enamel (since white is used most widely as the final coat) which can be applied directly to the steel or cast-iron base and result in a good appearance with one coat only. This can and has been done successfully but, frequently, the one coat may be inferior in lustre when compared with a piece having two coats. Also, imperfections are very noticeable in white and the economy of using only one coat may be offset somewhat by higher rejections.

Low-temperature vitreous enamels—To provide a coating where the high gloss or decorative enamels are not required, ceramic coatings have been developed which can be applied by spraying and firing at a temperature of as low as 700° F for about 15 minutes. These have found a limited field of use for containers, marine hardware, ammunition boxes, radio parts, cartridge cases and machine-gun mounts. The composition is said to consist of an alkaline aluminum silicate.

SECTION 8

MISCELLANEOUS INORGANIC COATINGS

Cements—These coatings differ from vitreous enamel in that they are not always fused to the steel, although the constituents consist largely of finely ground, vitrified products. Cracking vessels in the oil industry are sometimes protected by a mixture of furnace cement and sand to which short fiber asbestos and water glass are added. In this instance, curing is facilitated by heating to about 900° F. The interior of cast-iron or steel pipe and steel tanks may be coated with cement to resist corrosive waters, salt solutions, oil having a high sulphur content and the like. Concrete coatings are used on the exterior of pipe when it is buried in extremely moist or corrosive soils. This concrete is a rich mixture approximating two parts sand and one part Portland cement and may be two to four inches in thickness. The alkalinity of cements

usually inhibits corrosive attack of the steel to which they are applied.

Core Plate—These coatings, which are discussed in greater detail under silicon or electrical-steel sheets (Chapter 46), may sometimes be inorganic in nature and are usually applied to silicon-steel sheets used for transformer laminations to improve the insulating properties. Other core plates used for a similar purpose or for insulating motor laminations are organic-varnish coatings.

Metal Powders in Inorganic Vehicles—Metal powders may be incorporated with inorganic silicates or phosphates to produce a protective coating. Usually, such coatings require some baking in order to obtain satisfactory adherence and hardness. Bronze paint and aluminum paint are examples.

SECTION 9

ORGANIC COATINGS

Temporary Organic Coatings—For temporary protection in shipment or storage, steel is usually coated with oils known as *slushing oils*. Mineral oils alone are sometimes used where corrosive conditions are not severe. More often, the mineral oils are mixed with inhibiting or polar compounds which deter rust formation. Slushing oils are generally removed subsequent to fabrication and prior to application of a permanent organic coating. At

times, when diluted with solvents which vaporize and leave only a very thin coating, the permanent organic coating can be applied satisfactorily without removal of the temporary protective film. Often, however, unless the temporary protective film is removed, troubles are encountered due to its incompatibility with the permanent organic coating. For severe conditions such as outdoor storage or overseas shipment, heavy greases or waxes

compounded with inhibitors are applied. When conditions are unusually severe and the value of the steel product justifies the cost, plastic films are applied, which can be removed by stripping. This latter expedient may be used for overseas transportation and storage of expensive equipment.

Permanent Organic Coatings are commonly known as paints, varnishes, enamels, lacquers and japans. The pigments for organic coatings are generally of inorganic nature. **Paints** are mixtures of pigments with drying oils, usually linseed or tung oils, which dry by oxidation. **Varnishes** are solutions of resinous material in oils or volatile liquids which dry by evaporation or oxidation. **Enamels** can be called varnishes to which some pigment has been added. **Lacquers** comprise solutions of shellac, resins, cellulose derivatives or polymerization products in suitable solvents, all of which dry by evaporation. **Japans** are varnishes compounded to permit drying at a temperature high enough to keep their oleoresinous compounds in a liquid state until oxidation is completed. As indicated in Table 36—IV, the subject of organic coatings is too extensive and complex for discussion in this book.

The importance of such coatings in the protection of steel is, however, too great to dismiss without a brief discussion of some of the types of excellent coatings which have been developed. This field is in a constant state of flux or change due to rapid application of newly developed materials.

As mentioned previously, paints may be considered as mixtures of pigments with drying oils. The service life of the painted steel will depend on the quality of the paint applied, the type of environment to which the painted article is exposed, the surface preparation and the care exercised in application of the paint.

Special Polymers—Rapid development in the synthetic-resin field has produced many synthetic finishes of extraordinary resistance to various corrosive conditions. Many of these are limited to special fields because of high cost but their use has increased as means have been found to produce them more economically. Some, such as the polyvinyl-acetate resins and copolymers of vinyl acetate and vinyl chloride, are finding wide application because of their resistance to chemical attack, superior adhesion and unusual toughness. Polymers of certain derivatives of acrylic and methacrylic acids possess optical clarity and superior light transmission as well as resistance to chemical attack. Certain pigments incorporated in paint films inhibit both the start and spread of corrosion. Zinc and lead chromates, and red and blue leads are useful in this respect. Rubber modified with chemicals such as chlorine is a very suitable substance for paints intended to resist corrosive chemicals.

Asphaltum finishes based on coal tar or petroleum asphalt are black and possess good heat resistance where temperatures are not too high. They are commonly incorporated with other materials to increase their durability.

Application and Drying of Organic Finishes—Since the bond between metal and coating is the weak point in most paint systems for metals, the method of application is extremely important. Prior to application, thorough cleaning of the surface is necessary. Since no paint system is entirely impermeable to moisture, durability is increased by chemical treatments or inhibitive washes of the steel base, many of which are proprietary in nature such as "Bonderizing." The application of such treatments prior to painting is practiced extensively in

plants fabricating steel articles, although recently their use has increased on structural-steel work after erection. Tests at the National Bureau of Standards indicate that the rust-inhibitive solution should be allowed to react with the steel, which then dries. Thorough washing is then advisable, to remove the excess inhibitor, followed again by drying prior to application of the primer paint. A satisfactory wash originated by the U. S. Engineer's Office has the following composition:

Ingredients	Per Cent by Weight
Commercially-pure ortho phosphoric acid (H_2PO_4)	7.00
Sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$)	0.75
Caramel solution	0.50
Wetting agent (such as "Cellosolve," ethylene glycol monoethyl ether, $C_2H_5OCH_2CH_2OH$)	0.50
Water	91.25

The older and more common methods of application of finishes by brushing or dipping are still widely used but in factories the installation of conveyor systems has increased the use of roller coating methods for flat products and spraying for more complicated or formed shapes. These operations are usually performed mechanically and are often followed by a closely controlled baking treatment. Banks of infra red lamps, or gas fired or electric ovens, may be used. In some instances, this heating merely serves to drive off excess solvents. In other cases the oxidation of the coating, required for a durable finish, is also accomplished. Here, the composition of oven atmosphere is important. Baked coatings are usually harder, tougher and often more durable than those which are air dried, and quite often the coating mixture for an air-dry coating is different than one for baking. With the more general use of continuous coating methods, continuous baking is a common practice in quantity production. These methods are utilized in the production of small and large parts of the majority of manufactured articles.

Chapter 37

THE MANUFACTURE OF TIN PLATE

SECTION 1

TIN-MILL PRODUCT TERMINOLOGY

Tin-mill products originate with flat-rolled, mild (low-carbon) steel in relatively thin gages. They comprise **black plate**, **tin plate**, and **short terne plate**. Of these, tin plate is the most important commercially, accounting for about four-fifths of the combined tonnage of all tin-mill products. Black plate accounts for most of the balance. Short terne plate, at one time produced in quantity, is now a relatively minor factor in tin-mill production, and is discussed in Chapter 38.

Black Plate—Although originally designating thin steel plates produced by hand hammering, the term "black plate" has persisted and now defines the product of the cold-reduction method in gages No. 29 and lighter (thicknesses 0.0141 inch and under). Some of the details of rolling and heat treating such light-gage product were discussed in Chapter 34.

"Black" plate does not have a black appearance. Present methods of manufacture generally result in a flat-rolled product having the typical appearance of clean steel. The appearance of black plate may be affected, however, by modifications of annealing practice, or of processing methods that affect the roughness of the surface texture.

Black plate as such is sold either in cut sheets or in coil form and is used for fabricating a variety of items including containers, trays and toys. When coated with suitable organic coatings, it exhibits considerable resistance to corrosion and its use for containers is increasing. Uncoated, black plate is extremely susceptible to rusting and precautions to prevent condensation of moisture must be taken during shipment and warehousing. Some manufacturers are equipped to apply thin films of protective oils to minimize rusting. Other mills are equipped to produce chemically treated steel (CTS), which is black plate given a protective chemical treatment to enhance rust resistance and adhesion of organic coatings. Such treated plate usually requires a protective organic coating applied by the user. Precautions to prevent condensation of moisture are necessary during shipment and warehousing.

The most important use of black plate is in the manufacture of tin plate, as described hereafter.

Tin Plate—Tin plate may be described as full-finish black plate additionally processed and coated on both sides with commercially pure tin. The widespread use of this major steel-mill product arises from its combination of the strength of steel with the protective properties and solderability of tin. When coated by the hot-dip process (see Section 5), the tin plate is termed **coke tin plate**, **charcoal tin plate**, or **silver tin**; these terms are defined under "Hot-Dipped Tin Plate," immediately following this paragraph. When coated by the electrolytic process (see Section 6), it is termed **electrolytic tin plate**. In the United States at the time this is written, approximately

80 per cent of the tin-plate tonnage produced represents electrolytic tin plate and the remaining twenty per cent tin plate made by the hot-dip process.

Hot-Dipped Tin Plate—Tin plate formerly was produced by the hot-dip tinning of thin plates hammered or rolled from bars of puddled iron. The pig iron used in puddling might have been made in blast furnaces using charcoal or coke as fuel. Plates made from "charcoal iron" were considered a more ductile and higher grade product; hence, tin plate made by coating charcoal iron plates with tin (charcoal tin plate) was regarded as a product of higher quality than tin plate with a coke iron base (coke tin plate). At present, the designation "charcoal tin plate" merely indicates plate with a relatively heavy tin coating as compared with "coke tin plate" as described below, and has no significance so far as quality of the steel base is concerned.

Various grades of hot-dipped tin plate are produced at present, the terminology indicating in a general way the weight of tin coating or, indeed, more exactly indicating the amount of tin used to produce the given unit or base box of plate. Coke tin plate has always designated the plate produced with the lowest amount of tin and formerly was called "Cokes" or "Common Cokes." Currently, in ascending weight of coating, the various grades are Common Cokes, Standard Cokes, Best Cokes, Kanners Special Cokes. "Charcoal Tin Plate" carries still heavier coatings including 1A and 2A. Silver tin is made by hot-dip tinning a mechanically roughened steel base. It has a dull surface, but carries a heavy coating of tin.

Electrolytic Tin Plate is available in both melted and matte (unmelted) finish. The former has bright luster and is similar in appearance to hot-dipped tin plate. Matte finish tin plate is lacking in luster.

Electrolytic tin plate theoretically can be produced in any coating weight. The commercial grades of electrolytic tin plate available at present include coating weights of 0.25, 0.50, 0.75, and 1.00 lb. of tin per base box, identified by the numerals 25, 50, 75, and 100, respectively; in addition, tin plate identified as 100-25 differential tin plate is available that carries a 1.00 lb. per base box coating on one side and a 0.25 lb. per base box coating on the other. Although normally sold in sheet form, electrolytic tin plate is available in coil form also.

The 100-25 differential plate was developed to conserve tin, the 100 surface being employed as the inside surface of containers where maximum protection is required. The light-coated surface of 100-25 differential is identified by making it less lustrous than the heavy-coated surface. This is usually done either by roughening the steel surface during temper rolling or by anodizing the plated surface in a suitable electrolyte just before melting. Other methods for producing a non-lustrous surface are under consideration.

Symbols and Definition of Base Box—Tin plate is sold on a weight per unit area basis rather than a gage thickness basis. The unit of area is the base box, equal to the area of 112 sheets, 14 by 20 inches, or 31,360 square inches (217.78 sq. ft.).

In the early eighteenth century in England, 14 by 20-inch plates were packaged in lots of 112 sheets to make one hundred-weight (112 lb.). When the plate was heavier, it was identified as IX or one cross. The cross denotes an increase in weight of 28 lb. or one quarter hundred-weight.

The use of symbols to designate gage now has been displaced by base weight classification. Base weights (or basis weights) which indicate the approximate thickness of the plates are expressed in pounds per base box. Estimated weights of tin plate of other sizes than 14 by 20 inches are computed readily through the use of base box ratio tables. Table 37—I shows the nominal weights in pounds per base box of the plate commonly produced. The table applies to hot-dipped tin plate produced in sheet form. Present continuous strip plating lines for electrolytic tin plate are normally designed for producing the lighter basis weights, up to about 135 pounds per base box.

Table 37—I. Nominal Weights of Tin Plate Commonly Produced

Weight (lb. per base box)	Equivalent Weight (lb. per sq. ft.)	Weight (lb. per base box)	Equivalent Weight (lb. per sq. ft.)
55	0.2526	155	0.7117
60	0.2755	168	0.7714
65	0.2985	175	0.8036
70	0.3214	180	0.8265
75	0.3444	188	0.8633
80	0.3673	196	0.8954
85	0.3903	208	0.9551
90	0.4133	210	0.9643
95	0.4362	215	0.9872
100	0.4592	228	1.0469
107	0.4913	235	1.0791
112	0.5143	240	1.1020
118	0.5418	248	1.1388
128	0.5878	255	1.1709
135	0.6197	268	1.2306
139	0.6383	270	1.2398
148	0.6796	275	1.2628

SECTION 2

OCCURRENCE, MINING, AND REFINING OF TIN

Tin, though one of the common metals, is the most sparsely distributed metal in common use. Its main sources at present are the Malay States, Dutch East Indies, Bolivia, Siam, China, Belgian Congo and Nigeria. These deposits produce probably 85 per cent of the world's supply. The large portion of the remaining 15 per cent is accounted for by the deposits in Australia, the centuries-old mines in Cornwall, the Union of South Africa and India.

The most abundant source of tin is the oxide, cassiterite, or tin stone, and the greater portion of the world's supply from workable deposits is derived from alluvial deposits in river beds. The cassiterite originally occurred in veins and lodes in highly acid igneous rocks. The ore may be found also as primary veins in metamorphosed sedimentary rocks. Cassiterite has a relatively high specific gravity (6.4-7.1).

Alluvial deposits of tin stone occur associated with gravel, which may be bonded with clay and covered with more or less overburden consisting of soil, clay, etc. This type of deposit, found in the Malay States, Dutch East Indies, Siam, China and Nigeria, is worked by various types of hydraulic mining. Washing of the deposit with running water causes a breaking up of the gravel and a carrying away of the lighter pebbles while the heavier tin stone is retained and recovered. The concentrates are hand picked to remove non-stanniferous metals, and may be rewashed in small sluice boxes and concentrated by hand jiggling.

Tin ore in Bolivia and Cornwall is practically all vein tin. Here the tin ore is found in lodes and beds, in older rocks such as granite, gneiss and mica schist, associated with a large proportion, perhaps 95-99 per cent, of gangue consisting principally of silica and silicious minerals, metallic minerals like the sulphides of iron, copper, lead and zinc, iron oxides and wolframite (a tungstate of iron and manganese). The ore first is crushed to pass approximately a twenty-mesh screen and then concentrated by washing. The finely washed ore in the slimes is treated in settling tanks, or on slime tables.

Regardless of which method is used to concentrate

the ore, the concentrates then are roasted to remove sulphur and arsenic. This operation in turn is followed by a second washing, although in some cases the roasted ore is treated in magnetic separators to remove iron oxide and wolframite prior to washing. The tin stone is then ready for the smelter. Reduction of the tin ore is accomplished either by the use of a reverberatory furnace or a blast furnace. The crude tin thus obtained then is refined by a liquating operation in which advantage is taken of the low melting point of tin. The impure metal is heated on the inclined bed of a furnace to a temperature just above its melting point. Comparatively pure tin trickles down to a basin below, leaving the higher melting point impurities on the bed of the furnace. The low melting point impurities, lead and bismuth, are removed by either or both of two oxidizing methods. The first of these is an operation called **boiling**, in which sticks of green wood are immersed in the molten metal and undergo destructive distillation to produce bubbling by the steam and gases generated to agitate the molten metal bath. Different portions of the metal thus are exposed to air and are oxidized. The oxidized impurities float on top of the molten metal to form **dross**. The oxide drosses then are skimmed from the surface of the bath. Similarly, pouring ladlefuls of molten metal from a height into the bath permits the oxidation of impurities. This latter operation is called **tossing**. Drosses may be resmelted to recover tin losses.

In more modern extraction methods, ore concentrates are calcined with or without additions intended to facilitate further processing. The iron and other impurities then are removed readily by leaching the ores in solutions of hot hydrochloric acid. Leaching is followed by filtering of the chloride solution. After washing with dilute acid, the residues are of such purity that subsequent treatment in reverberatory furnaces will yield a metal containing at least 99.80 per cent tin. It is possible to obtain metal of 99.98 per cent tin content through refinement by electrolytic means, but electrolytic methods on a commercial scale were abandoned in the United States in 1923.

Properties and Uses of Tin—Tin has a silver color with a slight bluish tinge, a brilliant luster, a structure which is distinctly crystalline, and is soft and malleable at ordinary temperatures. Other physical properties of tin are:

1. Atomic Weight—118.7
2. Atomic Number—50 (isotopes with masses 112 to 124)
3. Density—7.31
4. Specific volume—0.1395 at 20° F
5. Hardness on Mohs' scale—1.8
6. Tensile strength—about 2200 lb. per sq. in. and elongation of 86 per cent

7. Melting point—449.4° F (231.9° C)

8. Boiling point—4120° F (2270° C)

Tin is alloyed with other metals to make bronze, Britannia metal, pewter, solder, or white bearing metal. Pure tin or lead-tin alloy, rolled very thin, is known as tin foil. Tin amalgam is used in making mirrors, and tin condenser tubes are used in laboratory stills. Tin, in conjunction with an acid, is used as a reducing agent.

Stannic oxide is used as a polishing powder, and as an opacifying agent in glasses, glazes and enamels. The chlorides are used as a mordant in weighting silk and in dyeing. The largest use of tin at the present time is the manufacture of tin plate.

SECTION 3

USES AND IMPORTANCE OF TIN PLATE

Tin plate represents one of the major items produced by the steel industry in the United States. In normal non-war years, the tonnage has represented approximately 5 to 7 per cent of the total steel production. Statistics compiled by the American Metal Market show that production has increased steadily from about 340,000 tons in 1900 to about 2,750,000 tons in 1940; new facilities have increased capacity so that by 1948 it was about 4,000,000 tons and by 1955 it was about 5,600,000 tons. This increase has kept pace with the growth of the food preservation industry.

The continued increase in consumption of tin plate attests to the unique properties of this product, in which are combined the strength of steel and the corrosion resistance of tin. Tin plate is fabricated and soldered

readily on high-speed forming equipment. It has a pleasing appearance. It is relatively inexpensive and is non-toxic. Because of these and other properties, tin plate has been found to be the ideal fabrication material for food and other containers (tin cans), crown caps and other bottle caps or closures, for kitchen utensils such as baking pans, for various drawn or fabricated parts in radios, such articles as electrical equipment, and toys.

The largest use of tin plate is for containers, and the improvements in its manufacture have been dictated largely by the requirements of the container industry. The cans are used not only for foods, but also for paints, oils, tobacco, detergents, insecticides, proprietary drugs and beverages.

SECTION 4

PROCESSING OF STEEL FOR TIN PLATE

Types of Steel Used—Most of the steel used for the production of tin plate is made by the open-hearth process. Depending on the stiffness required for the various applications, the phosphorus content may vary from residual to as high as 0.15 per cent. Acid Bessemer steel, because of its relatively higher phosphorus content, is stiffer than average basic open-hearth steel, and has a distinct advantage where greater stiffness is desirable.

The steels utilized for tin plate production commonly are classified as "dead soft" carbon steels having a maximum carbon content of 0.15 per cent. The great preponderance of tin plate steels are produced as either rimmed or capped steels. The rimmed steels are utilized in general for the softer and deep-drawing tin plate requirements, whereas the capped steels find application in meeting the stiffer tin plate requirements of stamping or forming. The capped steels for tin plate have the definite advantage of being relatively uniform throughout in grain size, cleanliness, and chemical composition.

Of special importance in the manufacture of hot-dipped tin plate is the selection of the proper composition of steel base for the job. Virtually all tin plate is made with a base having composition (of the metal in the ladle) falling within the following composition ranges:

Carbon	0.04 to 0.15
Manganese	0.20 to 0.60
Phosphorus	0.15 max.
Sulphur	0.050 max.
Silicon	Residual
Copper	0.20 max.

For particular applications, as determined by temper requirements and pack corrosivity, the desired ranges will be selected. The acid fruit products represent in general the most corrosive media. For these applications the phosphorus, silicon, copper and "tramp" elements in the steel are held to low limits.

Equipment and Practice—The sequence of operations in the manufacture of tin plate is as follows: slabs are heated and hot rolled to coiled breakdown form on the hot-strip mill. The breakdowns are continuously pickled and taken to the cold-reduction mills where they are reduced to black-plate gages. The cold-reduced material is cleaned, annealed and temper rolled in coil form; these coils are the starting material for the hot-dip tinning process described in Section 5 of this chapter, beginning with shearing of the plate into sheets.

As preceding sections of this book discuss and describe in detail the equipment and operation of the continuous hot-strip mill, the continuous pickler, the cold-reduction mills, and all other equipment necessary for the processing of hot-dipped tin plate up to the actual coating operation, the following explanations will be limited to general control measures designed to produce the most suitable product.

In continuous hot-rolling, the slabs of steel, ranging from 4 to 7 inches in original thickness, are hot reduced at an elevated temperature to a single continuous length which, for ease in handling, is rolled up into the form of a coil. This coil product may be as thin as 0.065 inch or as thick as 0.125 inch, depending upon the desired thickness of the product after cold reduction; it will

generally be between 0.070 and 0.090 inch for the bulk of the tin plate produced in this country. Factors such as type of hot-rolled surface desired, ease with which oxide can be removed prior to the cold-reduction operation, hardness of the hot-rolled product desired and resultant mechanical properties, grain size and corrosion resistance of the final product, all must be considered in establishing an optimum hot-rolling practice. In general, the 0.070 to 0.090 inch thick hot-rolled product will have a temperature between 1500° and 1600° F at the exit side of the last finishing stand. Similarly, this product going into the coiler generally will be in the range of temperature between 1100° and 1250° F.

For the production of tin plate, it is sufficient to say that the primary functions of continuous pickling are to remove uniformly all of the hot strip mill scale and oxide from the surface of the steel and subsequently to oil the pickled product. These operations are necessary prior to taking the very heavy cold reductions necessary to obtain the light tin plate gages and to ensure the clean surface finally necessary for the tinning operation.

The importance of the cold-reduction operation to the over-all quality of tin plate cannot be over-emphasized. This operation determines the gage uniformity and, to a great extent, the surface quality and flatness of the final tin plate product. These three properties require particularly close control because of the demands of the very sensitive coating operations and the high-speed automatic can-making operations. To attain the 80 to 90 per cent cold reduction used on the base metal for tin plate manufacture, nearly all plants in this country use four-stand or five-stand four-high tandem cold-reduction mills with delivery speeds of 2000 to 6000 feet per minute. The design and operation of these mills are described in Chapter 34. It should be mentioned here that the mills used are generally from 42 to 56 inches wide to produce the usual 24 to 36-inch widths and that, where a mill is installed solely for the manufacture of tin plate, the five-stand mill is more satisfactory than the four-stand for rolling the light gages involved.

The cleaning operation is particularly important in the manufacture of coated products, as the efficiency with which the cleaning operation is performed has a marked bearing on the subsequent coating operation and the quality of the final coating. Its function is to remove all traces of cold-reduction lubricant from the coil product, leaving a bright, clean surface for subsequent operations.

This cold-reduced product is quite hard, having a Rockwell (30-T scale) hardness of approximately 80 to 85, and must be softened by annealing. Both batch-type (box anneal) and continuous annealing furnaces are used and the trend is toward further use of continuous-annealing furnaces. In the **box-annealing process**, steel for tin plate is heat treated in coil form in a protective atmosphere. Considering both equipment limitations and quality evaluation of the annealed product, it has been found generally desirable to box anneal the coiled product within the steel-temperature range of 1150 to 1250° F, with soaking periods of 4 to 12 hours. This type of subcritical annealing is known as **process annealing**. While the heating cycle in relation to the metalloid content

of the steel largely determines grain size of the finished product and exerts a strong influence on the mechanical properties of the finished tin plate, the cooling cycle plays an important part as regards surface. A clear, bright, relatively oxide-free coil product can be obtained if the deoxidizing gas is allowed to circulate under the inner cover until the steel temperature drops below approximately 250° F; such a surface is considered desirable for tin plate. In the **continuous-annealing process**, the steel is heated in protective atmospheres to about 1200° F in a fraction of a minute at strip speeds of 1000 feet per minute in existing furnaces and at projected speeds of 2000 feet per minute in newer furnaces. Continuously annealed strip is inherently stiffer than box-annealed strip, but possesses good formability; thus, continuous annealing offers a method for obtaining tin plate of higher temper without change in steel composition.

The function of the temper mills in the manufacture of tin plate is threefold: to impart the desired surface finish to the product, to produce acceptable flatness and to develop the desired mechanical properties.

The surface finish is controlled largely by the smoothness of the exit work rolls. Smooth-ground rolls impart a bright, dense surface finish whereas rough-ground or shot-blasted rolls impart a rougher finish. All grades except matte finish (No. 5 finish) and silver tin are finished with smooth rolls.

Flatness is obtained by proper adjustment of such factors as roll contour, finish, pressure and strip tension.

For the softest tempers, temper rolling (also called skin rolling) is done on a conventional four-high single-stand coil temper mill although these tempers can be produced with care on two-stand tandem temper mills. The objective here is to flatten the strip and impart the proper surface in one pass with a minimum of hardening effect due to cold working of the product, the thickness reduction being held to less than 1 per cent. For the higher tempers, a two-stand four-high tandem temper mill is employed, or the strip is given two passes through single-stand mills. On such material, temper rolling has the added function of increasing the steel hardness, and thickness reductions of 2 per cent and higher are common. As an aid to temper rolling, the work-roll surface of the first mill stand is relatively rough, being rough-ground or shot blasted, and the work rolls of the second stand or finishing mills are ground smooth. Thus, superficial hardening, arising from second-stand smoothing of the rough strip surface imparted in the first stand, is added to the full-section hardening of the actual strip extension under rolling pressures and reel tension. Modifications of temper mills for tin plate include means for applying high strip tensions and for developing heavier drafts in the first stand, as mentioned in the section on finishing.

Rockwell hardness-testing machines are used to measure the "temper" of the coils. If the hardness values are too low, the coils are rerolled.

After temper rolling, coils are conveyed either to a shear line, where they are cut to sheets for sale as black plate or for hot-dip tinning, or to a side-trimming and recoiling line for preparation for electrolytic tinning.

SECTION 5

HOT-DIPPED TIN PLATE

Shearing Practice—At the flying shears, the coils for conversion to hot-dipped tin plate are side trimmed and cut to sheets. A micrometer, operating continuously, rejects off-gage sheets which are diverted automatically

into an off-weight piler and thus separated from product of correct thickness. Perforated sheets are detected with an "electric eye" and are rejected automatically.

White-Pickling Practice—Pickling to remove all sur-

FIG. 37-1. Schematic arrangement of equipment comprising a modern tinning stack.

face contaminants, such as light oxides resulting from the annealing treatment before tinning, is commonly termed **white pickling** to differentiate from other pickling processes. A clean, uniformly pickled surface is a requisite for successful hot tinning. The cold-reduced product is pickled in sulphuric acid of 2 to 6 per cent concentration at 150° to 180° F for 2 to 4 minutes, followed by rinsing in cold water. Pickling inhibitors frequently are used to prevent over-pickling or etching of the plate. The pickled steel is stored in a "bosh" or steel storage tank containing a 0.10 per cent hydrochloric-acid solution until ready for tinning.

Electrolytic pickling is supplanting white pickling in many plants. Sheared plate is fed automatically into the electrolytic pickler and thence into the tin pot (Figure 37-1). Various feeding devices may be employed and common acids used in such a unit. Its advantages include the elimination of the heavy manual labor necessary in hand-loading and unloading the white pickler and in providing uniform and controllable pickling action.

The Hot-Dip Tinning Operation—A typical hot-dip tinning shop or tin house normally consists of a long rectangular building with the tin stacks arranged side-by-side in a straight line. The individual tin stacks usually are hooded completely to draw off all fumes from the flux, palm oil and tin baths and to minimize as much as possible loose bran particles in the air from the branning unit. A modern tinning stack consists of an assembly of equipment arranged to perform a number of operations in a continuous manner (Figure 37-1). The integral parts of this assembly, in the order in which they perform their function on the sheet being coated are as follows:

1. The feeder
2. The tin pot and tinning machine
3. The wet washing machine
4. The branner
5. The piler

Modern hot-dip tinning lines are commonly of two sizes,

FIG. 37-2. Schematic diagram of a tin pot and tinning machine. The feeding unit at the left is known as a Poole feeder. The brushes on the tinning rolls have been omitted.

the 64-inch and the 75-inch machine. These designate the length of the roll bodies in the tinning machines. The 64-inch normally operates as a two-way machine (two sheets of tin plate pass side-by-side through the molten tin bath) whereas the wider 75-inch machine may be used as a three-way machine on narrow product.

The feeding mechanism varies in design from plant to plant. Feeding may be done manually or by automatic feeding machines. The Poole feeder (Figure 37—2) is a common automatic type, in which individual sheets are lifted by a magnetized roller from the feeder tank to the supplementary tinning machine equipment.

This tinning equipment consists of a series of guides and rolls to convey and guide the sheets being coated from the feeding mechanism downward through the molten flux and tin baths, then upward out of the molten tin and through a bath of hot oil onto the conveyor, as shown in Figure 37—2. The axes of each set of rolls lie in the same horizontal plane. Three pairs of rolls are positioned in the hot oil so that the lowest pair is slightly above the molten tin level and the top pair is just below the top level of the oil. The tinning machine rolls normally range from $3\frac{1}{2}$ to 4 inches in diameter and are of high-carbon steel heat treated to high hardness. Their surfaces are very accurately finished by machining and grinding. The tin pot, which holds from 8,000 to 17,000 pounds of commercially pure molten tin at about 620° F, is filled to a point approximately 4 inches from the top of the entry side. The pot is made of plate steel, enclosed in a brick chamber, and generally is heated by gas or oil burners or by an immersion heater. The flux box is a long narrow box with its sides converging downward but without any top or bottom. It is located on the entry side of the tin pot and the lower edges extend downward into the molten tin bath. The flux bath, approximately 3 to 4 inches in depth, floats on the surface of the molten tin bath. The space between the bottom of the flux box and the opening in the partition is equipped with top and bottom guides. In addition, either an apron or guides are provided in the tin bath chamber to control the path of the plate from the flux box into the nip of the bottom rolls in the tinning machine (see Figure 37—2). The flux in common usage is essentially a water solution of zinc chloride which may contain some ammonium chloride.

The tinning rolls in the palm oil are equipped with wipers or brushes, whose function it is to aid in the control of the tin coating. These brushes are, of course, adjustable from outside the actual oil chamber. They commonly are constructed of either soapstone or asbestos or of laminated combinations of these materials. Directly above the exit set of rolls, approximately 18 inches away, is the catcher. This mechanism consists of a frame supporting guides and rolls which feed the coated and oily sheets from the exit side of the pot past a jet of cooling air to the conveyor.

The palm-oil bath on the exit side of the tin bath, in addition to protecting the surface of the molten tin bath from oxidation, tends to keep the tin coating on the sheet in a molten condition and thus allows the tinning-machine rolls and brushes to control the distribution and thickness of the tin layer. Temperature of the palm oil is maintained as low as is consistent with satisfactory operating conditions, usually about 465° F. Oil generally is recirculated through a central reservoir. Excessive oil temperatures may cause the formation of oxide films of various colors, resulting in unsightly tin plate. Tin oxide films are discussed more fully later under "Metallurgical Aspects." The viscosity of the palm oil is also of prime importance because excessive oil is carried out of the bath if it is too viscous.

After being transferred by the catcher to the conveyor, the plate travels through the wet washing machine (Figure 37—1). The purpose of this unit is to remove the excess of palm oil from the surface of the coated sheet. The washer contains a hot water solution of soda ash or trisodium phosphate at a concentration of 0.10 to 0.15 per cent total alkalinity. The solution in most plants is circulated from a central storage tank which supplies the entire tinning shop. The inflow of solution is controlled automatically and the overflow is collected in a drainage system or sump. The palm oil is removed at this point for future use.

The washed sheet is now relatively free from oil. Since the sheets are unsatisfactory for ultimate use without some oil being present, the sheet is next passed into a branner where a light oil film is distributed across the sheet surface. The branner unit consists of tandem sets of cleaning rolls composed of thousands of cotton flannel discs about 4 inches in diameter tightly compressed on a long square steel mandrel. Bran or middlings (a mixture of wheat and rye) are fed into the first set of rolls to absorb the moisture, and distribute uniformly the oil that remains on the plate surface from the washer. The last rolls of the machine, together with a combination of vacuum and pressure hoods, are used to minimize the presence of bran on the sheets. From these hoods the product passes down the conveyor to the piler, which automatically stacks the plate in neat piles without scratching or otherwise marring the tinned surface.

Coke Tin Plate—Tinning Roll Practice—The most commonly supplied grades of hot-dipped tin plate are Standard and Common Cokes. On Standard Cokes the mills aim for an average tin coating weight of 1.35 pounds per base box of plate and for the Common Cokes the aim is an average tin coating weight of 1.10 pounds per base box. In order to obtain the best possible uniformity of coating, the middle and top sets of tinning-machine rolls in the exit side of the pot usually are grooved spirally. The depth of grooving varies with the results desired for a given tin-house practice, but in general the grooves on the top set of rolls are shallower than on the middle set. The heavier the coating desired, the deeper is the grooving. As previously mentioned, the roll brushes also play an important part in the control of coating weight and coating distribution.

HOT-DIPPED TIN PLATE COATING WEIGHTS

The following is a quotation from American Iron and Steel Institute Steel Products Manual "Tin Mill Products," July 1954, with the table number altered to conform to present text:

"There are several classes of hot dip tin plate which are designated by terms that have been used since the early days of tin plate manufacture. The distinction between classes is based upon a difference in the weight of tin used to produce a base box of tin plate. This weight, by custom, is referred to as tin pot yield and reflects the total weight of tin used in the manufacturing operation. The actual average weight of tin coating on the plate is less than the pot yield for each class due to unavoidable losses of tin in the tinning operation.

"On hot dip tin plate, the coating is mechanically distributed over the plate surface by tinning rolls. Due to the nature of the hot tinning operation and the elevated temperature of the tin metal it is not possible to control, within close limits, the tin coating weight on individual plates and from plate to plate.

"Coke Tin Plate, other than Best Cokes and Kannars Special Cokes, did not carry a specified coating weight prior to the second World War. The necessity for the conservation of tin caused the United States Govern-

ment to issue restrictions on the amount of tin to be used on tin plate. Federal Material Orders were promulgated which limited the amount of coating on hot-dipped tin plate on the basis of pot yield, and later orders stated, 'coating shall be determined on the basis of pot yield, in the case of hot dipped tin plate.' The orders limited the pot yield, or the amount of tin consumed in the manufacture of hot dip tin plate, requiring that the over-all average must not exceed 1.25 pounds per base box for 1.25 pound coke tin plate and 1.50 pounds per base box for 1.50 pound coke tin plate, now customarily designated as Common Cokes and Standard Cokes, respectively.

"The tin coating weight test values shown in Table 37—II are the minima which one may expect to encounter when the plate is tested according to the procedure recommended under Sampling. Experience has shown that the average tin coating is substantially higher than these values. Typical tin coating weight distribution data are contained in Report of Industry Survey of Coating Weights of Hot Dip Tin Plate, Contributions to the Metallurgy of Steel, No. 39, April 1952, published by the American Iron and Steel Institute. Production control test records indicate that over an extended period the average coatings on Common Cokes and Standard Cokes will approach 1.10 and 1.35 lb. per base box, respectively. Due to limitations of the process, these averages cannot always be maintained in the production of specific items.

"The coating weight in localized areas on occasional plates, as determined by spot samples selected in the manner described under the recommended sampling procedure, varies as much as 0.25 lb. per base box under the values shown in Table 37—II. Exceptional instances of even lower coated areas sometimes occur.

"Other classes of coke tin plate carrying heavier coatings, as shown in Table 37—II, are Best Cokes and Kanners Special Cokes.

"Charcoal Tin Plate—The distinguishing characteristic of charcoal tin plate is higher luster, due to heavier coatings, and these in the order of their increasing weights are designated: 1A and 2A. Coating weight test values for these classes are shown in Table 37—II. Charcoal tin plate is used in the manufacture of articles, the appearance of which is an important consideration, and where greater resistance to corrosive conditions is requisite.

Table 37—II. Coating Weights of Standard Grades of Tin Plate

Class Designation	Minimum Average Coating Weight Test Value (Pounds per base box)
Common Cokes (1.25 lb. per base box pot yield)	0.85
Standard Cokes (1.50 per base box pot yield)	1.05
Best Cokes	1.19
Kanners Special Cokes	1.40
1A Charcoal	1.80
2A Charcoal	2.30
3A Charcoal	2.80
4A Charcoal	3.50
5A Charcoal	4.20
Premier Charcoal	4.90

"Silver Tin—Silver tin has a dull surface, the base plate of which has been mechanically roughened and which carries a heavy tin coating of no specific weight.

"Sampling—When coating weight check tests are conducted on a shipment of any specific item of hot dip tin plate, based on experience the following procedure is recommended.

"One plate is taken at random from each 50 packages, with a minimum of three sample plates, each taken from different multi-package units from any one item of a specific shipment. Each sample is spot-tested at three positions taken on a diagonal across the plate. Spot samples are customarily discs or squares, each of 4 sq. in. area. In order to secure representative samples they are taken so that the outer edge of the sample is at least one inch from any edge of the plate. The average value of all spot tests on all plates tested represents the average coating weight test value.

"Experience has revealed significant variations in test results. The variations arise in part from the use of different tin coating determination methods, and they are also affected by the personnel and techniques of the testing laboratories. The significance of test results and comparison of them with check test results depend also on close control of sample locations on the plates tested. For such reasons great care should be exercised in making the tests as well as in the interpretation of the results of those tests. (End of quotation)."

Heavy-Gage Tin Plate—For the heavier gages, a longer sweep is necessary in passing through the pot to avoid pronounced "bowing" or "breaking" of the plate and for this purpose, a "hillside" machine is usually used. In this design, the tinning rolls are positioned at an angle (approximately 45 degrees) rather than one of them being directly over the other, and more liberal radii of curvature are employed on guides and aprons.

Manufacture of Charcoal Tin Plate—In order to produce the heavier coated charcoal plate, it is necessary to modify the tinning equipment in such manner that the tinning rolls carry more metal. This is accomplished in a conventional machine by replacing the brushes on the top or top-and-middle rolls with pans. Tin is supplied to these pans by ladling or pumping molten metal into them; the bottom of the rolls revolving in the tin. These rolls have grooves up to 0.008 inch deep.

Assorting of Hot-Dipped Tin Plate—After the tinning operation, the coated sheets must be inspected and classified. Individual standards for a given grade and application may vary somewhat, but the general classifications are (1) primes, (2) seconds, (3) menders, and (4) waste-waste. These classifications are defined as follows:

1. **Primes** are tin plates free from defects readily observed by the unaided eye.
2. **Seconds** are tin plates having imperfections in moderate degree or extent.
3. **Menders** are those tin plates having imperfections in coating, which product, upon recoating, will produce either a "prime" or "second" quality sheet.
4. **Waste-waste** are tin plates which, either through imperfections of coating or base metal cannot be recoated to produce a "prime" or "second" quality sheet.

The plates from the tin stack pilers are inspected visually on both sides for various base-metal surface defects, tinning defects and handling damage. During the assorting operation, the product is checked for individual sheet weight and commercial flatness. The sorters soon

develop a high degree of skill in detecting slight differences in weight and recognition of surface defects as they handle individual sheets. In recent years some semi-automatic assorting machines have been installed. By the latter method, the individual plates travel on belt conveyors by an inspection station and are automatically turned over to permit two-side inspection. In the manual assorting operations, the same end is accomplished but the assorter must turn over every plate by hand and

properly classify it at the same time. Each assorter maintains separate bins for menders and waste-waste, but most hot-dipped tin plate orders permit the inclusion of primes and seconds together. Hence, these two quality classification types are placed in the same pile after classification. Following the assorting operation, the prime and seconds plates are "reckoned" or counted individually, packaged in containers as specified by the customer, tagged, wired and shipped.

SECTION 6

ELECTROLYTIC TIN PLATE

Introduction—Prior to 1937, all tin plate produced commercially was manufactured by the hot-dipping process. While the electro-deposition of tin on steel had been a known process for many years, its application to the production of tin plated sheets could not be made to compete economically with the hot-dipping process due to much higher equipment and labor costs. However, with the introduction to the sheet and tin plate industry of continuous cold-reduction mills in the early 1930's, the possibility of continuous high-speed electro-tinning became obvious. As early as 1935, small experimental units were designed and constructed capable of continuously electroplating tin on steel strip moving at relatively high speeds. From the results of these studies, electrolytic tin plate appeared on the market as a commercial item in 1937.

The early development of electrolytic tin plate was given a major impetus by the requirements of the dry package market for a light-coated product which could not be produced by the hot-dip process. The precipitous necessity to conserve vital tin during World War II resulted in a phenomenal expansion of this development so that by 1948 over half of the tin plate produced was light-coated electrolytic tin plate and by 1955 it was 80 per cent.

The superiority in tin coating uniformity which electrolytic tin plate exhibits as compared to hot-dipped tin plate, together with the close control of tin coating weight which is obtained, has resulted in large savings of tin.

Basic Principles of Electroplating—To the famous English scientist, Michael Faraday, belongs the credit for placing electrochemistry on a quantitative and orderly basis. In 1833, he postulated certain laws which today bear his name and which can be summarized as follows:

1. In any electrolysis, the quantities of materials liberated at the electrodes bear a direct relationship to the quantity of electricity passed through the system.

2. An equal number of equivalents of substances are set free by the same quantity of electricity.

It can be seen from a study of these laws that tin plating can be controlled when the electrode reactions are known. Electroplating can be accomplished with acid or alkaline electrolytes.

In the acid processes the anode reaction consists of direct oxidation from metallic tin to the bivalent stannous ion with the liberation of two electrons as follows:

The reaction is usually 100 per cent efficient, thus making the quantity of tin driven into solution directly proportional to the electrical energy used. The reverse reaction takes place at the cathode,

thus causing metallic tin to be deposited on the cathode which, in electrolytic tinning lines, is the moving steel strip. The cathode reaction may be 100 per cent efficient or it may be somewhat less. The latter condition is desirable since the resulting tin build-up in the solution eliminates the necessity for additions of tin salts when solution losses occur. The use of organic addition agents in acid baths appears to be essential to the production of dense adherent tin deposits. While such agents may lower the operating cathode efficiency somewhat, the effect is slight.

There are several successful acid baths used for electroplating, among them being the phenol-sulphonic acid bath, the fluoride-chloride bath, the fluoborate bath and the sulphate bath. In each of these the electrode reactions are the same. Additions of acid are commonly made to raise the conductivity of the electrolyte and thus lower the plating power consumption.

The electrode reactions which take place in the alkaline baths are somewhat complex. The over-all effects are well known, however, thus permitting satisfactory control of the deposition. The net reaction at the anode is to oxidize tin from its metallic state to the quadri-valent stannic condition, as follows:

It will be noted that four electrons must be liberated to drive an atom of tin into solution in this process as compared to two electrons in the acid process. This means that twice as much electric current is required to dissolve one pound of tin. It must be emphasized that the anode reaction shown above is an over-all effect since the actual mechanism at the anode indicates the formation of intermediate tin compounds during the transfer process. This complexity of the tin anode reaction in the alkaline stannate process limits its operating current density and thus necessitates the use of large plating areas to achieve high operating speeds.

At the cathode (steel strip) the tin is reduced again to the metallic condition with the absorption of four electrons per atom:

When operating temperatures are kept above 200° F, the electrode efficiencies of the alkaline processes are quite close to 100 per cent.

Commercial Electrolytic Tinning Equipment—The equipment used for the production of electrolytic tin plate in no way resembles the more common electroplating equipment seen in most plating shops. The complex and bulky machinery required to handle the heavy steel coils and the fast moving steel strip itself is much more expensive and usually takes up more space than the plating unit proper.

Figure 37—3 is a schematic diagram of the equipment used in United States Steel Corporation units. An actual

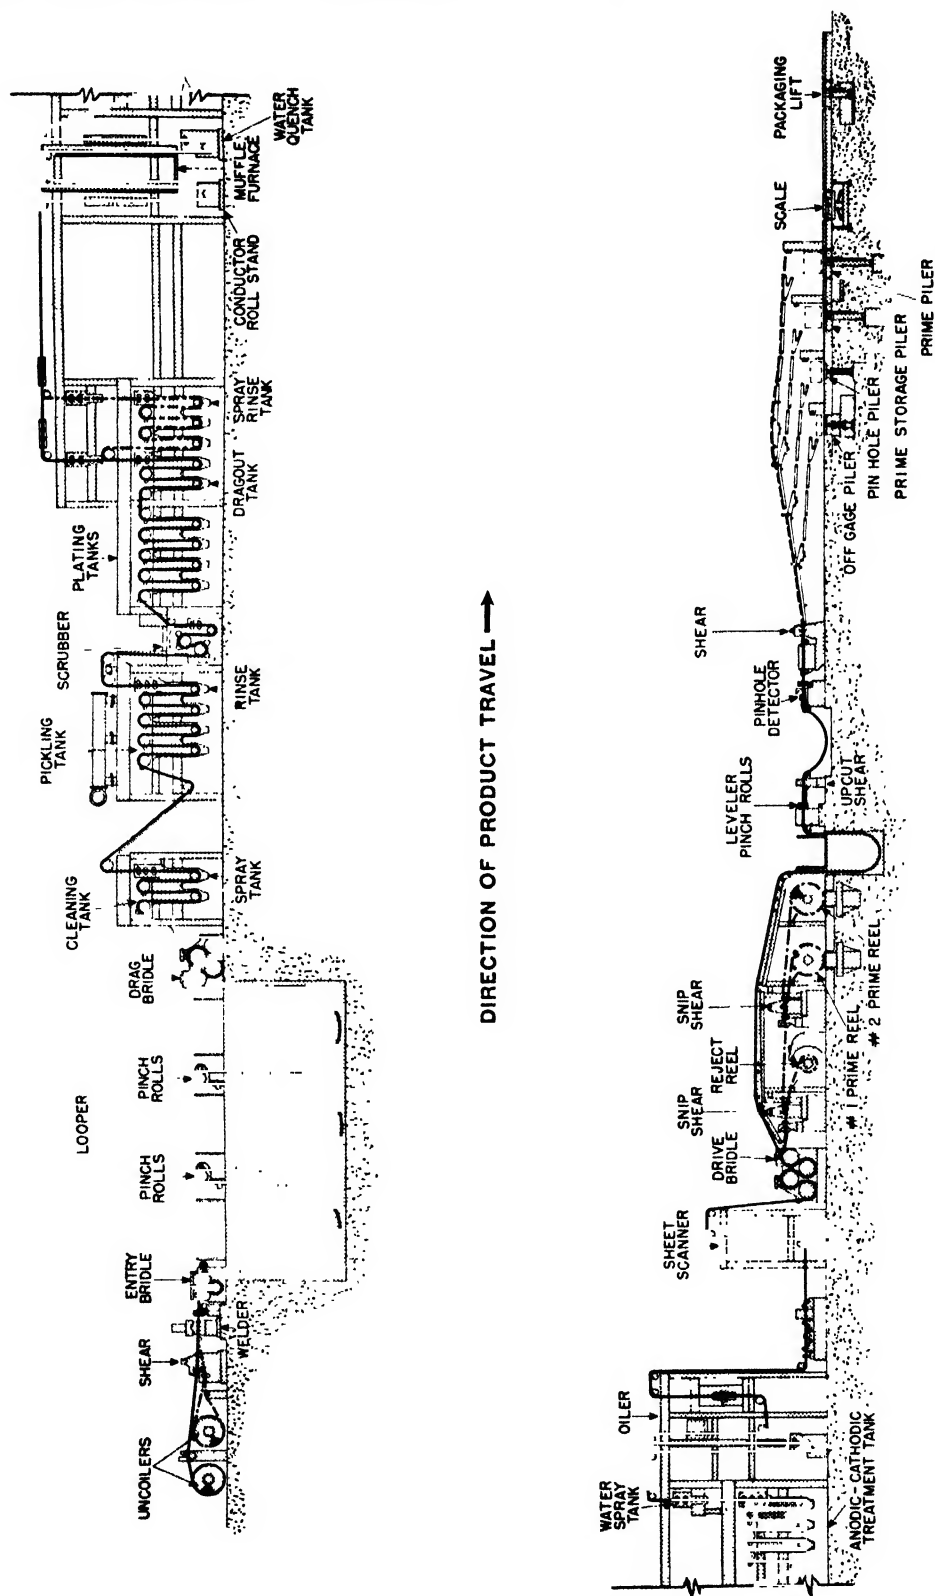

FIG. 37—3. Schematic arrangement of the handling and processing units comprising a sulphonic acid electrolytic tinning line.

FIG. 37—4. Close-up view of the plating unit of a sulphonic acid electrolytic tinning line, with melting tower immediately behind in right center background.

installation is shown in Figures 37—4 and 37—6 through 37—9. The electrolyte used is a solution of stannous sulphate and phenolsulphonic acid, capable of carrying current densities up to 400 amperes per square foot or more at cathode efficiencies of 95 per cent or better; such operating conditions permit the use of relatively small plating tanks. The alkaline stannate units, also in wide use, are basically similar in design but require considerably larger plating units. This difference in design is necessary because of the low current density limit of the alkaline bath, which is usually a solution of sodium stannate and sodium hydroxide. The alkaline electro-

lytes in general operate at current densities up to 60 amperes per square foot.

The third common type of electroplating line makes use of an acid halogen type electrolyte and is so constructed that the bottom side only of the strip is plated in horizontal baths during its travel through the unit. The plating section of the line is composed of many individual plating tanks with tin anodes resting on the bottom of each. The horizontal tanks are set one above another. As the strip leaves a lower tank and passes over a roller guide to reverse its direction of travel and enter the tank at the next higher level, what was the bottom

FIG. 37—5. Side-trimming unit that prepares cold-reduced, annealed and temper-rolled coils of flat steel for electrolytic tinning by removing excess material from side edges to produce strip of exact desired width. An air-operated shear following the side trimmer cuts off the crop ends of coils preparatory to seam welding of successive coils together to form larger single coils weighing up to 30,000 lb.

FIG. 37-6. Entry end of an electrolytic tinning line, with one uncoated coil being paid off into the line and another in reserve position. The trailing end of the coil being fed will be welded to the leading end of the reserve coil (after squaring in the shear) to provide a continuous feed to the line.

surface of the strip becomes the top surface. Thus, the strip is reversed on each plating level to permit even deposition on each surface of the strip. Current densities vary from 50 amperes per square foot upward.

Regardless of the type of plating unit used, the steel strip for manufacturing electrolytic tin plate is similarly prepared. The strip itself is manufactured as described elsewhere; that is, it is hot rolled from slabs, continuously pickled, cold reduced, electrolytically cleaned, box or continuously annealed and temper rolled. In box annealing, a protective deoxidizing atmosphere is used to insure a uniform, bright surface and the temper rolling operation is carefully controlled to maintain this condition. At this point in the processing, strip for electro-tinning takes a different course than that for hot-dipped tin plate as the retention of a long, uninterrupted unit of strip is needed for the success of the operation. Accordingly, the coiled temper-rolled strip is usually delivered to the side trimming units (Figure 37-5) where it is uncoiled, run through pairs of rotary knives and recoiled. The rotary knives are adjustable in such a manner that the strip can be very accurately side trimmed to the width ordered by the customer. It is general practice to adjust the slab selection and hot-rolling practice to obtain about $\frac{1}{2}$ inch protective over-width on the process strip which is removed at these slitters. In some instances, this strip side trimming is done after tinning in a separate shearing operation. In many plants where the strip is trimmed before coating, lap welding equipment is included in the side trimmers to permit welding several coil units together and thus provide a continuous section of steel strip for plating, up to six or seven miles long. In other plants, the side-trimming operation is performed in the electrolytic tinning unit itself.

The entry end of an electrolytic line is usually so designed as to provide two uncoilers in line (Figure 37-6). This permits the operator to "pay off" from one uncoiler while charging a coil into the other. Electrolytic tinning units do not require any special type of unreeling equipment and either the conventional cone or expanding

types are in use. All of the auxiliary uncoiler equipment such as brakes, forward and reversing drives, hydraulic lifts, and strippers are usually to be found on all units.

In preparing a coil for processing, the lead edge of the strip is manually engaged in a set of small pinch rolls which can be opened and closed by air pressure and which are usually motor driven. The function of these rolls is to permit the operator to advance the lead edge of a new coil into the welding assembly. This welding assembly consists primarily of an up-cut shear, a lap welder, and a set of large pinch rolls.

It is desirable to maintain a high strip speed in the plating baths, so facilities are provided to join fresh coils to the strip without reducing line speed. As the coil in process is being unrolled, the operator takes care that the maximum amount of strip is contained in the looper located just after the large welder pinch rolls. When the last several wraps of the coil unwind from the uncoiler in use, the operator stops the large welder pinch rolls, "trues-up" the tail end of the coil with the up-cut shear, moves this tail end into welding position with the head end of the new coil, welds the two together and starts the welder pinch rolls into motion. All this must be done before the strip previously stored in the looping unit has been completely used. The welder pinch rolls are then run at some speed greater than line operating speed to refill the loop at which point automatic electrical devices slow these rolls back to synchronism with the rest of the unit. Since these looping units are usually designed to accumulate 300 to 500 feet of strip, it is obvious that the welder operator must act rapidly in order not to slow a line operating at 600 feet per minute. These loopers may be a "tower" type, a "pit" type, or a combination of the two. The "tower" type looper, as its name indicates, is constructed predominantly above ground and usually consists of fixed and movable sets of rolls over which the strip is passed. The top set of rolls moves down or up, depending on whether strip is being expended from or accumulated in the equipment. The "pit" type looper consists of a deep pit in which hangs a long catenary of strip.

From the looper the strip enters the main process section of the line. In the acid lines, the process section usually consists of a dynamic tension device (often called a tension bridle), an alkaline electrolytic cleaner, a rinsing unit, a pickler, another rinsing unit, a plating unit, a third rinsing unit, a fusion unit, a quench tank, a chemical treating unit, a fourth rinsing unit, a drying unit, an oiling unit, a drive or pull-through bridle, and finally a set of recoilers or a shear or both. The alkaline lines have the same sequence of units except that the alkaline cleaner is not part of such lines inasmuch as the alkaline plating bath itself does sufficient cleaning.

The function of the tension bridle is to produce sufficient drag on the strip to maintain a positive strip tension throughout the line. It consists of a series of rolls, some of which may be pinch rolls, through which the strip passes out of the looper. These rolls are usually geared together and to a generator. By controlling the field voltage on this generator and "shorting out" the armature through a resistance, a controllable drag can be applied to the strip through the geared rolls.

In the acid electrolyte units, the strip passes from the drag bridle to the alkaline electrolytic cleaners. In some lines these cleaners are of conventional design, with horizontal electrodes as described in the section on the electro-cleaning of cold-reduced strip. In other lines, vertical units are used. Current densities in these units vary from 50 to 300 amperes per square foot. The clean-

ing solutions are alkaline detergents. Strip polarity may be either anodic or cathodic since it is found that both conditions yield good cleaning performance.

The strip passes from the alkaline cleaner into a rinsing and scrubbing unit. Its function is to remove all alkali from the strip in preparation for the pickling operation. This rinsing unit is usually comprised of water sprays playing on both sides of the strip and of rotary bristle brushes which rotate vigorously against the strip. There is a trend toward the use of high-pressure water sprays and the elimination of brushes in such units.

The strip pickling units, which are used on all electrolytic tinning lines, may be of the hot immersion type or of the cold electrolytic type. The immersion type usually consists of a large rubber- or brick-lined tank through which the strip passes vertically or horizontally. These tanks are filled with hot sulphuric acid of a strength varying up to 12 per cent and the pickling time is regulated by the operating strip speed. The electrolytic picklers are usually small units as the control of pickling is maintained by regulation of the electric current. These units are built similar to the alkaline cleaning tanks and the electrical circuit is also similar; the strip may be alternately anodic and cathodic, assuring effective surface cleaning. After pickling, the strip is again rinsed in a unit similar to the one used after the alkaline cleaner and enters the plating tank.

As explained earlier, the main difference in the vari-

FIG. 37-7. Tin anode being placed in the plating tank of an electrolytic tinning line, with other anodes lined up awaiting placement.

ous electrolytic tinning units lies in the type of electrolyte used; hence, the type of plating tanks used. The unit used in phenolsulphonic acid lines is designed for operation at high current densities and consists of four vertical compartments in each of which the strip passes over metal contact rolls and down into the electrolyte between banks of tin anodes. (A fifth compartment in line with the four plating tanks and identical in appearance plays no part in the plating operation but merely collects the solution dragged out of the plating system.) Thus, the current can be considered to pass from the tin anodes through the solution to the strip and up the strip to the metal deflector rolls which act as the negative contact of the system. By such a circuit, the tin is deposited from the solution onto the strip and is also equally driven into solution from the anodes. The tin anodes consist of tin bars which, for example, may be 3 inches by 4 inches in cross section and approximately six feet long, weighing close to 200 pounds each (Figure 37-7). The life of the individual anode depends on the quantity of electric current passing through it. The electrolyte is constantly recirculated through the plating tanks after passing through a settling tank and several water coolers. The temperature of the bath is generally maintained at about 100° to 120° F. All of this equipment must of necessity be constructed of corrosion-resistant materials and care must be taken to provide sufficient insulation in the system to prevent electric current leakage. Generating equipment capable of developing 45,000 amperes at 8 volts has been a typical installation.

The alkaline-type plating bath, while essentially of the same basic design, requires much greater floor space than the acid type. Inasmuch as alkaline stannate baths are operated at temperatures in excess of 200° F, no recirculation of the electrolyte for cooling is necessary.

These plating tanks are fabricated as a single large unit with contact rolls placed at the top of the tanks and rubber deflector rolls placed in the bottom. The tin anodes used in the alkaline units are usually very large slabs of tin hanging under and between the contact rolls. These slabs are large enough to allow several weeks of operation before replacement is necessary. Alkaline lines are provided with up to 90,000 amperes at 10 volts, with current densities of about 45 amperes per square foot permitting strip speeds up to 600 feet per minute on half-pound coatings.

The third type of unit (halogen) consists of a series of small cells, each with its own circulation system, contact roll and anode bank. These tanks are so designed that the strip is barely immersed in the electrolyte and is plated on the bottom side only. After passing through a number of these units, the strip is deflected upward and backward so that the original top of the strip now becomes the bottom. It then passes through another series of similar plating cells until an equal amount of tin is deposited on this side of the strip. The halogen type electrolyte used exclusively in these units is constantly recirculated through the cells, cooled and filtered during its circulation. The tin anodes used in the individual cells resemble regular pigs of tin and rest on side supports just under the strip pass line. Halogen lines have been designed for strip speeds greater than 2000 feet per minute. Generator capacity exceeds 100,000 amperes at a voltage of from 8 to 10 volts. The current density used is approximately 300 amperes per square foot.

The plated strip, regardless of plating process, is now freed from the dragout and rinsed in pure water or condensate. The electrolyte which is dragged into this wash water is all or in part returned to the plating tank. To accomplish this, drag-out recovery systems varying

FIG. 37-8. General view of an electrolytic tinning line, looking toward the entry end and showing the melting tower in the center foreground.

from complex recirculation and evaporation systems to simple counter-current rinsing with partial recovery are used. Too much emphasis cannot be placed on the necessity for efficiently recovering the dragged-out electrolyte since solution losses from this source can be enormous at high speeds, reaching as much as 30 gallons per minute.

The tin coating, as it emerges from the plating bath, is grey-white and semi-lustrous. It does not in appearance resemble tin plate as it is commonly known. While some attempts have been made to plate bright tin coatings, no commercially successful developments of this type are at present practiced. Instead, it is universal practice to melt and quench the electrodeposited tin which gives it the brilliant luster typical of hot-dipped plate (Figure 37-8).

There are three types of units in which this tin fusion is accomplished. They vary only in the source of heat and not in basic construction. One of these melting units makes use of electrical resistance heating. The strip is run in a vertical loop between two contact rolls, the second of which is partly immersed in water. These two contact rolls form the terminals of an alternating-current circuit in which the strip is the closing resistance. Thus, by regulation of the current flow through the strip (or applied voltage) it is possible to bring the plated strip up to 450° to 455° F just prior to passage into the water. The maximum temperature to which this strip can be heated falls in a very narrow range because excessive heating causes discoloration of the product and/or high iron-tin alloy, whereas insufficient heating naturally results in failure to melt. A second type of melting unit utilizes high-frequency induction for melting. In this unit, the strip passes down and through a water-cooled copper coil on which is impressed a high-frequency voltage. The induced eddy currents in the tin plate strip cause it to heat up with resulting fusion of the tin coating. Control is again exercised by voltage variations on the induction coil terminals. The third type of melting unit in commercial use is gas-heated and equipped with special ceramic burners which radiate controlled amounts of heat to the strip. Control on such units is exercised by lateral movement of the burner banks, closer to or farther away from the strip, depending on whether more or less heat is required. Further limited control is available by regulation of the gas supply to the unit. As in the other units, the strip is

quenched directly after fusion of the tin is accomplished.

The fused and quenched coating is now given a **filming** treatment which may be either chemical or electrochemical, as described later in this section. After such treatment, the tinned strip is rinsed with clean water and is dried either by blasts of hot air or high-pressure steam.

Unlike hot-dipped tin plate, the electrolytic plate is not oily as it emerges from the coating operation; hence, it is necessary to deposit a controlled oil film on the product in order to improve its handling properties in succeeding operations. The oil used is usually cottonseed (synthetics such as dioctyl sebacate, DOS, are also finding favor) which is applied in several ways. Two oiling methods now widely used on electrolytic tinning units are the emulsion and electrostatic processes. The first of these consists of passing the strip through a bath or a spray of unstable oil emulsion. Control of the resulting oil film is exercised by emulsion composition and operating temperature. After exposure to the emulsion the strip passes through wringer rolls, is rinsed and dried and passes into the pull-through bridle ready for recoiling or shearing. The electrostatic method of oiling strip makes use of a high potential between the strip and a fixed electrode which creates a powerful electrostatic field around the moving strip. Into this electrostatic field is allowed to rise vaporized palm or cottonseed oil. Since such vapors consist essentially of charged particles, they are deflected onto the strip by the proper adjustment of strip polarity. Despite the relative complexity of the equipment, these oiling units operate very satisfactorily and economically.

The strip next enters the unit which supplies tractive power to the strip to pull it entirely through the electrolytic line. This piece of equipment is called the "pull-through" or drive bridle. It actually does the pulling of the strip through the process section and is the basic unit with which the plating current and both entry and delivery ends are synchronized. The equipment itself is usually quite similar to the tension bridle described elsewhere in this section. However, instead of a drag generator being geared to the rolls, they are coupled with a powerful motor which is sufficiently large to pull the strip through the whole process section at high speeds. A tachometer generator attached to this motor provides the impulse to regulate the plating and melting currents in required relation to strip speed.

FIG. 37-9. Discharge end of an electrolytic tinning line, showing sheared-plate pilers (left) and inspector.

A great many of the tinning units currently operating are provided with loopers and two recoilers on the delivery end into which the strip passes from the drive bridle. Such an assembly performs in a reverse manner to that of the entry end previously described. The looper acts strictly as a strip accumulator. It normally operates with a minimum length of strip between rolls so that it is capable of accumulating strip at line speed while recoiler switching is underway. As soon as this switch is made, the operating recoiling unit speeds up until the loop is absorbed, at which time it automatically falls into synchronism with the processing section of the line. The coil of coated product is discharged from the inoperative recoiler and sent to the conventional shearing units where it is sheared to size, oiled (if not so treated in the electrolytic unit itself), assorted, counted and piled. At least one modern line is now provided with both flying shears and quick-change coilers. The latter need to be used only for product which is shipped to the customer in coils, and are not preceded by a looping device.

In those units where flying shears only are included in the equipment assembly, no "loopers" are necessary. Instead, a very small catenary is maintained immediately in front of the shear in order that perfect guiding into the shear knives can be accomplished. Failure to guide properly into a shear results in miscutting and "out-of-square" sheets. The flying shears themselves are conventional units for light-gage-strip shearing, as described elsewhere in this chapter. There are some modifications, however, which should be mentioned. The most important ones concern the adaptation of these units for careful inspection, classification and counting of the product (Figure 37-9).

The flying shears are equipped with four piling stations and a system of conveyor belts which allows the deposition of sheets in any of these pilers at the will of the operator.

In lines containing four pilers, all sheets containing

perforations are accumulated in the first piler. Sheets containing bad surface defects and product which is outside the accepted gage tolerances are accumulated in the second piler. The third piler is intended for disposition of sheets which, while not acceptable as prime product, contain only superficial coating defects. Such product is usually referred to as "menders" inasmuch as it is common practice to pass it through a hot-dip unit for conversion to hot-dipped tin plate (thus "mending" the product). The fourth or end piler is the so-called "prime" piler. As the sheet counter is located between the third and this prime piler, the product delivered into it is usually counted into ten-, twelve-, or fifteen-package bundles (1120, 1344 or 1680 sheets) ready for packaging and shipping.

The methods of inspection and classification of electrolytic tin plate on these flying shears are rather ingenious. Located somewhere after the melting unit is a non-contacting thickness gage. When the strip is too thick or too thin to meet specifications, the gage actuates an electronic memory device which rejects those particularly heavy or light sheets at the second piler. Likewise, a photoelectric cell continuously scans the coated strip and causes sheets with perforations to be deflected into the first piler.

Trained inspectors are located at the pull-through bridle and the shear, respectively; they operate contact buttons which allow them to deflect at will any defective product they detect into the second or third piler (depending on product classification) and pass prime product into the fourth piler where the attendant sees that it is properly counted and that the shear operator is kept advised of the product flatness.

Laboratory determinations are made regularly to determine the tin coating and oil film weights on the finished product. Various laboratory controls of cleaning, pickling and plating solution characteristics are necessary.

SECTION 7

METALLURGICAL ASPECTS

General—A fuller appreciation of the metallurgical aspects of tin plate may be had by considering it as a nine-layer sandwich (Figure 37-10), the layers of which consist of:

1. Oil layer
2. Tin oxide
3. Free tin
4. Tin-iron alloy
5. Steel base
6. Tin-iron alloy
7. Free tin
8. Tin oxide
9. Oil layer

Adaptability for a specific purpose may depend on the properties of a given layer. To illustrate, for a pressed part, such as a toy, the drawing characteristics of the steel base may be the controlling factor. In the case of electrolytic tin plate, the chemical filming treatment gives an oxide layer found beneficial for adhesion of lacquers and enamels. Similarly, tin plate must have an oil film adequate both to promote good "feeding" in automatic equipment and to prevent scratching during fabrication and yet not so heavy as to cause difficulty during roller coating with lacquers or printing inks. Thus, each layer requires adequate control for some of the applications. Generally, since the manufacture of tin plate is on a mass production basis, it is most economical to standardize on the optimum quality of each layer for total tin mill production.

The Steel Base—The metallurgical controls of the steel

base are similar to those employed for the production of sheet and strip and, hence, will not be elaborated on further. It is sufficient to point out that mechanical properties of the finished tin plate depend on the composition of the steel, the heat treatments and the rolling opera-

FIG. 37-10. Schematic enlarged cross-section of a sheet of tin plate, showing approximate relative thicknesses of the various "layers." The approximate thickness in inches of the individual layers is as follows:

Layer	Thickness (In.)
Oil film	10^{-7} (0.0000001)
Tin oxide	10^{-7} (0.0000001)
Tin	10^{-4} (0.0001)
Alloy layer	10^{-6} (0.00001)
Steel base	10^{-2} (0.01)

tions. Inasmuch as the steel used is a low-carbon mild steel and as the usual hardening agents are looked upon with disfavor because of their detrimental effect on corrosion resistance, as well as cost, strengthening by variations in composition is limited to addition or control with respect to phosphorus and nitrogen. Phosphorus has been used in amounts up to 0.15 per cent but its use is limited to tin plates employed for non-corrosive food and non-food containers.

Strength, or temper, is further controlled by regulating the amount of temper or "skin-pass" rolling. The tin

plate industry has adopted the Superficial Rockwell Hardness test as a control measure of the temper of the strip. This test is described elsewhere.

As the major portion of tin plate is used for containers, the requirements of this application dictate most of the metallurgical considerations in the processing of the steel base. As will be pointed out more fully in a later paragraph, the corrosion resistance of tin plate to food products is an important consideration—and in this respect the production of steel sheet for tin plate differs from the production of sheets for other applications.

FIG. 37—12. Illustrating the rate of growth (increase in thickness) of the iron-tin alloy layer with increasing time of immersion of the steel base in molten tin at a temperature of 600° F.

Many factors affect the corrosion resistance of tin plate, but quality of the steel base is probably the most important. Besides the composition, the various processes, such as hot-strip rolling and the annealing after cold reduction, are subjected to even closer control than would be necessary from the standpoint of mechanical properties alone.

The various cleaning and pickling operations, previously described, are also closely controlled so as to prepare a suitable surface for subsequent coating with tin.

The Tin-Iron Alloy Layer—When a clean steel surface comes in contact with molten tin, a reaction takes place with the formation of a tin-iron alloy layer intimately bound to the steel surface. This alloy layer is quite thin (about 10 to 15 millionths of an inch), in coke tin plate. Chemical analyses have shown the ratio of tin and iron to correspond to the intermetallic compound FeSn_2 .

The metallurgy of the tin-iron alloy has received considerable attention by various investigators. The phase diagram for the iron-tin system in Figure 37—11 reveals that there are probably at least three compounds of tin and iron.

1. Fe_2Sn , referred to as the epsilon (ϵ) phase, which is stable between 1400°F (760°C) and 1652°F (900°C) but can, in the presence of sufficient tin, react at 1472°F (800°C) to form FeSn or zeta (ζ) phase.
2. FeSn , or zeta (ζ) phase, which is stable at all temperatures below 1472°F (800°C) but which reacts with excess tin below 925°F (496°C) to

form the compound FeSn_2 , known as the eta (η) phase.

3. FeSn_2 , or the eta (η) phase, which is stable below 925°F (496°C) and does not react with tin to form a higher tin compound.

Inasmuch as tinning operations are always carried out at temperatures considerably below 925°F (496°C), it follows that the alloy layer should contain both eta (FeSn_2) and zeta (FeSn) phases. The results of X-ray diffraction studies and chemical analyses indicate that the compound FeSn_2 predominates.

It has been demonstrated that the amount of tin-iron alloy formed is a function of time and temperature. The initial formation is extremely rapid and subsequent growth is much slower (Figure 37—12).

The thickness of alloy can be determined by electrostripping, by chemical stripping, by magnetic testing, or by metallographic cross-sectioning. The most commonly used is the electrochemical stripping method. A 4-square inch sample is attached to a suitable holder and immersed in a 1 N solution of hydrochloric acid containing a carbon electrode and a silver—silver-chloride reference electrode. The tin coating is stripped anodically at a constant predetermined stripping current. The potential difference between the specimen and the reference electrode is continuously measured by a potentiometer recorder during the stripping operation. The slope of this potential-time curve will change as the stripping proceeds from the surface, to the alloy layer, to the base

FIG. 37—13. Flux pattern on the surface of the steel base (interface of iron-tin alloy and steel) of commercial coke tin plate having a coating weight of 1.49 lb. per base box, after removal of both the tin and the iron-tin alloy. Magnification: 3X.

FIG. 37—14. Reversal of flux pattern in corresponding areas on opposite sides of a sample of commercial coke plate (coating weight, 1.32 lb. per base box), showing steel surface (interface between iron-tin alloy and steel) after the tin coating and iron-tin alloy were removed. Magnification: 5X.

metal. With proper cathode-anode geometry, the changes in slope occurring when the potential changes at the several interfaces are clearly discernible. The distances between the so-called end points, or points where the slope changes (measured parallel to the time axis), are measures of the thickness of the free tin and alloy layers.

The alloy layer on tin plate has a very definite pattern according to the manufacturing practice. Hot-dipped tin plate produced with the use of a zinc chloride flux has a distinctive mottle shown in Figures 37—13 and 37—14. This pattern is the result of variation in thickness and crystal size of the alloy, the dark areas being thinner and finer grained than the light areas (see Figures 37—15 and 37—16). Electrolytic tin plate (melted) has a smooth fine-grained alloy layer similar to the dark areas in coke tin plate alloy layers (Figure 37—17). Matte finish (unmelted) electrolytic tin plate does not have an alloy layer detectable by ordinary metallographic or chemical procedures. Heating matte finish plate at temperatures below the melting point of tin will result in formation of tin-iron alloy, the amount formed being dependent on the time and temperature.

The alloy layer is important with respect to tin-plate quality, especially in 0.25 lb. per base box electrolytic tin plate, since an increase of thickness of the alloy layer results in a decrease of thickness of the tin layer and may result in soldering difficulties.

Physically, the compound FeSn_2 is very hard and brittle and of itself cannot stand much bending. In com-

mercial tin plate the alloy layer is very thin and is covered with a much thicker layer of ductile tin so that even sharp bending does not expose much of the base steel because the tin will bridge gaps in the alloy layer. With thick layers of FeSn_2 , bending will cause breaks through the tin. The crystallites in thick layers of alloy are produced only with prolonged heating at temperatures above the melting point of tin (450°F).

FeSn_2 crystals are also formed in the tin stacks by reaction of the molten tin with the equipment. This accumulation is known as tin dross which is periodically cleaned out of the pots. The tin dross is heavier than the molten tin and settles to the bottom but, because of the agitation by sheets passing through, small particles may become imbedded in the tin coating, resulting in coating defects known as scruff.

The Tin Layer—As seen in the photomicrographs, the tin layer is considerably thicker than the alloy layer. It is customary to estimate the thickness of the tin layer in terms of weight of tin per unit of area, rather than in terms of thickness measurements. Thus, coke tin plate will have on the average of 1.0 to 1.5 lb. of tin per base box, equivalent to 1.0 to 1.5 lb. spread over both surfaces of 31,360 square inches of steel. From the specific gravity of tin it is readily calculated that 1.0 lb. per base box of tin represents an average thickness of 0.00006 inch on a surface. The actual thickness at specific areas may vary considerably from the average.

The weight of coating is usually estimated chemically by dissolving samples of known area in hydrochloric

FIG. 37-15. (Above) Representative surface of iron-tin alloy layer on tin plate in dark areas, representing the interface between the iron-tin alloy and the tin of the coating, after removal of the tin portion of the coating. acid under non-oxidizing conditions and titrating the stannous tin to stannic tin with standard iodine or iodate solutions. Analytical textbooks give details of the procedure. Gravimetric stripping methods are also used but to lesser extent. Recent testing methods incorporate electrolytic methods for dissolving the tin followed by standard volumetric titrations. The tin plate from each producing unit is sampled periodically for tin coating weight.

Electrolytic tin plates are produced to much closer tolerances with respect to tin coating weight than are possible for the hot-dipped tin plates. At present, commercial grades include 0.25, 0.50, 0.75, 1.00 and 1.00-0.25 lb. per base box and the spread in tin coating weight is usually within 10 per cent of the average. Electrolytic coatings are capable of fairly precise control, variations being due to fluctuations in current flow or variations in distance of the strip (cathode) from the individual tin anodes.

Tin plate usually has a bright, lustrous, mirror-like surface. The luster varies somewhat with the surface finish of the steel base. Rough base finish will result in

poorer luster than smooth base finish. The luster is also affected by the thickness of the tin coating. Heavy tin coatings, as on charcoal tin plates, have bright luster irrespective of base metal roughness. The smoothness of the tin deposit on electrolytic plate also affects the luster.

Mild etching of the tin coating reveals a spangle which may take a variety of shapes. This spangling is evident on the interior of all non-lacquered cans which have contained fruits or vegetables. The pattern can also be seen on unetched surfaces when viewed under polarized light. The size of the spangle is a function of the rate of quenching. Slow cooling produces a massive grain or spangle whereas rapid cooling, as by water quenching in the electrolytic plating lines, produces a very small spangle. This is illustrated in Figure 37-18. The size of the spangle has no bearing on the quality of the tin plate.

The tin coating, even when as heavy as 6 lb. per base box, is not continuous but has microscopic areas of exposed base metal. These areas of exposed base metal are known as pores. The porosity of tin plate has been the subject of considerable research and excellent methods for indicating the degree of porosity have been devel-

FIG. 37-16. (Below) Representative cross-section through a light area similar to that shown above, etched to show the tin coating and the iron-tin alloy layer. Magnification of both photomicrographs: 1000X.

FIG. 37—17. (Above) Cross-section representative of commercial melted electrolytic tin plate (coating weight, 0.56 lb. per base box), etched to show iron-tin alloy layer. (Below) Unetched surface of iron-tin alloy layer (interface between iron-tin alloy layer and tin coating) after removal of the tin portion of the coating shown above. The surface of the iron-tin alloy has a pebbly appearance, indicating that it is not of uniform thickness. Magnification: 1000X for both photomicrographs.

oped: details of the procedures are summarized in International Tin Research Institute Bulletin, Series A, No. 7.

W. E. Hoare reports that the total area of iron exposed in pores is only about 0.7 sq. mm. per square meter of surface. The satisfactory commercial service of tin plate for fruit containers shows that despite these minute pores, the tin coating has excellent protective properties. This will be discussed more fully under resistance to corrosion.

The Tin Oxide Layer—An extremely thin oxide film is developed on tin plate immediately upon contact with the air as it emerges from the tin pot. At this stage the film is invisible. Depending upon the atmospheric conditions during storage this oxide film grows during long periods of storage. Experience has shown that areas of high humidity, such as adjacent to the Gulf of Mexico and on the West Coast, are the most critical in regard to expediting the natural growth of the tin oxide film. In the most severe cases the film becomes sufficiently thick to be visible. However, in the majority of instances the film is not visible until the baking operation which follows lacquering or lithographing. The visible films are very objectionable as they cause poor enamel adhesion and adversely affect solderability.

Just as temper colors are produced on steel surfaces by oxidation, so are varying colors developed on tin surfaces. Initially, tin surfaces show only their characteristic metallic luster, but as the thickness of the oxide film increases, interference colors develop, beginning with yellow. As oxidation proceeds, the color changes from yellow through brown and purple to blue. Under ordinary conditions, the various shades of yellow and brown are the only colors noted. Occasionally, under severe baking conditions, purple may be noted. When such colors appear on tin plate, it is said to be "discolored" and is likely to be unsatisfactory for some purposes. Inasmuch as the yellow color is most common, such films are generally known as "yellow discoloration" or "yellow stain." A further distinction is sometimes made, in that discoloration arising from baking operations is called "baking discoloration," whereas discoloration developed during storage is known as "warehouse discoloration."

Another objectionable type of surface film is the "sulphide discoloration" or "process discoloration" which develops on the interior surface of tin cans as a result of the action of sulphur-containing foods. This discoloration is evidenced by brown, purple, blue or black areas, and the color is often imparted to food in

FIG. 37—18. Effect of cooling rate on the comparative size of spangles produced on tin plate. Small-grain spangle at left resulted from rapid cooling (water quenching); larger spangle at right resulted from cooling at a slower rate (quenching in oil).

contact with the discolored surfaces. In the severest cases of sulphide discoloration, there are formed gelatinous masses of yellow sulphide. Such masses often contain black iron sulphide formed by reaction of food sulphur with the steel base exposed at pin holes or dented areas. Sulphide discoloration can be prevented by coating the inside surface of the can with zinc oxide impregnated enamel.

Tin surfaces, along with surfaces of most common metals, begin to oxidize immediately upon exposure to air. Attempts have been made to generalize on the fact that the thin oxide films on some metals effectively inhibit further oxidation of the base metal while others do not. Pilling and Bedworth (see "Bibliography" at end of chapter) concluded with considerable accuracy that an oxide may be protective when the ratio of the specific volume of the oxide to the specific volume of the metal is greater than unity. In the case of tin, however, with an oxide-metal volume ratio of 1.34, the classification fails when the service requirements for the normal oxide film on tin plate are considered. It is possible, nonetheless, to treat tin surfaces in such a manner as to produce oxide films which effectively inhibit further growth of the oxide. Such films also provide considerable resistance to the growth of sulphide films.

The treatments for providing protective oxide films on tin plate may be divided into two classifications. First, there are the chemical treatments in which the plate to be treated is immersed in or sprayed with a treating solution. Such treatments generally require that the plate be in contact with the hot treating solution for periods of time in excess of five seconds. If only resistance to baking discoloration is needed, a short treatment is satisfactory. When the plate must resist yellow discoloration throughout long periods of storage or is expected to resist sulphide discoloration, treatments of 30 seconds or more may be required. The commercial solutions used for chemically treated tin plate contain chromic acid or an alkali salt of chromic acid. The chromic-acid treatment is the most common of the two and utilizes hot chromic acid at a concentration range of 0.50 to 1.00 per cent.

The second type of treatment makes use of electrochemical action. Cathodic treatments of one second or less in a dilute solution of sodium hydroxide, sodium carbonate, trisodium phosphate or the like usually offer only slightly improved resistance to yellow discoloration. Cathodic treatment followed by anodic treatment in the same solutions provides further slight protection against yellow discoloration, but greatly enhances resistance to sulphide discoloration. Cathodic treatment in an acid or alkaline solution of a chromate produces a thin oxide film which is very resistant to baking discoloration but which may lack adequate resistance to warehouse discoloration and sulphide discoloration. Cathodic-anodic treatment in a chromate solution permits the formation of films which are very resistant to all types of discoloration and requires a treating time of less than one second for each step. The anodic portion of this

last treatment must be conducted at a low anodic current density, if good lacquer adherence is to be obtained.

The Oil Film—It has been found necessary for tin plate to have a thin film of oil to permit feeding of sheets to fabricating equipment and to prevent scratching and abrasion during fabrication on automatic equipment. Too much oil, however, causes trouble if the tin plate is to be lacquered, because globules of oil immiscible in the lacquer film produce thin spots and uncoated areas. The oil, of course, must be edible since it comes in contact with food products. Palm or cottonseed oils are normally used, but recent trends are toward the use of synthetic oils such as dioctyl sebacate. Satisfactory oil films usually are about 0.10 to 0.30 gram per base box in weight. This means an oil film less than ten molecules in thickness. To illustrate the minute thickness of this oil film, imagine spreading one teaspoon of salad oil uniformly over a wall 10 feet high and 2000 feet long. That is the equivalent of 0.10 gram per base box.

In the hot-dipping method, the tin plate is initially covered with oil which is later mostly removed in the wet washers. The final oil film thickness on the sheets is controlled by the branner. The oil content of the wheat bran used as a polishing medium is maintained at the desired level by periodic addition of "oil mids," which is bran to which has been added fresh palm or cottonseed oil. In some mills the oil content of the bran is periodically determined by extraction with solvents and weighing the oil residue. The oil content of the bran required to deposit the required oil film on tin plate varies with the speed of tinning, as well as with the efficiency of cleaning of the wet cleaners.

Application of Oil Films to Electrolytic Tin Plate—Electrolytic tin plate does not require cleaning as does hot-dipped tin plate but it has been found necessary to apply an oil film. Several methods have been tried commercially, including:

1. Branning machines
2. Spray oiling
3. Emulsion oiling
4. Electrostatic oiling

The first two methods have been largely supplanted by the emulsion oiling method and the electrostatic oiling method. Conventional branning machines did not operate satisfactorily with the high line speeds in use. Emulsion and electrostatic oiling were discussed earlier, but will be briefly described here.

In the emulsion oiling process, an acid-stable emulsion of either palm or cottonseed oil stabilized with an amine is sprayed onto the moving strip. Squeegee rolls spread the emulsion over the tin plate strip. The oil is deposited on the tin plate and the water phase is removed by the squeegee rolls.

The electrostatic method utilizes a high electrical potential between a fixed electrode and the moving strip, which creates a powerful electrostatic field around the strip. Vapors of oil are allowed to rise into this field and they are deflected onto the strip by proper adjustment of strip polarity.

SECTION 8

CORROSION RESISTANCE

To a large degree the successful application of tin plate for containers depends on its corrosion resistance. Food products react with the tin coating and the base metal but the rate of reaction is generally sufficiently slow to permit fairly long storage or shelf life. The type of corrosion that takes place depends on the nature of the

corrosive media. Thus, the corrosion problem can be divided into:

- A. Atmospheric Corrosion—rusting.
- B. Discoloration of the Interior of the Container, as by etching due to food acids, or blackening by food sulphides.

- C. **Hydrogen-producing corrosion** by contents of cans giving rise to "swells" or hydrogen springers in which the pressure of the evolved gas bulges the ends of the cans, thereby making them unmerchantable. In some cases the cans may perforate.

Atmospheric Corrosion—Tin plate is very durable in dry air but all tin plate will rust eventually in the atmosphere, especially when moisture is present. The amount of external rusting depends, in large measure, on the porosity of the tin coating and the resulting area of steel base exposed. Under conditions involving moisture and oxygen, the exposed iron behaves as an anode and the tin as a cathode (see Chapter 35, "Theory of Corrosion"). Increasing the thickness of the tin coating reduces the rusting, by reducing porosity. Rust resistance of tin plate can be somewhat controlled also by the nature of the tin oxide film. Treatment of tin plate in solutions of chromates and phosphates have been shown to minimize rusting but to date such treatments have not been developed sufficiently to permit commercial usage, at least in the United States. The composition of the steel base also has some bearing on rust resistance under certain conditions. Copper-steel base tin plate (low metalloid) showed less tendency to rust under certain conditions. Silicon above 0.02 per cent in the steel has been shown to make tin plate very susceptible to rusting.

Hartwell has shown that silicon causes the formation of small cracks in the surface of the tin plate when it is fabricated into cans (see second Hartwell reference in "Bibliography" at end of chapter).

Discoloration of the Interior of Cans—When foods rich in sulphur-containing proteins are packed in plain tin cans (that is, without lacquer), it is generally noted that the inside of the can is stained purple, brown or black. This stain is tin sulphide and is in no way harmful. The usual method of preventing this type of corrosion is by lacquering, especially with zinc oxide impregnated lacquers. The sulphur reacts with the zinc oxide to form zinc sulphide which is white and not noticed in the can. Sulphide blackening may also be prevented by a surface filming treatment as mentioned under the section discussing the tin oxide layer in an earlier part of this chapter.

In some mildly corrosive foods such as evaporated milk, localized detinning or dark staining may occur if the tin-oxide film is not soluble in the food product. For evaporated milk cans, some users prefer electrolytic tin plate either with no chemical treatment (NCT) or plate filmed cathodically.

Non-chemically treated plate has limited storage stability because of susceptibility to form yellow stains on aging. Cathodically treated plate has better storage stability.

The etching of the tin plate by food products is no indication of spoilage. All food products react with tin, some very slowly and others more rapidly. Spinach and other greens, rhubarb and squash are rapid de-tinners. These products are frequently packed in lacquered containers.

Hydrogen-Producing Corrosion—The usefulness of tin plate for food-container manufacture depends largely on its resistance toward the formation of hydrogen "swells" or perforations.

The corrosion of tin plate containers by food products is a complex problem and the state of our knowledge is still largely empirical. There are many factors affecting the rate at which tin plate corrodes. Major factors include:

1. Type of food product.
2. Packing procedure used in canning.
 - a. The initial vacuum.
 - b. The headspace volume.
 - c. Use of inhibitors.
3. The storage conditions.

1. **Food Product**—Food can be roughly divided into three classes with respect to corrosiveness:

Most Corrosive—This group includes the highly colored fruits and berries. They are generally packed in lacquered containers because tin has a reducing action on the anthocyanin pigments which results in bleaching of the color. The acidity and pH (intensity of acidity) of the food product is no criterion of its corrosivity. In fact, corrosivity can often be reduced by adding an organic acid, as by adding lemon juice to dried prunes in syrup.

Mildly Corrosive—This group includes the bland fruits such as peaches, pears, apricots and the citrus juices from grapefruit and oranges. The mildly corrosive fruits are generally packed in plain (not lacquered) tin cans.

Slightly Corrosive—This group includes the vegetables and meat products which normally do not produce hydrogen springers in the time required to merchandise the products.

2. **Food Packaging Procedure**—The canning procedure is carefully controlled to provide maximum shelf life. Cans are sealed under a high vacuum to assure maximum exclusion of oxygen because the presence of oxygen within the can markedly accelerates corrosion. A high vacuum is obtained either thermally or mechanically. In the former procedure the cans are sealed at as high a temperature as feasible, normally above 165° F. At this temperature, water has an appreciable vapor pressure so that the atmosphere immediately above the liquid level of the can is largely water vapor which displaces the air that would normally be present. Upon cooling the can, the contents shrink, increasing the headspace volume and thereby producing the vacuum within the can. Mechanical methods of vacuumizing involve evacuating the chamber of the sealing machine in which the cans are sealed by a vacuum pump or sucking the air out of the headspace of the filled can with a jet of steam passing over the end of the container at the moment of attaching the lid. Mechanical vacuumizing eliminates preheating of the contents.

The headspace volume also affects the rate of corrosion by acting as a hydrogen reservoir. Overfilled cans require much less hydrogen to dissipate the vacuum and build up a pressure within the can than do cans with normal headspace. Slack filled cans, however, are prohibited by Federal statutes.

Sulphur in very small amounts markedly accelerates corrosion of tin cans by certain products. Spray residue on the fruit or contaminated sugar have been found to be the source of sulphur responsible for rapid corrosion failures in some instances.

3. **Storage Conditions**—The temperature of storage of packed cans profoundly affects the corrosion rate as, indeed, temperature affects the rate of most chemical reactions. The higher the storage temperature the shorter is the pack life. Cans of fruit which would normally last four years at 70° F might last only a year or less at 100° F sustained storage.

Characteristics of Tin Plate Affecting Its Corrosion—The resistance of tin plate to corrosion by food varies considerably according to the methods of manufacture.

FIG. 37-19. Chart comparing results of prune-pack test on (upper left) can with black-plate end, and (lower right) similar can with black-plate end protected with tin wire, illustrating cathodic protection of steel by tin under the conditions of the test.

Extensive study by numerous investigators has helped to clarify many misconceptions as to the nature of the corrosive attack. Fundamentally, the corrosion of a tin can is the corrosion of the tin-iron couple. Tin of itself is quite corrosion resistant in weak organic acids in the absence of oxygen, either gaseous or in the form of oxidizing substances. Iron, on the other hand, is much more readily corroded by weak organic acids even in the absence of oxygen. Experiments in which tin is coupled to iron and immersed in weak acids in the absence of oxygen reveal that the corrosion of the iron is inhibited whereas the corrosion of the tin is accelerated. The tin protects the iron under such conditions. In the presence of oxygen or oxidizing agents the cell may be reversed and the corrosion of the iron is accelerated.

It has been shown previously that the tin coating on tin plate is not continuous but contains numerous pores. In the region of these pores, local electrolytic cells are formed when the tin plate is in contact with an electrolyte. Depending on the electrolyte and the environment, either the exposed iron in the pores or the surrounding tin may behave as the anode. With normal conditions existing in a can, closed so as to have a minimum of oxygen, the tin generally behaves as an anode, protecting the exposed iron. Were this not so, cans would perforate very rapidly at the exposed iron areas. Actually, tin cans have a remarkably long shelf life.

An interesting experiment to illustrate the protective efficiency of tin consists of fabricating cans with the body and cover lacquered and the bottom end made of black plate. Such a can packed with dried prunes in syrup, sealed hot to eliminate oxygen, will withstand storage at 100° F for about four weeks before bulging due to hydrogen evolution. A similar can, to which a

pure tin wire grid so spaced as to have $\frac{1}{8}$ inch spacing is tack-tinned to the black plate bottom, will withstand up to sixty weeks at 100° F before bulging (see Figure 37-19).

The degree of protection given by tin varies with the nature of the steel base and also with the nature of the food product.

Characteristics of the Steel Base Affecting the Corrosion of Tin Plate—The composition and methods of manufacture of the steel base are probably more important in controlling the corrosion resistance of the resulting tin plate than any other factors.

Hartwell, by means of experimental packs of corrosive fruits in cans from many lots of tin plate, has shown that phosphorus, copper and silicon may have pronounced effects on corrosion resistance, whereas, within the limits usually found in tin plate steel, the effects of carbon and sulphur are not of commercial significance. Phosphorus and copper have a profound effect on the service life of enameled (lacquered) cans and silicon is more effective with plain cans. Increasing amounts of phosphorus and silicon are detrimental to the service life of containers, while copper increases or decreases the corrosion resistance, depending on the product packed. The detrimental effects of copper usually appear more serious than the benefits derived from its presence. Therefore, tin plate made from a steel base low in phosphorus (0.015 per cent maximum), copper (0.06 per cent maximum) and silicon (residual) is desirable for the strongly corrosive products.

Container manufacturers order tin plate according to the type of food product packed. The following grades are in general use:

Type L—Cold-reduced open-hearth steel containing:

Element	Per Cent (Max.)
Carbon	0.12
Manganese	0.60
Phosphorus	0.015
Sulphur	0.050
Silicon	0.010
Copper	0.06
Chromium	0.06
Nickel	0.04
Molybdenum	0.05

This is used for the most corrosive foods.

Type MR—Cold-reduced open-hearth steel similar to Type L except that the phosphorus limit is increased to 0.020 per cent, the copper limit is increased to 0.20 per cent and no tolerances are specified for nickel, chromium and molybdenum. This grade is used for mildly corrosive products.

Type MC—Cold-reduced open-hearth or Bessemer steel similar to Type MR except that phosphorus limits are increased to between 0.04 and 0.15 per cent. This grade is used for noncorrosive products where strength of the container is the main consideration.

There is increasing evidence that the manner of preparation of the steel strip for tinning may be as significant in controlling ultimate corrosion resistance as composition of the steel. Fairly rapid quenching after hot reduction and thorough annealing in dry, low-carbon and low-oxygen content atmosphere favor the highest corrosion resistance.

In a tin can, the hydrogen evolved during pack storage results primarily from corrosion of the iron and not from the corrosion of tin. Analyses of various food products stored in plain unlacquered cans show up to 120 parts per million of tin after about a year's storage at room temperature. Tin pickup from lacquered cans is very much lower, averaging 10 to 30 parts per million, according to Hirst and Adam (see "Bibliography" at end of chapter). The iron content of cans which have a good vacuum even after prolonged storage periods is invariably low, less than 20 parts per million. In springers or hydrogen swells the iron content invariably approaches or even surpasses the tin content.

Controlled experiments by a United States Steel Corporation research laboratory on rate of tin and iron pickup by dried prunes in water in plain cans have shown that at constant temperature the tin is corroded at a constant rate, or linearly with time. The rate of iron pickup, however, is not constant. During the early stages of storage there is little or no corrosion of the iron. After this induction period the iron goes into solution at an increased rate and the can becomes a springer. The vacuum-loss curve of the can is similar in shape and displacement to the iron pick-up curve. The length of the induction period varies with the corrosion resistance of the tin plate. Fast-corroding tin plates have a short induction period while slow-corroding tin plates have a long induction period.

In essence, the metallurgical problem of improving corrosion resistance of tin plate resolves itself into methods of slowing down the attack on the steel base. This can be accomplished by:

1. Improved quality of steel base.
2. Heavier tin coatings.
3. Coating with proper type of lacquer in certain cases.

Effect of Tin Coating Thickness on Corrosion of Tin Plate—Increasing tin coating weights results in increased corrosion resistance in plain cans but not necessarily in lacquered cans. The corrosion of lacquered

containers will be discussed in more detail later. The relationship between pack life and tin coating weight of hot-dipped tin plate has been difficult to establish quantitatively because of the variation in coating as well as the variation in behavior of different portions of the same sheet. With the commercial development of electrolytic tinning, it was possible to prepare test lots of accurately controlled tin coatings in various coating weights on adjacent portions of the same coil. Fruit pack tests (dried prunes in syrup) on such specially prepared lots show that above a certain minimum coating weight an increase in tin coating linearly increases the corrosion resistance within the range tested.

The slopes of the straight portions of the curves obtained for a large number of steels plated from different electrolytes are essentially equivalent. Similar curves for hot-dipped tin plate have been obtained by electrolytically stripping areas to reduce the relatively thick hot-dipped coating to predetermined coating thicknesses comparable to those on electrolytic tin plate.

Micro variations in tin coating thickness apparently do not affect pack life of plain cans packed with fruits. This could be expected from the cathodic protection afforded by tin to the steel.

Lacquered Tin Plate—Lacquered cans are normally fabricated from tin plate which has been lacquered in sheet form. In the United States the trade refers to the lacquers as enamels. The lacquers vary in composition but are either organic solutions of resins or mixtures of resins and vegetable oils, the resins being either naturally occurring or synthetic. They may be clear or pigmented.

Lacquered cans are normally used to prevent the bleaching of highly colored fruits or to prevent the sulphide staining caused by sulphur-bearing foods. Considerable success in the reduction of hydrogen swells has, however, attended the use of lacquered cans for certain food products. During World War II, considerable quantities of 0.50 lb. per base box electrolytic tin plate, and even black plate, protected by lacquered coats, gave satisfactory service life for meat and vegetable products. The use of lacquered 25 plate has increased substantially, so that currently it accounts for a major portion of cans.

The corrosion process in lacquered cans is considerably more complex than in plain cans. The type of lacquer and methods of application may be as important as the quality of the tin plate used. Generally, improved service life may be obtained by more continuous coverage, as by spray or flush lacquering the fabricated cans.

Cracks in the lacquer coating expose minute areas of tin and iron. At these areas the tin tends to protect the iron but, because of the limited amount of tin exposed, it is soon used up and corrosion of the tin plate may be found in areas which have no apparent discontinuities in the lacquer film. Indeed, lacquered cans of fruit, which have abnormally long service life, frequently show pronounced etching of the tin beneath the lacquer indicating that lacquer films may be acting as semiporous membranes and the corroding tin beneath the lacquer is protecting the iron cathodically.

Trial packs are used to determine whether pack life can be improved by the use of a specific lacquer on the tin plate. As yet there are no laboratory tests which will determine the suitability of a specific lacquer system for a specific food product.

Chapter 38

LONG TERNE SHEETS AND TERNE PLATE

Long Terne Sheets—Long terne sheets, or long ternes, are steel sheets that have been coated by immersion in a bath of terne metal, which is an alloy of lead and tin. Sheets coated with terne metal are duller in appearance than sheets coated with tin alone, and it is this feature of the product that gave rise to the name "terne"—meaning "dull." Long terne sheets fall within the dimensional ranges covered by the uncoated sheet commodities. In commercial practice, they seldom are manufactured thinner than 0.014 inch, thicker than 0.125 inch, or wider than 48 inches. Long ternes occupy a relatively minor position tonnage-wise in the sheet business, but offer a combination of properties that make them very suitable for such applications as air cleaners, fuel tanks and burial caskets.

Long Terne Coatings—The composition and weight of long terne coatings were drastically restricted in 1941, when the normal supplies of tin were cut off by World War II. Prior to that period, it was customary to coat with terne metal containing approximately 80 per cent lead and 20 per cent tin, although this composition was not mandatory and could be varied for specific applications. Since the object of terne coating is to apply to the steel base an inexpensive, corrosion-resistant coating of lead, the percentage of tin used need only be sufficient to obtain a smooth, continuous coating. Lead alone does not alloy with iron, so that it is necessary to incorporate a certain amount of another element, in this case tin, which alloys readily with the steel base and forms a solid solution with the lead. It was formerly thought impractical to coat with terne metal compositions containing much less than 15 per cent tin but experience gained during the war period proved otherwise, for during this time, when government restrictions limited the amount of tin in long terne metal to 10 per cent maximum, terne coatings of entirely satisfactory quality were produced. It is to be noted, however, that decreasing the amount of tin in the coating alloy necessitates higher pot temperatures and lessens the alloying or "wetting" properties of the terne metal.

Prior to 1946, the coating weights of long terne sheets were designated by pounds per double base box, a term used in the tin plate and short terne industry, and never logically applicable to long ternes. With the exception of roofing long terne sheets, which are still produced to coating weights of 20, 30, or 40 pounds per double base box in specific gages and sizes, this designation is no longer used. Long terne sheets are now ordered to a coating weight specified in ounces per square foot, with weights ranging from "commercial" (no minimum amount) to 0.55 ounces per square foot. The designation of terne coating weights in terms of ounces per square foot follows the practice used in designating coating weights of galvanized sheet, as long ternes are commonly made on equipment located in galvanizing shops. Table 38—I lists the various weights of coating commonly available and the applicable sheet gage numbers. Commercial coating is furnished unless a special coating

weight is ordered. Long terne sheets with commercial coating are well-coated sheets but are not subject to any minimum coating test.

The thickness and nature of the coating are the most important factors governing the corrosion resistance of long terne sheets. Both lead and tin are highly corrosion resistant, and their combinations as used on long terne coatings also resist corrosion well. However, both lead and tin are cathodic to iron under most conditions of exposure, so that terne metal will actually accelerate corrosive action on the steel base when any portion of the steel surface becomes exposed to attack. Since a light coating has a greater tendency to form pinholes or other discontinuities than does a heavier coating, exposure of the base metal is minimized and corrosion resistance is increased as the thickness of the coating increases. However, even the most heavily coated ternes should be well-painted when maximum protection against corrosion is desired.

Table 38-I. Ordered Coating and Minimum Coating Weight Limits for Long Terne Sheets.

Ordered Coating	Weight (Oz. Per Sq. Ft.)		Applicable Sheet Gage Numbers	Nominal Coating, Lb. Per Double Base Box
	Minimum Coating By Sheet Weight Test	By Triple Spot Test		
Commercial	No Min.	No Min.	10 to 30	Commercial
0.35	0.30	0.26	16 to 30	9.00
0.45	0.38	0.34	18 to 30	12.00
0.55	0.47	0.41	20 to 30	15.00

Composition and Preparation of Steel Base—The steel base of long ternes may be provided on either a "commercial quality" or a "drawing quality" basis. In the former case, rimmed, capped, or semi-killed steel is generally used; in the latter, specially selected rimmed or aluminum-killed steels are provided, because of their superior ductility. All of these steels usually fall within the following composition limits:

Carbon (%)	Manganese (%)	Phosphorus (%)	Sulphur (%)	Silicon (%)
0.03-0.10	0.25-0.50	0.025 max.	0.050 max.	0.020 max.

Selection of the composition and treatment of the steel to be used for the base of long terne sheets is governed by the end use of the products to be fabricated from them and hence must take into consideration a number of factors, important among which are the customers' fabricating practices. Factors normally considered in

addition to the usual requirements for flatness, finish, and weight of coating, are such forming hazards as breakage in deep drawing operations, fluting, stretcher strains, and the conditions under which the material is to be used. In this latter connection, for example, a copper content of 0.20 per cent minimum is usually recommended for applications involving corrosion hazards, such as may be encountered when used for roofing or for burial caskets.

The treatment accorded the steel base used in manufacture of long terne sheets, depends upon the desired combination of gage, surface finish, and physical properties. It is basically identical with the treatment which would be given a cold rolled sheet or a hot rolled sheet manufactured for the same type of customers' fabricating operations. Product 18 gage and lighter generally is rolled on cold reduction mills while 16 gage and heavier usually is rolled on a continuous hot strip mill; some overlapping in method of rolling occurs, however, in the range 18-14 gage.

The continuous cold reduction process involves the use of lubricating solutions containing oil, the removal of which from the surface of the steel prior to annealing is of vital importance in producing a base metal which is to be terne coated. Any oil which remains upon the sheet or strip will decompose when heated to the annealing temperature. The relatively inert, carbonaceous residue which results can interfere seriously with the application of a smooth, continuous coating of terne metal, since these residues are not attacked to any appreciable degree by the pickling solutions commonly employed for descaling and cleaning the steel prior to terne coating. As a result, they prevent the terne metal from "wetting" or alloying with the steel base, causing rough coating or entirely bare areas where the film is particularly heavy. Some manufacturers make use of an electrolytic cleaning operation prior to annealing in order to prevent the formation of the "carbon smudge"; others cold reduce the base metal in thin mixtures of volatile water-soluble oil.

Cold reduced product is usually box annealed since it is more economical than normalizing and the sheets or coils may be kept scale-free by using a deoxidizing atmosphere, thereby reducing the iron loss due to pickling. The temper rolling operation may be eliminated on certain gages and applications wherein it is known that the customer's fabrication involves a deep-drawing operation in which fluting or straining of the base metal is not objectionable. Final preparation of the base metal prior to coating may involve shearing coil product to sheet form on a flying shear unit, with or without surface inspection, and in these operations it is important that the sheets be kept free of oil or grease, for the reasons previously stated.

When the base metal is rolled to gage on a continuous hot strip mill, the hot rolled coil is sheared to sheet form before any further processing takes place. Sheets intended for deep-drawing and stamping generally are normalized, while material for less severe applications may receive no more than a flattening operation after shearing, because in these heavier gages the steel strip is sufficiently soft for moderate forming operations.

The pickling practice prior to coating is essentially the same as that used in the production of galvanized sheets and the operation is performed in the same shop or department. Hydrogen embrittlement of the base metal, especially cold reduced product, is an ever-present hazard and close control of the pickling operation is required to avoid deleterious effects.

Long Terne Coating Application—There are two methods generally used for applying terne metal in the

manufacture of long ternes. The chief objective of both of these methods is to bring the properly prepared surface of the steel base into contact with the molten terne metal, and to remove the coated sheets from the pot, under conditions that will assure a uniform distribution of the coating. In both methods the aim is to produce a continuous coating of terne metal as free of discontinuities as possible.

The flux process, as the name indicates, employs a flux of molten (or a water solution of) zinc chloride, or a solution of zinc chloride in hydrochloric acid, to remove any oxides of iron that may be present and also effect a rapid drying of the sheets. This latter feature makes it possible to use a coating machine similar to that used in the tin plate industry. In fact, the flux process is quite similar to the methods used in tinning, with the exception that the temperature of the terne pot is higher than that of the tin pot because of the higher melting points of the terne metal compositions. The terne pot temperatures commonly employed range from 620° to 680° F. The process is carried out in a "rigging" or machine which carries the sheet through the several steps of the process as follows: The pickled sheets are fed from water boshes or piles into rubber pinch rolls, which conduct them through a hydrochloric acid wash tank. The object of this acid dip is to remove the iron hydroxide which may have formed on the sheets subsequent to pickling. Another set of rubber pinch rolls squeezes excess acid from the sheet, and the entry rolls of the coating rigging carry the sheet into the flux box, where it is cleaned and dried. The sheet then passes downward through the molten terne metal, where the coating is applied, then upward through a bath of oil (palm oil, fish oils, mineral oils, or combinations thereof) floating on top of the metal, being conveyed through the oil by the oil rolls. The oil bath on the exit side of the metal bath, in addition to protecting the surface of the molten metal bath from oxidation, tends to keep the coating on the sheet in a molten condition and thus allows the oil rolls to control the distribution and thickness of the coating. As the coated sheets leave the oil bath they are conducted to the conveying system of the cooling and cleaning train.

In the combination process, a coating machine using the flux process is followed by another machine of the same type but with oil substituted for the zinc chloride. This type of arrangement permits complete control over the coating conditions within the entire range of coating weights commonly available. Since most long ternes are ordered in the lighter coating weights, the bulk of the material produced is coated on a single unit by the flux process.

After the coating operation, the freshly coated sheets must be cooled sufficiently to permit cleaning without injury to the soft coating. Terne plate, because of a heavier steel base and higher temperature of the coating bath, requires more time than tin plate to cool to the proper temperature for cleaning, therefore special equipment is needed. In general, this equipment consists of a hooded conveyor against which blasts of cool air are directed from a distributor pipe. Control of the volume of air through the distributor main and branch tubes is effected by varying the speed of the blower and regulating the flow through the individual tubes by a system of dampers. The conveyor system carries the sheets in a horizontal position with both surfaces exposed to the cooling action of the air blast. This conveyor consists of a series of deeply hollowed rolls, sometimes referred to as double-cone sets, because each roll is so deeply concave that it resembles two cones mounted on a shaft with their apexes abutting. When a

sheet passes over the conveyor only its edges are in contact with the rolls; and with the air distributors suitably arranged, both surfaces are equally exposed to the cooling action of the air blast.

Regardless of the coating process used, the terne plate emerges from the coating operation covered with oil. Part of this oil drips from the sheets as they pass over the cooling conveyor and is collected in a grease pan located under the conveyor, but the remainder must be removed with special cleaning equipment. Long terne sheets are produced with a "dry" or "bright" finish, and an "oil" finish. Sheets leaving the cleaning equipment practically free of oil are designated as dry finish, but if they carry an appreciable amount of oil, or are subsequently coated with oil, they are designated as oil finish.

The residual oil present on the surfaces of long terne sheets after coating is usually removed by a branner similar to that used on hot-dipped tin plate. Contrary to tin plate practice, however, the long terne branner is preceded by a pair of cloth squeezer rolls, which remove much of the heavy oil film before the sheet enters the regular branning operation. Middlings or sawdust may be used in the branner. Steel rolls thinly wound with flannel may be used at the exit end of the branner to exert a smoothing action on the surface when a bright finish is desired. For best results in cleaning, two branners are normally employed, one following the other. When oil finish is specified, oiling rolls may be inserted in the line to apply the desired amount of oil on the surface, or it may be accomplished as a separate operation in a regular oiling machine. Upon completion of cleaning, the sheets are ready for inspection by the inspectors stationed at the end of the line.

Inspection and Testing of Long Terne Sheets—The inspection of long terne sheets normally takes place when they have completed their travel along the conveyor system, through the branners, and are being removed for piling into lifts. All but a small percentage of the sheets coated are primes, i.e., sheets free from any injurious defects recognized as such in the trade. However, even with the best practice and control of processing variables, a certain percentage of the sheets from the terne pots have defects which are of such a nature or magnitude that they are classified as rejects. **Recoats** are sheets containing defective areas which may be reconditioned to prime grade by rerunning them through the terne pot a second time. **Scrap sheets**, which are those totally unsuitable for reconditioning or salvaging, are normally the result of cobbles in the rigging of the terne pot itself or in the branners. The terne coating from scrap sheets is reclaimed by placing them in palm oil, heating to the proper temperature, and allowing sufficient time for most of the coating to run off and collect in the bottom of the container.

The defects of long terne sheets may be classified into three general types, depending on the basic origin of the defect. These types are as follows:

- (1) Those due to an imperfection in the steel base.
- (2) Those due to faulty processing of the material prior to the coating operation.
- (3) Those due to faulty coating practice.

The major defects encountered in category (1) are blisters and seams, the latter sometimes being designated as "skin laminations" or "slivers." As in galvanized sheet production, the blister defect occurs most frequently. The basic causes and the method of formation of blisters and seams, as discussed in the chapter on galvanized sheets, apply also in the case of long terne sheets.

Defects which may be classified in category (2) include rolled-in scale, pits, gouges, scratches, under-pickled areas, and other imperfections of a minor nature which may be eliminated by making corrections in preceding processing operations. Another defect falling into this category is the previously mentioned "rough coating," which results when the terne metal fails to "wet" or alloy with the steel base because of a film of reduced iron or carbonaceous residue which has not been satisfactorily removed in pickling. In this connection, it is to be noted that the cleanliness of the base metal is much more critical in the coating of long ternes than in the case of hot-dip zinc coatings.

Defects comprehended in category (3) include such items as bent corners, uncoated areas, oil stains, branner marks, and other minor items which may be controlled by the pot operators. In addition to the inspection for the above enumerated defects, the sheets are also checked for gage, size and flatness by the pot inspectors and are stamped with the appropriate identification marks.

The tests to which long terne sheets are subjected after completion of the coating operation may be classed as chemical, microscopic and mechanical. It is also necessary to have some type of immediate control test to determine the amount of coating being applied to each lot as it is being coated, and the sheet weight test is used for this purpose. The sheet weight test is made on a lot of from one to ten sheets, depending on the gage. The test lots are weighed after the pickling, washing and drying operations, and then weighed again after coating. The weight of coating in ounces per square foot is calculated by dividing the difference in weight so obtained by the total area of the sheets comprising the test lot. This type of test is conducted frequently for each coating unit so that an adequate control of the coating weight may be maintained and adjustments made to the coating machine as the occasion arises. For accurate determination of the weight of terne coating on the sheet and to determine conformance to specifications it is customary to use the **triple spot test method**. Where the product is coated in sheet form, three specimens exactly 2.25 inches square, or discs of equivalent area, are cut from each test sheet, one being cut from the center and the other two from diagonally opposite corners. The end spot tests are cut not closer than 4 inches from the ends and 2 inches from the sides, in order to avoid the heavier coating on these areas. In testing product made by the continuous-strip coating process, since the coating-weight difference for the back and front of the test sheet do not exist, it is acceptable to take all three spot tests across the width of the sheet. After each specimen has been weighed on an analytical balance the coating is dissolved by immersion in an appropriate solution. The specimen is then washed, dried and reweighed, the difference in weight in grams being numerically equal to the weight of coating in ounces per square foot. From time to time, and particularly when certain specifications governing the composition of the terne coating must be met, the coating on a test sample is chemically analyzed to determine the percentages of tin and lead present.

A microscopic examination of a properly polished and etched cross-section is made to determine the ferrite grain size of the steel base. Since the adherence of the coating to the base metal is never a problem in the production of long terne sheets, adherence testing is not required as it is for galvanized sheets. **Mechanical property tests** are used primarily as a guide in determining the ductility of the coated sheet and its suitability for the intended application. These mechanical tests include

Rockwell hardness, Olsen cup, bend, fluting and tension test. Hardness tests are normally made on the base metal after the coating has been removed since the soft coating would give erroneous values if the hardness impression were made through it. Besides providing a measure of the ductility, the Olsen test is a valuable tool for detecting hydrogen embrittlement of the base metal. In the Olsen cup test the material normally "necks" at the periphery of the base of the cup, but when absorbed hydrogen has embrittled the base metal, a ragged fracture will occur on the side of the cup or, in extreme cases, at the base of the cup. Fluting tests are made by forming a suitable test piece into a cylinder and observing the presence or absence of flutes or creases.

Continuous Strip Production of Long Ternes—The advantages of the continuous terne coating of strip have long been recognized. Constant improvement, development and adaptation of existing terne coating equipment have now made continuous hot-dip coating possible. The first major step was the development of completely synchronized drives, so that long coils could be run without gain or loss in the loop between rolls. Other developments included the perfection of automatic welding equipment and vertical branners. Continuous coating lines may be of the semi-continuous or the fully-continuous type. The semi-continuous line has only one payoff reel and one tension reel, which necessitates threading each individual coil through the line. The fully-continuous line is equipped with double payoff reels, welder, and looping towers or pits, which permit a continuous flow of strip through the coating unit.

The base metal for coating on continuous lines usually consists of cold reduced, box annealed and temper rolled coils, although hot-rolled, pickled coils may be used. The treatment of the base metal prior to coating is identical to that given sheet product, with the exception that all the operations are accomplished in coil form. The pickling operation is performed in the line prior to the actual terne coating operation.

The equipment contained in a continuous coating line may vary from shop to shop, depending on numerous operating conditions and the preference of the manufacturers concerned. Essentially, the equipment and process involved are as follows: A coil holder, followed by a payoff reel, feeds the strip into a pinch-roll unit, which in turn is followed by a squaring shear and a welder if the process is fully continuous. The strip then enters an acid pickling tank, which may consist of a single-dip tank, wherein normal chemical pickling is effected, or which may be an electrolytic pickling unit; if the latter, it may be followed by a short non-electrolytic hydrochloric dip. In either case, the object of the operation is to provide a chemically clean surface for the effective application of the terne coating. If desired, provision may be made for an alkaline cleaner unit equipped with suitable rinsing and scrubbing facilities just ahead of the pickling tank. From the pickling unit the strip then enters a pinch roll unit which conveys it into the terne coating pot. Upon emerging from the pot, the strip is cooled and conveyed to the branner (vertical in modern installations) which removes the residual oil. At this point in a continuous line, provision may be made for shearing the strip into cut lengths, using a gage table, shear, and piler or, if the material is to be shipped in coil form, a shear for cutting out the weld and a tension reel are available to recoil the strip.

The process of continuous terne coating has several unique advantages which suggest that its use will become more widespread. The first of these is the elimination of the intermittent operation characteristic of sheet

pots, whereby a space of from 1 to 3 feet is left between each sheet as it passes through the line. The next distinct advantage is the uniformity of the coating that can be realized by having a continuous flow of the base metal through the coating rigging with no break in the operation. As has been indicated, the sheet method results in a heavier coating on the front and back ends, "entry" and "list" ends respectively, so that continuous coating makes more efficient use of a given quantity of coating metal. A disadvantage of the continuous process lies in the fact that it is less adaptable to producing small, varied types of orders since it is most efficient when used to produce coils of one coating weight. The operation of a continuous coil terne line is quite similar to a sheet unit and the principles of the coating technique are identical. Since it is not possible to make use of the sheet weight test as a routine check on coating weights, the operator must rely on a determination made by electrical or chemical means. The final product may be shipped to the customer in coil form or may be sheared to sheets.

Recent developments in continuous terne coating have pointed toward the elimination of oil as a part of the coating operation. The use of oil entails a number of operating disadvantages, among which is the necessity of including a cleaning apparatus to remove excess oil from the coated strip. This operation can apparently be avoided by dispensing with oil finishing rolls and substituting partially submerged exit rolls, using a molten zinc chloride flux with ammonium bromide or ammonium chloride dissolved in it. The zinc chloride acts as a solvent for the ammonium bromide or ammonium chloride to prevent its dissipation by volatilization and makes the entire process quite similar to conventional galvanizing.

Applications of Long Terne Sheets—The major portion of the long terne sheet production is used in the manufacture of gasoline tanks for the tractor, truck and automotive industries. Automotive gas tanks are usually drawn in two halves, top and bottom, and seam welded around the perimeter. Truck and tractor tanks are sometimes drawn in the same manner, but are also fabricated by forming the sheets into cylinders by using bending rolls and then lockseaming or soldering the ends. The use of long ternes for these applications is dictated by the resistance of the coating to corrosion by gasoline, water and air. Other automotive parts manufactured from long ternes include water distributor tubes, radiator parts, mufflers, oil pans and air cleaners. The latter use is considered a minor corrosion hazard but manufacturers of this item prefer to draw the shapes involved from long ternes because of the lubricating value of the coating in deep drawing operations. Other uses are for roofing, hand fire extinguishers, outboard-motor gasoline tanks and burial caskets. The latter application involves hand rubbing and polishing to a high luster for a pleasing appearance. An important wartime use was the manufacture of expendable gasoline tanks for aircraft.

Terne Plate—Terne plate, a tin mill product of relatively minor importance, is black plate that has been pickled and coated with terne metal. Known occasionally as **short ternes**, this commodity is made on hot-dipped manufacturing equipment. Its approximate sheet thickness is expressed as basis weight and its coating weights are expressed in terms of pounds per double base box. The terne metal used for terne plate generally contains a maximum of 15 per cent tin; the balance of the coating is lead.

Roofing ternes are commonly ordered in the standard sizes, 20 by 28 inches or 14 by 20 inches, the standard

basis weights of 107 lb. and 135 lb., and the standard coating weights of 8 pounds, 20 pounds and 40 pounds per double base box. The base metal is copper-bearing steel.

Firedoor ternes are ordered in the standard size 20 by 28 inches with a basis weight of 107 lb. or heavier and a coating of 20 pounds per double base box.

Manufacturing ternes are short ternes of any tin-mill size produced by using approximately 6 pounds of terne metal per double base box. **Heavy-coated manufactur-**

ing ternes are short ternes produced in coating weights of 8, 15, 20 and 40 pounds per double base box. **Special-coated manufacturing ternes** are short ternes customarily produced with no specified amount of coating but carrying the lightest practical coating consistent with thorough coverage of the plate.

Chapter 39

PRODUCTION OF GALVANIZED SHEET AND STRIP

SECTION 1

GENERAL

Production and Uses of Galvanized Sheet and Strip— The importance of providing protection against corrosion for steel articles having a light section is obvious, and coating the steel with zinc is a very effective and economical means of accomplishing this end. Zinc coatings are commonly applied by dipping or passing the article to be coated through a molten bath of the metal. This operation is termed "galvanizing," "hot galvanizing" or "hot-dip galvanizing" to distinguish it from zinc electroplating processes which are termed "cold" or "electro-galvanizing."

The present discussion is limited (1) to **hot-dip sheet galvanizing** which is the hot-dip galvanizing of cut-length sheets by passing them one by one and in close succession through the molten zinc, and (2) **continuous (strip) hot-dip galvanizing**, in which material in coiled form from the rolling mills is uncoiled and passed continuously through the galvanizing equipment, continuity of operation being achieved by joining the trailing end of one coil to the leading end of the next.

The word "strip," as used in this chapter, denotes the *physical form* of the material in process; i.e., a continuous strand of steel of sheet gage and width. Commercially, the meaning of the term "strip" has the limitations outlined in Chapter 33.

Of all the common metals used for protective coatings, zinc enjoys the lowest cost per pound. With the single exception of tin, it is used to protect a greater area of steel than any other coating metal. In 1954, 398,000 tons of slab zinc were consumed by the galvanizing industry. Of this amount, 181,000 tons were used for the galvanizing of sheet and strip. The balance of the zinc was used largely in wire galvanizing, pipe galvanizing, and in hot-dipping prefabricated articles such as range boilers, wash tubs, garbage cans, pails, etc. The reported shipments of galvanized sheet and strip in the United States during 1954 amounted to over 2.5 million tons.

In 1954, about 37½ per cent of the galvanized-sheet production was used to satisfy construction-industry requirements. Construction of grain-storage bins, stock tanks, feeding equipment, farm machinery and buildings in the agricultural industry consumed 10.4 per cent of the production. The electrical industry consumed about 2½ per cent of the total, and about 34 per cent was shipped to warehouses for miscellaneous uses. Substantial tonnages were used by the appliance and container industries. The railroads consumed around 1 per cent and the export trade about 6½ per cent of the total.

Specific uses for galvanized sheets include roofing and siding, eave troughs, conductor pipe, air ducts, heating furnaces, air-conditioning equipment, metal

lath, corner beading, switch boxes, chimney flues, metal awnings, railroad-car roofs, garbage cans, oil cans, ash cans, pails, tubs, coal hods, refrigerators, deep-freeze units, kitchen equipment, laundry tubs, automatic washers and dryers, minnow buckets, storage tanks, beverage coolers, well casings, culverts, poultry equipment, manure spreaders, hay loaders, tractors, and wagons.

FACTORS INFLUENCING EFFECTIVENESS OF GALVANIZED COATINGS

The amount of zinc on a galvanized sheet is stated in terms of ounces per square foot of sheet; since the sheet is coated on both sides, the stated weight of coating is twice the average weight of coating per square foot of either side.

The effectiveness of a protective coating depends to a considerable extent upon the character of the environment in which it is used. In general, galvanized coatings are subjected to atmospheric and liquid corrosion and, less frequently, to soil corrosion. Their effectiveness in the atmosphere depends mainly upon the amount of acidic contaminants present. Thus, in the relatively pure air of rural districts, the life of zinc coatings is four to ten times that of the same coatings in industrial areas.

For any specific set of exposure conditions, the thickness of a zinc coating is the most important factor in determining its effectiveness. Coatings applied to sheets by the hot-dip process range, in general, from 0.6 to 2.5 oz. per sq. ft. of sheet, and the 2.5 oz. per sq. ft. coating can be expected to have approximately four times the life of the 0.6 oz. per sq. ft. coating under similar exposure conditions. For this reason, uniformity of coating is also an important consideration. As a practical matter a completely uniform coating is not produced in a commercial hot-dipping operation; however, no area or spot of a hot-dipped sheet should carry a lesser weight of coating than the trade-accepted minimum for the grade. These minimums vary with the grade or class ordered and are considerably less than the nominal weight of coating, i.e., coating class, specified; see "Coating Weight Requirements" below.

One of the advantages of zinc as a protective coating is its anodic relationship to iron in the electro-motive series. Due to this relationship, the protection afforded is extended to small areas of coating discontinuity adjacent to areas actually coated. Thus, lack of coating at a sheared edge or minor damage to the coating during fabrication or use of a galvanized article does not seriously impair its service life, provided, of course, the uncoated areas are not too large.

Table 39—I. Galvanized Sheet Gage Numbers with Equivalent Unit Weights

Galvanized Sheet Gage Number	Ounces Per Square Foot	Pounds Per Square Foot	Pounds Per Square Inch	Thickness Equivalents (Inches)
8	112.5	7.03125	0.048828	0.1681
9	102.5	6.40625	0.044488	0.1532

COATING WEIGHT AND GAGE REQUIREMENTS

Galvanized sheets are manufactured to several general specifications, the requirements of which have been found by usage and test to be the most suitable for the applications involved.

The so-called **Commercial Coatings** generally include those that are produced on sheets for direct weather-exposure applications. Galvanized Formed Roofing and Siding, and Galvanized Flat Sheets for Roofing and Siding, are produced to ASTM Specification "Steel Roofing Sheets" A361-55T with a 1.25 oz. per sq. ft. coating class, 0.90 oz. per sq. ft. check limit by triple-spot test, or 0.80 oz. per sq. ft. check limit by single-spot test. (Tests for galvanized sheets are described in Section 5 of this chapter.) Galvanized Flat Sheets for other than roofing and siding products, but for an intended equivalent corrosion hazard, may be produced to ASTM Specification "Steel Sheets, Coil and Cut Lengths" A93-55T with a similar 1.25 oz. per sq. ft. coating class.

For applications in which the above Commercial Coatings might cause some difficulty in forming because of their thickness, or in which extreme corrosion resistance is not a consideration, galvanized sheets may be produced to ASTM Specification A93-55T, Light Commercial, with no minimum check limits specified.

Heavier than Commercial Coatings are supplied when required for specific applications. The American Zinc Institute "Seal of Quality" roofing sheet is specified as 2.00 to 2.25 coating class with a minimum 1.80 oz. per sq. ft. check limit by triple-spot test and a minimum 1.50 oz. per sq. ft. check limit by single-spot test (see Section 5). Culvert sheets are required to carry a minimum 2.00 oz. per sq. ft. coating when tested by the triple-spot-test method.

Galvanized sheets are produced to weights per unit of sheet area. The Galvanized Sheet Gage, established by custom, is based on the United States Standard

Gage, each Galvanized Sheet Gage weight being 2.5 ounces per square foot heavier than the gage weight of the same United States Standard Gage number, regardless of the coating weights. For example, the equivalent unit weight of a 20-gage galvanized sheet is 26.5 ounces per square foot regardless of the weight of coating. Adjustments are made in the weight of the base metal to compensate for heavier or lighter weights of coating. Galvanized sheet gage numbers and their weight equivalents are given in Table 39—I. Thickness equivalents are also shown in this table. Table 39—II shows the coating class in ounces per square foot and the minimum coating check limits for coatings heavier than Commercial Galvanized Coatings.

GENERAL QUALITY DESIGNATIONS

Sheets of "Commercial Quality" are suitable for bending and moderate forming requirements. They must be capable of withstanding standard bend tests.

Table 39—II. Coating Class and Minimum Coating Check Limits for Galvanized Sheets (Oz. Per Sq. Ft.)

Coating Class	Minimum Check Limit by Triple-Spot Test*	Minimum Check Limit by Single-Spot Test*
2.75	2.35	2.00
2.50	2.10	1.80
2.25	1.85	1.60
2.00	1.65	1.40
1.75	1.40	1.20
1.50	1.15	1.00
1.25 (Commercial)	0.90	0.80
Light Commercial	—	—

* Test procedures are described in Section 5 of this chapter.

The adherence of the coating must be sufficient to withstand bending without flaking when tested in accordance with ASTM Specification A-93.

When "Drawing Quality" steel is supplied, the producer assumes responsibility for selection of steel, control of processing, and performance of the material within established limits. There is no standard of coating adherence for drawing operations, so this item is subject to agreement between producer and user. Drawing Quality sheets are made from rimmed steel.

For critical forming requirements, "Drawing Quality—Special Killed Steel" should be specified. The limitations described above for "Drawing Quality" also apply to this grade of material.

Temper rolling may be employed to produce an "Extra Smooth" sheet for applications involving critical end uses when galvanized sheets are required to have one smooth, clean surface of a higher degree of smoothness than is normal for regular commercial quality, or drawing quality product. Examples are for sign and panel work.

To obtain satisfactory performance in lock-forming operations, "Lock-Forming Quality" sheets should be employed.

For superior resistance to atmospheric corrosion, copper-bearing steel should be employed.

SPECIALTY PRODUCTS

Roofing and siding are produced either flat or in the form of "Corrugated Sheets," "V-Crimped Roofing," "Corrugated Roll Roofing," or regular "Roll Roofing."

Standard 2½-inch corrugated sheets have 10 corrugations to a sheet of siding and 10½ corrugations for a sheet of roofing for a covering width of 24 inches. The width of each corrugation is actually 2.66 inches and the depth is ½ inch. In siding, both edge corrugations are turned the same way and the overall width of the formed sheet is 26 inches. In roofing, the edge corrugations are turned in opposite directions and the total sheet width is about 27½ inches. Lengths of 5, 6, 7, 8, 9, 10, 11, and 12 feet are commonly available, but special lengths are sometimes supplied. Galvanized roofing and siding sheets are produced from 29-gage and heavier sheets.

The standard 1¼-inch corrugated sheets have 20½ corrugations, ¼ inch deep, to a sheet. With one edge each way, they have a formed width of 26 inches and a covering width of 24 inches. Stock lengths are the same as those for the 2½-inch corrugated stock and the gages supplied are similar.

V-crimped roofing is produced by forming 2, 3 or 5 longitudinal inverted "V" crimps in the sides or in the sides and centers of sheets. V-crimped sheets are supplied with the 24-inch covering width and the 5- to 12-foot lengths used for the corrugated material. Various modifications of the standard "V" crimp are used for roofing and siding sheets.

Various accessory fittings for use in assembling a corrugated roof usually are supplied by galvanized-sheet producers. Included in these are ridge roll, ridge cap, gambrel joint, side-wall flashing, end-wall flashing, lean-to filler, and overhang section.

SECTION 2

METALLURGICAL FEATURES OF THE HOT-DIP GALVANIZING PROCESSES

Hot-dip coatings are produced on steel objects by passing the properly prepared base metal through a bath of molten coating metal. Tin, zinc and lead are the common coating metals used. As in all coating processes, the surface of the base metal must be clean to insure satisfactory coating continuity. In addition, successful hot-dipping requires the surface of the molten bath to be kept clean, particularly at the entrance to the bath, since oxide films of the coating metal at this point will be picked up by the surface of the entering base metal to interfere with the wetting of the latter by the molten coating metal.

In the hot-dip galvanizing of steel, the cleanliness of the base metal is somewhat less critical than in electroplating operations since molten zinc is highly reducing to iron oxide and possesses a strong tendency to form intermetallic compounds with iron. Excessive contamination of the surface with any material, of course, cannot be tolerated and must be removed by acid pickling, alkaline cleaning or other preparatory treatment prior to introduction in the zinc bath. Satisfactory cleanliness of the steel and zinc is maintained by (1) the use of suitable fluxes either carried on the surface of the bath or applied to the surface of the steel just prior to entry into the bath, or (2) in the case of continuous operations which include an annealing or other heat-treating step immediately ahead of the galvanizing pot, by keeping the heated strip under the protection of the furnace atmosphere, preferably a reducing atmosphere, until it passes below the surface of the molten zinc.

For many years, galvanized sheets were produced by passing single sheets of steel in close succession through a coating pot; the operations are described in

detail in Section 3 of this chapter. However, with the development of wide strip mills capable of rolling to sheet gages, there has been a gradual shift to processing sheet products in strip form. In such operations, the steel is unwound from coils and passes as a continuous strand through the processing equipment. The product may then be recoiled or cut into individual sheets as desired. Processing in strip form is sometimes referred to as "continuous processing" to distinguish it from similar operations involving the treatment of individual sheets. Continuous processing permits many operations formerly conducted on separate pieces of equipment to be combined into one continuous processing line. In addition, certain problems inherent to operations on individual sheets disappear when the steel is processed in strip form. For example, in the hot-dip coating of sheets the necessary gap between successive sheets causes a considerable variation in the weight of coating applied to the leading and trailing ends of the sheet. The absence of this gap in operations on material in strip form therefore results in a more uniform coating and consequently affords better utilization of a given quantity of zinc. Continuous-type operations, however, require a very high investment in equipment. A detailed description of the application of continuous practices in hot-dip galvanizing of steel is given in Section 4 of this chapter.

At and above its melting point, zinc readily forms intermetallic compounds with iron. In hot-dip galvanizing, these alloys form at the interface between base metal and coating metal and ultimately constitute an appreciable portion of the finished coating. After solidification, the coating consists of an outer layer approaching the metal of the coating bath in composition, and

FIG. 39-1. Typical spangles on a "Tight-Coat" sheet galvanized with aluminum-free spelter. Average coating weight: 1.10 oz. per sq. ft. Actual size, unetched.

several inner layers, generally termed "alloy layer," consisting of intermetallic phases of iron and zinc, the latter becoming successively richer in iron with depth.

The outer layer of a hot-dip galvanized coating solidifies as a cast crystalline structure starting at scattered nuclei and developing into a more or less regular "frost-flower" or "spangled" pattern (Figures 39-1 and 39-2). The size of the spangles is influenced by the composition and prior treatment of the base metal, by the duration of the solidification period, and by the composition of the coating bath. The shape and general pattern of the spangles are largely influenced by the latter.

The alloy layer has been the subject of considerable investigation. It has been considered to be the bond between the outer layer of relatively pure zinc and the

steel base; but, paradoxically, many of the failures of galvanized coatings by flaking during fabrication have also been attributed to its presence. Actually the exact role of the layer in adherence of the coating has not been clearly established.

It has been known for a number of years that the addition of aluminum in small amounts (0.10 to 0.25 per cent) to the zinc bath suppresses the alloy formation and produces coatings of increased tightness. However, upon metallographic examination, coated samples made with a nominal 0.15 aluminum spelter sometimes show a relatively thick alloy layer and yet pass severe forming tests. Moreover, although the presence of a heavy alloy layer on steel sheets galvanized with aluminum-free spelter generally portends bad flaking, sheets galvanized in the same manner but galvanized, i.e., the coating

FIG. 39-3. The iron-zinc constitution diagram, according to J. Schramm

converted entirely to alloy, will exhibit excellent adherence. Thus there are indications that the composition of the layer may be significant and that the thickness of the layer is a factor; however, any generalizations must be accepted with reservation.

The equilibrium relationship between iron and zinc at different temperatures has been studied by various investigators. The constitution diagram as developed by J. Schramm (1938) is shown in Figure 39-3. The composition and lattice structure of each phase indicated on the diagram are shown in Table 39-III.

Intermetallic compounds present in hot-dipped galvanized coatings produced under a variety of conditions are indicated in Figures 39-4 through 39-7. This series of illustrations shows that the clarity of definition and the relative amounts of the various constitu-

ents of the alloy layer can be varied by varying time and temperature of immersion. The composition of the steel also, particularly the silicon content, can have a noticeable influence on the layer. The presence of tin, antimony and cadmium in the usual amounts found or used in spelter have been reported to have very little effect on the character of the layer; however, aluminum in excess of 0.10 per cent has a decided effect. Figure 39-8 is a photomicrograph at 1000 diameters showing the cross-section of a sheet galvanized coating of aluminum-free spelter.

Figure 39-9 is a similar photomicrograph of a strip galvanized coating of aluminum-bearing (nominal 0.15 per cent Al) spelter. It will also be noted that almost all the coating in the latter instance consists of the eta phase.

COATING METAL USED IN HOT-DIP GALVANIZING

There are a number of commercial grades of zinc or spelter available for hot-dip galvanizing. A list of the different grades is given in Table 39—IV.

Table 39—IV. Composition of the Different Grades of Zinc and Spelter

Grade	Composition, Maximum Per Cent of			
	Pb	Fe	Cd	Pb + Fe + Cd
Special High Grade ..	0.010	0.005	0.005	0.01
High Grade ..	0.07	0.03	0.07	0.10
Intermediate .	0.20	0.03	0.50	0.50
Brass Special .	0.60	0.03	0.50	1.00
Prime Western.	1.60	0.08

In either sheet or continuous-strip galvanizing, it is the general practice to add small quantities of other metals to the coating bath to control the appearance and properties of coatings. The general effects of elements that are either found in or are added to molten commercial grades of zinc are discussed in the following paragraphs:

Lead, in certain percentages, is necessary for the production of a spangled finish. If present in amounts exceeding its solubility in zinc (around 1.00 per cent at coating temperatures), the excess lead settles to the bottom of the coating pot and serves as a cushion to support a bed of zinc-iron alloy or dross that forms during the coating operation.

Antimony is not present in commercial spelter grades and it may be added, if desired, either as an alloy of zinc or as the metal itself. In small amounts it assists in producing an attractive low-relief spangle.

Cadmium, which is present in most virgin splatters, assists in producing a frosty low-relief spangle finish.

Tin additions of from 0.3 to 1.50 per cent have been used for many years to produce a frosty spangle finish in conventional galvanized coatings.

Aluminum additions of between 0.10 and 0.25 per cent increase the adherence of galvanized coatings. The addition cannot be used in conjunction with practices utilizing any of the common chloride fluxes floating on the surface of the zinc, since the aluminum is rapidly removed from the bath by the flux as $AlCl_3$, which is highly volatile at galvanizing temperatures.

A small amount of iron is always present in a hot-dip galvanizing bath. The excess above its low solubility limit gradually settles to the bottom of the pot as dross.

STEELS USED FOR HOT-DIP GALVANIZING

Hot-dip galvanized coatings may be successfully applied to a variety of ferrous metals, ranging from cast iron to low-carbon and alloy steels. In the coating of sheet, the bulk of the production is from low-carbon basic open-hearth steel. The following is a general classification of the grades used in galvanizing:

- A. Rimmed Steel
 - 1. Regular low-carbon
 - 2. Pure iron, copper-bearing
- B. Capped Steel
 - 1. Mechanically capped
- C. Killed Steel
 - 1. Aluminum killed
- D. High-Strength Steel
 - 1. High-strength low-alloy

Copper may be added, if desired, to any of the above grades to improve atmospheric corrosion resistance. Steels containing between 0.20 per cent and 0.30 per cent copper are designated as "copper bearing."

Chemical requirements for the various steel grades, as specified by a majority of the producers, are shown in Table 39—V.

MILL TREATMENT OF STEEL PRIOR TO HOT-DIP GALVANIZING

Sheets used for sheet galvanizing may be processed by hand-mill rolling operations (now practically obsolete) or by continuous rolling processes. Hand-mill sheets are hot rolled, box annealed, cold rolled, and pickled to prepare them for hot-dipping. Continuous-hot-rolled sheets may be either hot rolled in strip form or hot rolled and pickled in strip form before shearing to cut lengths and pickling for the galvanizing operation. Shot blasting after shearing is sometimes used to facilitate the production of heavy coatings on heavy-gage material. Cold-reduced sheets are either hot-rolled, pickled, cold-reduced, and recoiled, or they are hot rolled, pickled, cold reduced, recoiled, and sheared to cut-length sheets before box annealing. Alkaline cleaning is often used after cold reduction to remove rolling lubricants. Material that is box annealed in coils is temper rolled and sheared before pickling for galvanizing, and material that is box annealed in sheet form is temper rolled before pickling for galvanizing.

Coils for continuous galvanizing may be prepared in a number of ways. Thus, they may be hot rolled and pickled; hot rolled, pickled and cold reduced; or hot rolled, pickled, cold reduced, box annealed and temper rolled before processing. Again, alkaline cleaning may be used after cold reduction to remove rolling lubricants. Because of the inherent properties of the base metal, coated sheets made from cold-reduced coils have been found to possess ductility superior to that of coated sheets made from handmill products.

SPECIAL FINISHES

In addition to the regular spangled finish produced in sheet or strip galvanizing, provision may be made in the processing facilities to accommodate the production of special finishes. **Galvannealed sheets** may be produced by passing the material, after it leaves the coating pot, through a heated chamber that maintains the coating metal molten until it alloys completely with the base metal. Galvannealed coatings possess a silvery matte finish of relatively low reflectivity. They have good paint-adherence properties without additional surface preparation and are capable of withstanding moderate forming.

A **bonderized finish** may be produced by processing in line or as a separate supplementary processing operation. In the bonderizing process, a thin film composed largely of zinc phosphate is formed on the sheet surfaces. Bonderized sheets are outstanding with regard to their paint-adherence properties.

Extra-smooth finishes may be applied after galvanizing, galvannealing, or bonderizing, by temper rolling with shot-blasted or with smooth rolls. On bonderized

material the extra-smooth finish may, in some instances, be applied before bonderizing.

Metal sheets shipped and stored in piles or coils are subject to white or variously colored stains when water is allowed to remain in contact with surfaces in the interiors of piles and coils for any appreciable period of time. This condition is usually designated as "wet storage stains." Common sources of moisture may be rain water, melted snow, or condensation, the latter

resulting from sudden temperature changes. Various chemical films and oil films have been found to be effective in retarding the appearance of the discoloration, but, even with filming treatments, wet storage stain is a hazard when sheets or coils get wet.

Good packaging, handling and adequate warehousing facilities have been found to be essential requirements for preserving the original finish until the material is used.

SECTION 3

HOT-DIP SHEET GALVANIZING

Pickling for Sheet Galvanizing—Pickling for sheet galvanizing is usually conducted as a batch operation in stationary tubs provided with an agitating means. This operation may sometimes be conducted as a continuous process in equipment provided with a sheet conveyor and means for electrolytic acceleration.

Very light pickling requiring only a short-time exposure to the pickling solution has been found suitable for products, such as roofing and siding, that require little mechanical deformation. Deep etching of the base metal has generally been found to be necessary when forming requirements are severe.

Following the pickling operation, a thorough water rinse, with or without an alkaline neutralizing dip, is employed to remove iron salts and residual acid. A prolonged immersion in boiling water may be used, when necessary, to minimize hydrogen embrittlement.

Equipment for Sheet Galvanizing—The equipment used for sheet galvanizing (Figure 39—10) consists of mechanical facilities for transporting cut-length sheets successively through acid washing, fluxing, hot-dipping, and cooling operations. The coating bath itself is contained in a heated low-carbon steel vessel or pot. A framework or rigging with suitable entry feed rolls, sheet guides, driven bottom pinch rolls, and driven

exit rolls, is suspended in the bath in such a manner as to completely submerge all but the entry rolls, part of the exit rolls, and part of the supporting framework. A baffled section or flux box at the entry end contains a floating fused-chloride flux prepared from sal ammoniac and the zinc of the bath.

General Arrangement and Operation of a Sheet-Galvanizing Line—A typical sheet-galvanizing line consists of a feeding table, a muriatic (hydrochloric) acid tank, a coating pot, a spangle and cooling conveyor, a water rinse tank, a dryer, a roller leveler and an inspection table (see Figure 39—11). In operating the line, pickled sheets are either fed dry from a feeding table or wet from water boshes directly into a set of driven rubber pinch rolls. The sheets pass forward through a shallow muriatic-acid bath and a second set of rubber pinch rolls into steel intake rolls that force them downward into the flux box of the coating pot. The sheets then pass into the coating bath downward to the driven bottom rolls, and upward through exit rolls, the latter being located at the bath surface. As they emerge from the exit rolls the sheets may have blasts of air, sulphur-dioxide fumes, or powdered sal ammoniac directed against their edges to produce the surface finish desired. To control the amount of coat-

FIG. 39—10. A sheet galvanizing line in operation, showing the hooded setting which contains the galvanizing machine immersed in the pot containing molten zinc, the spangle conveyor, and control station.

FIG. 39—11. Schematic side elevation of a conventional sheet galvanizing line.

ing applied, the level of the bath may be adjusted or the pressure against the exit rolls may be regulated.

Endless belts for conveying coated sheets away from a galvanizing pot are generally made of coarse woven-wire netting. The meshes of the netting contact the sheet in such a manner as to cause rapid solidification at regularly distributed points. These provide nuclei for crystallization and serve, to some extent, as a means for spangle control. A cooling run-out conveyor, usually provided with air blasts, follows the spangle conveyor in a typical installation. Cooled sheets from

the conveyor are roller leveled in line before inspecting and piling. In some coating lines, a water-rinsing and drying operation precedes the leveler. At the delivery end of the coating line the sheets are inspected, counted, stenciled, and stacked into lifts, after which they may be branded and bundled or otherwise prepared for shipment.

If a special finish, such as a bonderized finish, is to be applied to the galvanized sheets, they may be delivered from the galvanizing line to further processing units before shipment.

SECTION 4

CONTINUOUS (STRIP) HOT-DIP GALVANIZING

General Arrangement and Operation of Continuous Galvanizing Lines—The processing of steel in the form of continuous lengths unwound from coils requires more elaborate equipment than the processing of cut-length sheets, but the grouping of several manufacturing steps in one operation makes possible certain economies in production and an overall improvement in control of product quality.

Several designs of continuous hot-dip galvanizing lines are in commercial use. In the simplest arrangement a continuous strip of box annealed and temper rolled steel is passed from an uncoiler through a long muriatic (hydrochloric) acid pickling tank into a galvanizing pot. The strip enters the pot through a layer of flux and regular spelter is used. The coated strip is cooled and sheared on the line to cut-length sheets. It is then inspected and prepared for shipment.

A more elaborate design utilizes the so-called "dry-fluxing" practice. In this modification a thin film of flux in aqueous solution is applied to the strip after it leaves the cleaner and the strip then passes through a drying furnace into the zinc pot. The cleaning, if necessary, can be acid or alkaline. The furnace is operated to deliver heated strip to the coating pot and thus supplies a portion of the heat required to maintain the bath at temperature. Aluminum-bearing spelter is used as the coating metal. The coated product may be re-coiled, or it may be sheared to cut-length sheets.

Another line is characterized by a continuous anneal during which the strip is exposed to a complex gas containing hydrogen chloride. The strip passes through the annealing furnace, a cooling compartment, and a muriatic (hydrochloric) acid bath before entering the flux box of a conventional galvanizing pot. Asbestos wipes are normally used instead of exit rolls on the discharge end of the coating pot. Coatings produced are very thin but are extremely adherent. Regular spelter is used.

Senzimir type lines include controlled oxidizing and reducing steps prior to coating. The cold-reduced strip passes from the uncoilers through an open-flame oxidizing furnace, which also serves as a flame-degreaser, into a reducing furnace where it is annealed or normalized and the oxide film formed in the first furnace is reduced. The strip is cooled in the rearward

zones of the reducing furnace to about the temperature of the coating bath and then passes into the zinc pot through a conduit extending from the end of the furnace to slightly below the surface of the coating bath. Cracked ammonia, introduced into this conduit to flow counter-current to strip movement, provides the necessary reducing atmosphere of the furnace. The degree of oxidation is said to be critical and must be controlled to achieve a uniform film ranging from pale yellow to blue or grey in color. Aluminum-bearing spelter is used.

In the continuous-galvanizing installations at the several United States Steel mills, strip material is alkaline cleaned, rinsed and dried, bright annealed, cooled to slightly above pot temperature and introduced into the coating bath while still protected by the furnace atmosphere. Between 0.12 and 0.18 per cent aluminum is maintained in the coating bath. Figure 39—12 is a schematic side-elevation of a line of this type designed to process 0.010 to 0.050 in. thick light-gage material at speeds up to 300 ft. per min. When coating 28-inch wide 29-gage strip at a speed of 250 ft. per min., the line can produce about 12.5 tons of galvanized sheets per hour. Figure 39—13 is a photograph of the input portion of a line designed primarily for coating heavy-gage material. Operational details are discussed below.

The starting material, which may be, for example, 5,000 to 50,000-lb. coils of full-hard cold-reduced strip steel, is fed from an uncoiler either of the single-mandrel or of the double-mandrel type, directly through pinch rolls to a squaring shear. A leveler may be used to flatten the head end of the strip prior to shearing. From the shear, the strip advances to a welder where the tail end of the coil being processed is attached to the head end of the new coil. Lap, butt or mash welders are used for this operation.

Following the welder, the strip enters the cleaning unit where residual cold-mill lubricant and any mill dirt picked up by the surfaces of this strip in prior processing or storage is removed. Dipping and scrubbing with a hot alkaline solution is used for this purpose on some of the lines; electrolytic alkaline cleaning on the others. Polarity of the strip during electrolytic cleaning, the nature and concentration of the cleaning agent and other cleaning conditions vary. Cleaning is

FIG. 39-12. Schematic arrangement (not to scale) of the units comprising a modern continuous galvanizing line for applying zinc coatings to cold-reduced light-gage strip steel. The steel is fed from the uncoilers into the line, successive strips being welded at their ends to provide an uninterrupted feed. The top part of the diagram shows in succession (left to right) the feeding, heat treating and coating stations. The bottom part shows the finishing end of the line.

FIG. 39-13. A modern, continuous galvanizing line for applying zinc coatings to cold-reduced strip steel in coil form. This particular line was designed to handle heavy-gage material.

followed by rinsing and drying. The strip is moved through the foregoing equipment by the drive bridle, at the end of the cleaning station, which feeds the clean, dry strip into a slack accumulator. A looping pit, 30 to 90 feet deep, as shown in Figure 39—12 is usually provided for this purpose; where excavation is impractical a tower-type or a horizontal car-looper is used. The speed of the drive bridle is automatically controlled to maintain a desired length of loop in the pit and the slack so stored permits the input end of the line to be stopped for the joining operations without affecting the operation of the other sections of the line.

Strip is pulled out of the looper by a tension bridle and passes into the annealing furnace. The latter is heated either by gas or electrically and is divided into several independently controlled zones that can be operated in such a manner as to permit the strip to attain the desired annealing temperature in the furnace and yet enter the coating metal at but slightly above bath temperature (thus maintaining the coating bath at operating temperature). A mixture of cracked ammonia and NX gas is maintained within both heating and cooling sections of the furnace to prevent oxidation of the strip in process. The discharge end of the furnace extends below the surface of the molten zinc and the gases, which may be introduced at several points along the length of the furnace, flow counter to strip movement to escape at the entry end of the furnace. Furnace atmosphere is maintained at a positive pressure of $\frac{1}{2}$ to 1 inch of water. A considerable portion of the gas is introduced near the end of the last cooling zone to aid in cooling the strip and to insure a non-oxidizing environment for the strip and zinc at their point of initial contact.

When starting operation, the metal in the coating pot is melted either with gas or electric heat. As stated earlier, the pot is kept at operating temperature by heat

that is carried into the bath of molten metal by the strip.

The coating pot contains a sinker roll for submerging the strip in the bath, as well as exit rolls for controlling the thickness and distribution of the coating. The exit rolls are driven and are mounted to operate about half-submerged in the zinc. As in sheet practice, weight of coating is controlled by adjusting the pressure between the rolls and the relative position of the rolls with respect to the level of zinc in the pot.

From the exit rolls, the strip passes vertically upward to a large-diameter roll mounted at the top of a cooling tower. Forced-air blasts are directed against the strip to assist in solidifying the coating before it reaches the tower roll. Air blasts may also be used on the downward pass.

The coated strip, after returning downward from the tower, passes through a drive-bridle assembly that furnishes the necessary tension to pull the material through the annealing and coating units. Space is usually provided immediately ahead of this drive unit for any special treating facilities, provision being made to by-pass or withdraw such apparatus when not in use.

At the finishing end of a continuous galvanizing line, operations are usually of such a nature as to require occasional interruption. For this reason, looping facilities similar to those described for the entry portion of the line generally are provided. For producing coiled galvanized strip, a roller leveler and recoiler may follow the looper. For producing cut-length sheets, a flying shear equipped with suitable pinch-roll and leveling equipment is used after the looper. At the discharge end of the line, a sheet leveler may be used to flatten the sheets before preparing them for shipment.

Various automatic devices are installed in the finishing section to facilitate handling and assorting; these include automatic reject and prime pilers following the inspection table.

SECTION 5

TESTING GALVANIZED SHEETS

The weight of coating on a galvanized sheet is determined by weighing a 2¼-inch square test piece or a 2.539-inch diameter circular-disc test piece, dissolving the coating in hydrochloric acid containing antimony chloride as an inhibitor, and reweighing the washed and dried test piece. The weight loss in grams is numerically equal to the coating weight in ounces per square foot of sheet. Triple-spot tests selected from the center of the sheet and from two diagonally opposed corners may be used for sheet material, and edge-center-edge spot tests may be used for the continuous product. It is customary to obtain edge spot tests two inches inward from the actual edge of the sheet or strip.

Bend tests are sometimes used for determining coating adherence and base-metal formability, especially in heavy-gage galvanized sheets. The bend, which may be made in a vise or punch press, is generally a full angle of 180° around a specified number of sheet thicknesses of the same gage as the test piece.

The **beading test** is commonly used for testing coating adherence in light-gage material. The width, depth, and radii of the beads vary somewhat throughout the industry, although definite standards have been established by individual operators. In conducting the beading operation, the impressions may be made to cross each other or run straight along the edge of the test piece, depending upon the severity of the test desired.

The **lockseam test** is used quite extensively in the sheet-galvanizing industry for testing coating adherence. For sheets that are to be used for seaming, the test also serves as a check on the formability of the base metal.

Tensile properties of the base metal are determined by the standard tension test using an 11/16-in. by 8-in. specimen machined in the center to a 0.5-in. width. In this test the yield point, ultimate strength and percentage of elongation in a 2-in. gage length are measured.

The **Rockwell "B" hardness** of the base metal is determined by subjecting a stripped sheet to the standard Rockwell testing procedure.

The **Olsen cup test** can be used to obtain an indication of the drawing properties of the base metal as well as the adherence of the coating.

Ferritic grain size can be determined by polishing and etching a longitudinal section of the base metal and comparing the microscopic grain structure with that of the proper standard grain-size chart.

THE MANUFACTURE OF STEEL WIRE AND STEEL WIRE PRODUCTS

SECTION 1

HISTORY AND IMPORTANCE OF STEEL WIRE

Historical—In general, wire is a term that may be applied to any metallic shred, thread, or filament, or to any exceedingly slender rod or bar of metal having a uniform cross section. Considering the term in this sense, wire is of very ancient origin. Gold wire is mentioned in the Bible in connection with the sacerdotal robes of Aaron, and was used to form part of a necklace, found at Denderah, which bears the name of the Pharaoh who reigned in Egypt about 2750 B.C. Evidences of the use of wire by the Assyrians and Babylonians as far back as 1700 B.C. have also been found.

As to the methods of manufacture used by these ancient peoples, practically nothing is known. The specimens of ancient wire that have been found so far are flat, and it is probable that they were produced solely by hammering.

How, when or of what material round wire was first made is not known. No doubt it was first produced by hammering, but the difficulty of forming a fine round wire by this method probably caused the metalworkers, early in the history of the art, to seek some better method. An old Latin manuscript written by Theophilus sometime during the 8th and 9th centuries describes a method of making wire of an alloy of lead and tin, which was cast into an ingot, hammered into a long slender bar and drawn through holes in a wire-drawing plate.

The draw plate, itself, is described as "a piece of iron three or four fingers wide, smaller at the top and bottom, rather thin and pierced with three or four rows of holes through which wire may be drawn." However, there is reason to believe that the art of wire drawing was known and practiced before this time.

The chain armor used by the knights in the great crusades against the Saracens and Turks is thought by many to have been made of drawn wire. Other authentic records are available to show that wire drawing on a commercial scale was practiced in France in 1270, in Germany in 1350 and in England in 1465. The first wire-drawing mill in this country was built in 1775 by Nathaniel Miles at Norwich, Conn. But, though three other mills, two of which were in Pennsylvania, were started during the next twenty years, none of these appear to have been very prosperous, for in 1820 practically no wire was being made in this country. In 1831, however, the industry was reestablished in this country by Ichabod Washburn of Worcester, Mass., who, with Benjamin Goddard, founded the firm of Washburn, Moen and Company.

Present Importance of Steel Wire Industry—From that date, 1831, the wire industry grew very rapidly. Aside

from the great quantities of wire made from other metals, such as copper and brass, the present annual production of steel wire alone is astonishing. For normal years, the production of steel wire rod now is about 5,500,000 tons. This tonnage represents about one-twentieth of all the steel produced in the country, and if it were all drawn into No. 12 gage wire, which is about average, it would have a total length of more than 70,000,000 miles or enough to girdle the earth about 2,800 times. The causes contributing to this growth were many and cannot be discussed in detail here, but they may be grouped or classified about as follows: (1) The great number of purposes to which wire, particularly steel wire, is adapted. (2) Development of inventions requiring great quantities of wire. (3) Improvements in the methods of producing steel and steel wire. It need not be pointed out that these causes are interdependent.

New demands stimulated efforts to improve the methods of manufacture, and as these improvements resulted in the bettering and the cheapening of the product, new uses were found for it.

Principal Uses of Steel Wire—The adaptability of wire to the manufacture of household articles of common use has expanded until it has become known as the steel product of 150,000 uses. These articles, including such items as pins, needles, brooms, strainers, hooks, egg beaters, toasters, etc., are almost indispensable to our comfort. Of the many inventions developed since 1820 that make use of large quantities of wire, only a few of the most important can be mentioned here. The first of these was wire rope. Rope made of bronze or brass wire is known to be of ancient origin, while iron wire rope was used in Europe as early as 1820. The first wire rope manufactured in this country was made in 1840 at Saxonburg, Pa., by John A. Roebling, founder of the firm of John A. Roebling's Sons Company. In 1844 the first telegraph line, extending from Washington to Baltimore, was completed by Professor Morse, but for more than ten years the growth of the telegraph was hampered because the wire essential in the construction of the lines could be produced only in short lengths, which required much time and labor for splicing.

The use of crinoline wire, a high-carbon heat-treated wire, for hoop skirts has been cited by some as a novel use of the product and as a great boon to the industry, but is better as an example of the unstable character of a business that depends on fashions. Starting about 1860, this business, for the next ten years, consumed about 1500 tons of wire annually, but suddenly collapsed with the passing of the hoop skirt in 1870. This was not to be the last time that feminine fashions would play a part

in the wire industry, for in 1916 some 15,000 tons of wire were being consumed annually in the manufacture of corsets and several hundred tons for hair pins, but these have largely disappeared as did the crinoline wire.

The collapse of the crinoline-wire business was replaced by more staple articles, for in 1868 the first patents were obtained on the use of wire for bale ties and barbed wire for fence. Both these articles came quickly into wide use, the latter article being especially useful in fencing the great unwooded lands west of the Mississippi River, which were rapidly being brought under cultivation about this time. By 1876 the development of the telephone had reached the practical stage, and began to create a demand for more wire of the same type used by the telegraph. It was in 1879 that the beneficial effect of sulphur on machinability was discovered, and the manufacture of high-sulphur screw stock was begun. Chas. H. Morgan also began the manufacture of coiled-wire springs in this year. In 1884 woven-wire fence was first made by machinery. This fence, of which there are now several types, fulfilled all needs that could not be met with barbed-wire or straight-wire fence and possessed all the advantages of any fence that could be constructed of wood, hence it was soon being used in all parts of the country. In 1851 the first American-made wire-nail machine was built by Thomas Morton; in 1875 the first steel-wire nails were made; and in 1888 the production of the wire nails exceeded that of the cut nail for the first time. Today, about twenty times as many wire nails as cut nails are made, and about one-fifth of all the steel wire produced is made into nails. Since 1890 no inventions making such unusual demands upon the wire industry have appeared, so that these items, with the two or three exceptions noted, remain the backbone of the steel-wire industry. However, innumerable items employing steel wire in smaller quantities have been developed, which, added to the rather rapid growth of these principal lines, have contributed to a continual expansion in the industry.

The extent of this expansion can be judged from the fact that the production of steel wire in 1923 was more than twice that for 1903.

Early Method of Manufacture—The methods employed at the time of the introduction of wire drawing into this country were wholly inadequate to meet the demands that were soon to arise. As the Bessemer and open-hearth processes for making steel were then unknown, practically all wire was made from wrought iron, or the softer metals like copper, brass, bronze, etc., though crucible steel in softer tempers was also used. Practices varied somewhat in different localities, and detailed descriptions of the operations are lacking but, from information gleaned from different sources, the process and operations for drawing wrought-iron and steel wire appear to have been about as follows: Starting with a small square bar or billet, the metal was heated and hammered into as small a round as practicable, say $\frac{1}{4}$ to $\frac{3}{8}$ inch in diameter and some 6 to 10 feet in length. One end of this rod was tapered to a size a little less than the hole in the die through which the rod was to be drawn. The rod was then scoured bright with a piece of sandstone or other abrasive. In the case of iron and steel, it was early discovered that this cleaning of the rod was not only essential to good work but was well worth the trouble, for the hard scale, when not removed, soon scored the die. Then, the tapered end of the rod was inserted in the proper hole of a draw plate made of cast iron or hard steel, where it was grasped with a pair of tongs attached to a lever, and the rod was drawn through the hole a few inches at

a time, about 5 inches at each stroke being the common practice. The lever could be operated either by hand or by water power, and the rod, as it passed through the hole, was generally lubricated with butter or other grease, to facilitate the drawing and save the die as much as possible. After the first draft, the operation was repeated through progressively smaller holes in the draw plate until the wire was drawn to the size desired or until it became too hard and brittle for further drawing. If the wire was to be drawn to still finer sizes, it was annealed at a red heat, generally in an oven sealed off from the air, after which the thin coat of oxide thus formed was removed by tumbling with a mixture of sand and water, or by immersing the wire for some time in sour beer or fermented barley water. The machine for drawing this fine wire differed somewhat from that used for drawing the rod. The draw plate was mounted on a table or bench in front of a drum or block that could be revolved by a hand-operated crank and gear drive. After pointing, the end of the wire was inserted into the die and drawn through by tongs, until it could be attached to the drum. Then, by revolving this drum, the drawing of the wire could be performed in one continuous operation, the wire being wound about the drum and thus drawn through the die.

Improvements in the manufacture of iron and steel wire have kept pace with the demands. In connection with this statement, it should be noted that the basic principles of wire making have remained unchanged. As already indicated, the process consists essentially in drawing a rod or a slender piece of the metal through a tapered hole in some harder material, or successively through a series of such holes. It involves the application of force in the simplest manner, a straight pull, and the use of one of the simplest tools, the wire-drawing die. The efficiency of the latter and the simplicity of both these elements have left little room for improvement, and many doubt the possibility of finding a substitute for the process that will do the work so well. The improvements that have been made pertain to the accessory equipment and to the complementary operations, rather than to the process of wire drawing itself. Thus, the need for long lengths was met not by any radical change in the wire-drawing process, but by changing the method of producing the wire rod. As long as the rod was made by hammering, it was too short to coil, or draw with a block; but when the need for long lengths began to be felt, efforts were made to roll the rod. About 1840, Washburn succeeded in adapting the wire-drawing block to coarse-wire drawing. This block was power driven, and provided a means not only of applying a greater pulling force continuously to the rod, but also of storing the wire as it was drawn through the die. This development made it desirable to use very long rods, and this demand was met first by the invention of the three-high mill about 1857, which was succeeded by the Morgan continuous mill about 1875 and the Garrett rod mill in 1882.

Another important development was the substitution of soft steel for wrought iron, made possible by the invention of the Bessemer and the open-hearth processes for steelmaking. This change was inaugurated in this country by the Washburn and Moen Manufacturing Company at Worcester, Mass., in 1871. Important improvements in methods for handling, cleaning, coating, or lubricating the rod, and in heat treating and finishing the wire, were also made.

This brief historical review serves as an introduction to the study of the manufacture of steel wire as it is carried on today.

SECTION 2

CLASSIFICATION OF STEEL WIRE

Bases for Classification—Steel wire products are classified in various ways, as indicated in Table 40—I. From the standpoint of a manufacturer, the factors of greatest interest are the kind and grades of steel; the size, shape and mechanical properties of the wire; and the methods of drawing and treatment. In commercial transactions, classifications based upon mechanical properties of the wire, its treatment and finish, and its commercial applications are of most interest. The following brief descriptions are intended to assist the reader to a better understanding of the classes listed in the table.

Kinds and Composition of Steel Used for Wire—The steel for wire is produced by all the modern processes, including the basic open-hearth, Bessemer, and electric-furnace processes. Some special grades of wire are still made from Swedish wrought iron. Plain carbon steels chiefly are produced by the basic open-hearth, and Bessemer processes; mainly stainless steels and alloy steels for certain special-purpose wires are made in electric furnaces.

By properly selecting and handling the plain carbon steels in drawing and heat treating, it is possible to develop a wide range of mechanical properties. Ordinarily, sulphur and phosphorus are kept within the usual limits for each grade of steel, while the silicon, manganese, and carbon contents are varied according to the mechanical properties desired. Occasionally, the sulphur content will be increased to improve the cutting qualities (machinability) of the steel.

In recent years, there has been a constantly increasing demand for wire possessing properties that cannot be

obtained by cold working and heat treating plain carbon steel. This demand has been met by the addition of alloying elements, such as nickel, chromium, manganese, silicon, vanadium, tungsten or combinations of them. Many of these alloy steels can be produced satisfactorily by the basic open-hearth process. For those that cannot and for the stainless steels containing large percentages of chromium and nickel, electric furnaces of the arc type are commonly used and, to a decreasing extent, the induction type of electric furnace is sometimes used. Each of these processes produces steel having the best properties for certain purposes or kinds of wire.

Wire Shapes—While wire is ordinarily thought of as being round, i.e., with a circular section, it may have any one of an infinite number of sectional shapes, as required by the particular use for which it is desired. After the ordinary round wire of circular section, the most common shapes are square, hexagon, octagon, oval, half-oval, half-round, triangular and flat. Besides these regular, or symmetrical, shapes, wire is also made in various odd and irregular shapes for specific purposes.

The American Iron and Steel Institute (AISI) Steel Products Manual, Section 17, defines a flat wire as a cold-rolled product, with a prepared edge, rectangular in shape, $\frac{1}{2}$ -inch or less in width, under $\frac{1}{4}$ -inch in thickness. "Low-carbon steel flat wire is generally produced from hot-rolled rods or specially prepared round wire, by one or more cold-rolling operations, primarily for the purpose of obtaining the size and section desired and for improving surface finish, dimensional accuracy and varying mechanical properties. Low-carbon steel flat wire can also be produced by slitting cold-rolled flat steel to the desired width. The width-to-thickness ratio together with the specified type of edge generally determine the process which will be necessary to produce a specific flat wire item." Those edges, finishes, and tempers obtainable in flat wire are similar to those furnished in cold-rolled strip.

Sizes of Wire—The size of round wire is determined by its diameter, which is expressed in absolute units, or decimal parts thereof, or by gage numbers. In this country the absolute unit is the inch, and the diameter is obtained by a micrometer capable of making measurements accurate to at least one thousandth of an inch. As stated in Chapter 50 on gages, there are several different gages in effect for the measurement of wire. The size of music wire is expressed in gage numbers of a system known as the Music Wire Gage (M.W.G.), which is the standard for this wire. For iron and steel telephone and telegraph wire, the standard gage is the Birmingham Wire Gage (B.W.G.), while for copper electrical wire the Brown and Sharpe Gage (B.S.G.), also known as the American Wire Gage (A.W.G.), is largely employed. With these notable exceptions the gage used by the American Steel and Wire Division of United States Steel and by many other manufacturers of steel wire, is the United States Steel Wire Gage (U.S. Stl.W.G.), or the Steel Wire Gage (Stl.W.G.), and all unidentified gage numbers used in this chapter will refer to this gage, which is shown in Table 40—II.

The size limits for the product commonly known as wire range from approximately 0.005 inch to under 1 inch for round sections, and from a few thousandths of an inch to approximately $\frac{1}{2}$ inch for square sections. Larger rounds and squares, and all sizes of hexagonal and octagonal shapes are commonly known as bars.

Table 40—I. Kinds and Classes of Steel Wire

Classification, according to:

Method of making the steel—Basic open hearth, Bessemer, basic electric furnace, and acid electric furnace.

Compositions of steel—Low carbon (C1006, C1008, C1010, C1012, B1006 and B1010), medium low carbon (C1013 to C1022, inclusive), medium high carbon (C1025 to C1041, inclusive), high carbon and alloy steel.

Shape—Round, half-round, oval, half-oval, square, rectangular, hexagonal, crescent, triangular, etc.

Method of drawing—Dry-drawn, wet-drawn, single-draft drawn and continuous drawn.

Size—Common wire or coarse wire, fine wire.

Treatment and finish—Bright (hard dry-drawn), bright soft (annealed in process; processed wire), normalized (pre-normalized), spheroidized, extra smooth clean bright, sully coated, annealed, black annealed (pot annealed), strand annealed (lead annealed), bright annealed, lime bright annealed, patented, oil tempered, liquor finished (coppered or bright coppered wire), galvanized, tinned, aluminum coated.

Uses or commercial applications—Armor wire, bale-tie wire, bolt wire, broom wire, cold-heading wire, concrete reinforcement, fence wire, music wire, piano wire, poultry netting, rope wire, spring wire, telephone wire, telegraph wire, tire wire, welding wire, wool wire (for steel wool), special wires, miscellaneous wires.

Classification of Common Round Wire According to Size—As wire may include a wide range of sizes, its classification has been governed somewhat by manufacturing equipment and methods of handling. It normally is separated into two broad groups known as **coarse** and **fine** wire. The fine-wire classification is usually recognized as including 16 gage and smaller wire, normally produced in 8-inch diameter coils. Coarse wire includes sizes 20 gage and coarser, normally drawn on 16-inch, 22-inch and 26-inch or 30-inch blocks. The distinction is not clearly drawn for 16 to 20 gage, inclusive, as this range is commonly regarded as coarse wire for some end uses, and as fine wire when made by a different manufacturing practice for other end uses. The most commonly used wire sizes are those drawn from a 7/8-inch rod to 8 to 20 gage, inclusive.

Surface Finishes of Wire—A variety of finishes on the wire may be obtained by controlled processing in manufacture. The more common finishes are usually designated as **bright**, **black annealed**, **liquor finished**, **coppered**, **tinned**, **galvanized**, **aluminum coated**, and **painted** or **enameled**. For certain specific uses, a drawn alumi-

num coated or a drawn galvanized finish is sometimes produced, by cold drawing the wire one or more drafts through a die after coating. The bright finish is obtained by dry drawing, liquor finish by wet drawing, black annealing finishes by oxidation of the surface in heat treatment, while the tinned, galvanized and painted finishes are produced by subjecting the wire to a coating process as a final operation. The methods used in producing these different finishes will be developed more fully in the description to follow.

Temper of Wire—In the wire industry, temper is a word used in referring to the hardness, stiffness and strength of wire. The temper is affected by the amount of carbon, manganese and phosphorus, or other alloying element present in the steel, the amount of cold drawing without annealing, and the heat treatment given the wire. Thus, increasing the carbon content of the steel or submitting the wire to drawing operations increases the temper, while heat treating may either harden or soften the metal, according to whether it is heated to the hardening-temperature range and quenched, or annealed. The strength and hardness of low-carbon,

medium-low carbon and medium-high carbon wires are regulated by drawing and annealing operations, and of high-carbon wires by drawing and patenting operations. The tempers of low-carbon wires are usually expressed as hard, medium hard, bright soft, soft and extra soft. Thus the **hard temper** is obtained by drawing through several dies in succession without annealing to obtain considerable reduction, **medium hard** by drawing (usually fewer drafts) to obtain somewhat less reduction or, in some instances, by subjecting hard temper wire to a partial or "slack" annealing, **bright soft** by giving the wire one light pass through the die after annealing, and soft and extra soft by annealing after drawing to size. Thus it will be seen that by properly correlating all these factors—composition, drawing, and

heat treatment—the mechanical properties of steel wire may be varied over a wide range of hardness, strength, toughness, ductility, or softness. As an illustration of the possibilities in varying these properties, there may be cited the strength of steel wires, which are regularly made with tensile strengths varying from 50,000 to as high as 500,000 pounds per square inch for the smaller gages of high-carbon wire. It must be remembered, however, that, with but one exception, whatever is done to strengthen the metal will decrease its ductility, and vice versa.

The exception refers to the special heat treating process known as patenting, which may, under certain conditions, increase both the strength and ductility of the

SECTION 3

ROLLING THE WIRE ROD

The Wire Rod—The slender rods or bars of metal from which wire is drawn are known as wire rod, and, as already indicated, all steel wire rod is now produced by hot rolling. It may be made in various shapes and sizes, but for common wires and fine wires, i.e., No. 8 and finer, $\frac{7}{32}$ -inch round rod may be considered as the standard. This size rod is the smallest round that is practicable to produce on a rolling mill and, while the diameter may vary, it is nominally 0.218 inch. For large wires the rod will, of course, be somewhat larger than the wire to be made from it. As the rod comes from the rolling mill, it is wound into coils. These coils are usually about thirty inches in diameter inside and weigh from 300 to 1200 pounds each. Each coil represents the rod made from a single billet, and its weight, therefore, is determined by the weight of the billet used. While the wire rod represents a finished product of the rolling mills, it constitutes the raw material used in the wire mill and should be considered as the first step in the making of wire, for upon the kind and quality of the rod depend largely the kind and quality or grade of wire drawn from it. Physical defects in the rod will either cause failures in drawing or remain as more minute defects in the wire. While some wire mills obtain their rods from outside sources, many mills, especially the larger plants, roll their own rods.

Types of Rod Mills—After it has been made according to specifications, the steel for wire is cast into ingots and rolled on the blooming mill in the usual manner. In some cases the blooming mill is succeeded by a billet mill, and the blooms are rolled into billets $2\frac{1}{2}$ inches square or less in size. Frequently the product of the blooming mill is a 4-inch by 4-inch billet, which is cut into lengths to give the weight desired, allowed to cool, inspected, reheated, and then rolled directly into rods. As pointed out in the first section of this chapter, the demand for wire in exceedingly long lengths and in large quantities has led to the development of special mills for rolling the rods. These mills are of four different types, known as: (1) the Morgan, or continuous, rod mill, (2) the Garrett, or looping rod mill, (3) the combination, or combined continuous and single Belgian, rod mill, and (4) the double Belgian rod mill. Of these the first two employ fundamentally different principles of roll arrangement, hence will be described somewhat in detail.

The Continuous Rod Mill represents a development which in this country began about 1870. At that time the mill most generally employed for rolling rods was the **single train Belgian, or looping, mill**. This mill, while

it represented a great improvement over the single-stand three-high mill, was comparatively inefficient and was limited as to the length of rod it could roll. Since all the rolls were run at the same speed, the billets could be roughed down much faster than the rod could be finished, and, owing to the loops formed and the length of time required for the piece to pass through the finishing rolls, the rod would become too cold to finish if its length exceeded certain limits. In 1839, however, the Washburn and Moen Manufacturing Company erected at their Grove Street Works, Worcester, Mass., an entirely new type of mill, which had been patented in 1862 by George Bedson of Manchester, England. This mill consisted of a number of pairs of horizontal rolls and an equal number of vertical rolls arranged in a series so that the first, third, and succeeding stands of odd number were horizontal, while the second, fourth, and other stands of even number were vertical. This arrangement of the rolls made the draft in any stand at right angles to that in the succeeding stand, and overcame the necessity of giving the piece a quarter turn between passes, as in the looping mill. Then, by placing the stands as close together as possible, he was able to drive the mill through two long shafts, on each of which was mounted a system of gears, whereby the rolls of each stand beyond the first was made to revolve at a rate definitely faster than the stand preceding. This system of driving was to regulate the speed of the different stands so that the peripheral speed of the rolls in each would be the same, or nearly the same, as the linear speed of the bar, which increases after each pass due to the elongation. In this way the looping of the rod between passes was avoided, and a billet once started in the first stand was rapidly carried through the mill in a straight line, being thus rolled into a rod in one continuous operation. This mill met all expectations as to speed and length of rods rolled, but its output was restricted at first, because the rods could not be coiled and taken out of the way as rapidly as the mill could produce them. But C. H. Morgan, who was then general manager for Washburn and Moen, soon overcame this difficulty by devising a power traction reel for coiling the rods. This was the beginning of the development of the automatic reels, which will be described later.

The Morgan Mill—While the Bedson mill represented a great advance in rod rolling, it possessed certain mechanical features which were objectionable. Its chief faults were found to be due to the vertical rolls. They were not easily kept in adjustment, and the shaft and

gears for driving them were all beneath the mill floor. The scale and water from the rolls fell upon these gears and bearings and caused excessive wear, which, combined with the difficulty of getting to them under the floor, made them a source of much trouble. After a few years' experience with the Bedson mill, therefore, Morgan and his associates developed the twisting guide, by means of which the vertical rolls could be eliminated and horizontal rolls substituted for them. This was a closed delivering guide in which the grooves were cut in a spiral, so that with this guide properly mounted after any pass the piece was forced through it and twisted a quarter turn before it entered the next pass. Besides overcoming most of the disadvantages of the Bedson mill, this Morgan plan presented the additional advantage of more than one rolling line, that is, of rolling two or more rods side by side at the same time and on the one set of rolls. This plan of increasing the capacity of the mill, however, increases the difficulty of keeping such mills in adjustment, and was not taken advantage of until some years after the erection of Morgan's first mill. Even with a single rolling line, the development of the mill to a practical basis of operation presented some difficult problems. It is evident that such a mill requires very fine adjustment of the draft, roll diameter, and speed of rotation, for these factors are brought into close relation. The relations of all these factors can be determined by proper mathematical calculations, but as the draft fixed by the grooves in the rolls is affected by the adjustment of the rolls, the temperature of the bar, the composition of the steel, and changes with the wearing of the grooves and bearings, much difficulty was at first experienced in getting the mill adjusted so that the piece would not loop or jam between the different stands of rolls. This was particularly true in the case of the last few roll stands of the high-speed finishing mill. This difficulty was finally solved by increasing the speed of the rolls enough to keep the rod under slight tension at all times, and by making the bottom as well as the top roll adjustable as explained under the heading of continuous billet mills.

Modern Continuous Rod Mills—Since the time of Morgan's first mill, various improvements have been made, not so much in the mill itself as in the auxiliary equipment. These improvements have made it possible to produce a more nearly perfect rod in greater and greater tonnages. The delivery speed of modern con-

tinuous mills rolling $\frac{7}{32}$ -inch rod ranges from 3700 to 6000 feet per minute. The actual output of a mill depends upon conditions and the number of rolling lines, which was formerly one or two, and in recent years has been increased to three or four. The number of stands of rolls in a mill and, to a considerable extent, the general layout of the mill, depends upon the size of the billets used and rod size to be rolled therefrom. As previously pointed out, there are several standard sizes of billets, $1\frac{3}{4}$, 2, $2\frac{1}{2}$, and $3\frac{1}{4}$ inches square.

Layouts for Rolling Small Billets—From the standpoint of general efficiency, accuracy, and uniformity in size of the product, continuous rod mills are designed, preferably, to roll billets from $1\frac{3}{4}$ to $3\frac{1}{4}$ inches square and approximately 30 feet in length. This length fits the former standard railroad freight car, while the section is about the largest that can be rolled satisfactorily without a reheating or increasing the speed of the mill beyond the limits of safety and practicability. To work these sections into a $\frac{7}{32}$ -inch rod (0.218-inch) without unduly increasing the danger of developing rolling defects, requires from 16 to 23 passes. For straight continuous rolling, that is, where the rolls are all in the same straight line, these passes are split into two groups, known as the roughing and the finishing sets (Figure 40—1). The roughing set consists of 6 to 9 stands of rolls, the first of which is set as near to the discharge door of the heating furnace as possible, usually within 6 to 12 feet. Since the furnace is of the continuous side-discharge type, this arrangement makes it possible, without removing the billet entirely from the furnace to push one end into the rolls, which then withdraw it no faster than it is being rolled. Immediately following the last roughing stand is a flying shear, which permits the cropping of bad ends before the billet enters the high-speed finishing sets. To provide space for these and also for a little slack between the two groups of rolls, so as to make it easier for the roller to keep the mill in proper adjustment, the first stand in the second group is placed about 20 to 30 feet from the last roughing stand. The second group of rolls contains 10 or 12 stands, the last of which is known as the finishing stand. Following the finishing stand, tube-like pipe guides are provided for conducting the rod to the reeling machines which are located some 20 to 60 feet beyond and usually number twice the number of rolling lines or strands. The chief advantages in this arrangement lie in its

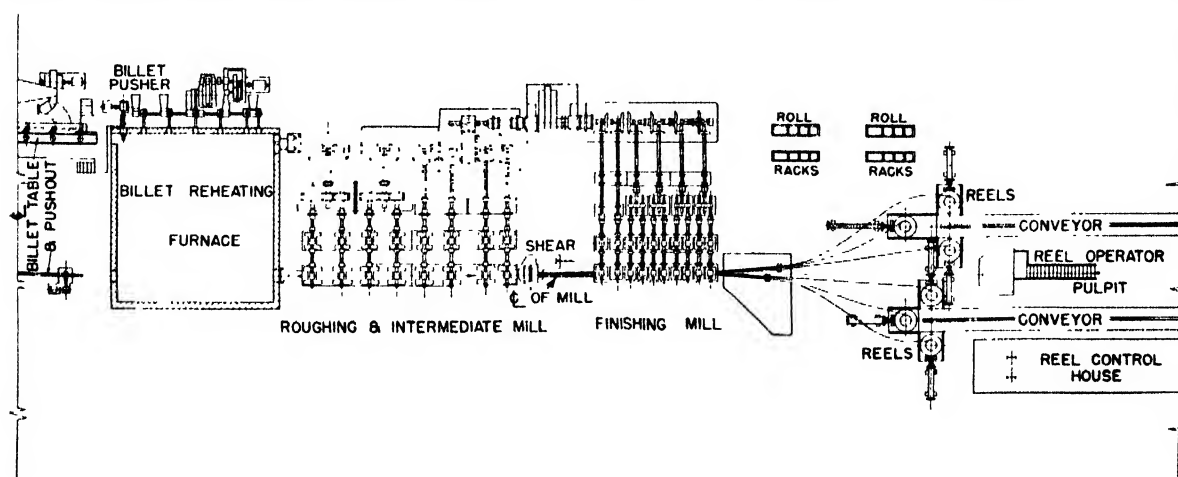

FIG. 40—1. Plan and layout of continuous rod mill for 2-inch billets, including reels and part of the rod bundle conveyor.

compactness, which aids in maintaining uniformity of rolling temperature and provides for a choice of different methods of driving. The control of temperature possible is evident from the fact that at the time the forward end of the rod reaches the reels, about one-half of the billet is still in the furnace. For driving the mill, two motors, one for each group of rolls, may be used, but some mills of this type are driven through two shafts connected by gears to a single motor or steam engine.

The Looping Continuous Mill—To provide greater flexibility and make it easier to keep the mill adjusted, in some recent installations of continuous rod mills, the finishing group of rolls also has been split up into three smaller groups of four, two and four stands each. The two-stand group is both preceded and followed by 180-degree loops. The roughing rolls and the first four intermediates are in the same straight line, and driven in the usual way by a single motor, while the next two groups, driven by another motor, stand in two separate lines parallel to the first line, with the two-stand group a little in advance of the finishing stands. Since the roll speeds are adjusted to the elongation of the piece being rolled, the loops, once formed, increase very little in size, and cooling of the rod through this exposure is very slight and uniform for each unit of its length. Also, this placing permits ironing out some of the effect of tension in the early part of the mill.

Layouts for Rolling 4-Inch by 4-Inch Billets—Although the continuous mill is best adapted to roll small long billets, local conditions frequently make it desirable or necessary to start with a larger size of billet. To meet such conditions, many continuous mills have been designed to use 4-inch by 4-inch billets. In designing these mills, the engineers have developed two plans. In one of these an additional group of roughing or breaking-down rolls is provided, and the rod is rolled directly from the billet, as in the straight continuous plan for small billets. The plan has some drawbacks, the chief of which may be noted as follows: If all the rolls are speeded to correspond to the elongation of the bar, the speed of the first roughing group is very slow. Even with the finishing roll revolving at the rate of 1350 r.p.m., the speed of the first roughing rolls, with a roll diameter of 14 inches, would be close to 3 r.p.m. The long time the piece is thus kept in contact with the cold rolls results in cooling it to a point where it becomes difficult to finish. If the first roughing group is speeded up, then the piece must be held ahead of the first intermediates and is cooled even faster and more unevenly than in the former instance. In some cases a solution to this difficulty has been sought by placing a heat retainer, a long narrow brick chamber heated by gas, between the roughing and intermediate groups. By passing the billet through this chamber slowly some of the heat lost in the previous rolling may be restored before it enters the intermediate sets of rolls. But the best plan involves the use of a reheating furnace between these two groups of rolls. In this plan, which is in effect equivalent to placing a billet mill before the usual straight continuous rod mill, the first group of rolls, consisting of several stands driven by a separate motor or engine, breaks the 4 by 4 by 72-inch billet, for example, down to a more suitable size billet about 30 feet long. This long billet is immediately charged into the continuous reheating furnace, where its rolling temperature is fully restored before being rolled to finished size. From this point the arrangement of the mill does not differ materially from the straight continuous plan already described.

Operation of Continuous Mills—With the mill prop-

erly designed and erected, its efficient operation depends largely upon the skill of the operating crews, headed by the roll turner and roller. For best results the roll diameters for the different stands must be carefully selected and maintained in proper proportions; the roll passes, especially for the finishing group of rolls, must be skillfully adjusted and accurately turned; the rolls and guides must be carefully set in the housings; and thereafter the draft must be regulated through the mill screws to suit the conditions. The uniform heating of the billet is also a matter of importance, as is seen from the following facts: Under a given pressure, a hot bar or rod will elongate more than a colder one. Translated into operating terms, this statement means that if the mill is adjusted to roll the colder rod properly, the hotter rod will buckle between passes and cause cobbles. The mill must, therefore, be adjusted to the hottest bars, and if the draft on the different passes is regulated to keep this bar under slight tension the same adjustment will produce a pull of considerable force on the colder bars. Thus pull is the cause of the longer "finny" ends which are characteristic of rods rolled on straight continuous mills, and it also produces a difference in section between the ends and the middle of the rod, causing it to exhibit a tendency toward flatness in the middle. This matter is especially important in the case of mills rolling more than one line, or strand, at a time. In such a mill, any adjustment of the screws to correct a fault in one pass affects the draft on the corresponding pass of the other strand also, and it is practically impossible to overcome any variation in temperature of the two strands through adjustment of the rolls only.

The Garrett Mill—Up to 1882 the continuous rod mill had no competitor as to speed, length of rod, and tonnage produced. On the Belgian, or looping mill, which was the only other type of mill used for rolling rods, the longest lengths that could be rolled would not exceed 300 feet, the heaviest coils weighed less than 50 pounds, and the tonnage produced daily would not, in case of small rod under 0.2-inch diameter, much exceed 20 tons. On such mills the best rolling practice of that day for steel involved the rolling of the ingots to 4-inch by 4-inch blooms, which were cut into lengths convenient for hand rolling and allowed to cool. These blooms, or billets, were then reheated and rolled on a three-high billet mill to a 2-inch square or its equivalent in rectangular section. These small billets were again sheared into lengths to give the weights required and allowed to cool, when they were reheated and rolled into rods on the looping mill. In endeavoring to overcome the advantages enjoyed by the owners of the continuous rod mill, William Garrett, who was then superintendent of the plant of the Cleveland Rolling Mill Company, conceived a plan whereby the looping mill could be modified to roll No. 5 rod in long lengths and direct from 4-inch by 4-inch billets without reheating. In formulating this plan, he reasoned that, since a large section loses heat less rapidly than a small one, the 4-inch by 4-inch billet could be rolled in the roughing mill to a size suitable for the rod mill in so short a time that it would still retain enough heat to be finished if it were not exposed so long in the looping mill. So he combined the three-high billet mill with the rod mill, and split up the latter into three groups or trains of rolls, which he arranged in echelon and drove at progressively increasing rates, so as to rough at low and finish at high speeds. By this arrangement the speed of the finishing trains could be adjusted to the elongation of the rod, so that not only could a given length be rolled in a shorter period of time, but the size of the loops could be controlled and their length reduced.

FIG. 40-2. General layout of Garrett rod mill.

Garrett erected his first mill in 1882, and at once he was able not only to roll rod in much longer lengths, but also to double, and more than double, the output of the older looping mills.

Accessories to Garrett's Mill—After the erection of his first mill, Garrett was able, from time to time, to add certain improvements. One of the most important of these improvements was the use of repeaters. As pointed out in connection with merchant mills, these are semicircular trough-like guides placed so as to guide the end of the piece from one pass to the next. As the repeaters are open at the top, a loop once formed is free to rise out of the trough, and enlarge to correspond to the elongation, or otherwise adjust itself to any difference in the speeds of the two passes. A looping mill fully equipped with repeaters is practically as automatic as a continuous mill. In the case of the earlier looping rod mills, however, repeaters did not work equally well on both sides of a mill. In these mills, the passes from the first few roughing stands to the finishing are alternately oval and square, the squares coming out on one side of the mill and the ovals on the other. On entering the square passes, the ovals must be turned on edge, and the use of guides for doing this work generally resulted in the production of much scrap, due to their frequent failures to edge the ovals properly. In some present-day Garrett mills, however, oval repeaters have been perfected and catchers are necessary only at points where cropping must be done.

Number of Strands—Another improvement introduced by Garrett, who was the first to employ the scheme, was the practice of finishing more than one rod at a time. Due to the shortness of the billet, the roughing train was able to break down the billets much faster than the finishing train could roll the rod in a single strand, even when the latter was speeded up to 550 r.p.m., which is the maximum speed at which it was practicable to run this train. Since the rod makes only one pass in the finishing and most of the intermediate stands, there was a great amount of roll space unused in rolling a single strand. By adopting power reels, and reeling each strand on independent reels, Garrett found no difficulty in finishing two strands at once in the same trains and thus doubling the output of the mill. In present-day Garrett mills, four, and even six, strands may be rolled simultaneously. The number of strands rolling in a mill has considerable effect upon the forming of the rod, and it is considered good practice to keep the mill as full as possible.

Floors—Another characteristic of looping rod mills is the sloping floors, which, though a simple device, play an important part in their operation. Since it is necessary to run the rolls in each finishing train at the same rotative speed, and it is not practicable to take up all the elongation of the piece, or equalize the rolling time of the different passes by using rolls of different diameters, it is necessary to allow the loops, which are formed after catching or repeating, to grow upon loop floors. If

these floors are level the frictional resistance soon becomes so great that it stops the forward motion of the loop, when the rod will pile up and become hopelessly twisted. In the old days, boys were employed to draw the loops back with hooks or tongs, but in Garrett mills this frictional resistance is overcome by laying the looping floors at an incline, sloping from the rolls, except on the oval side where a narrow level space is left to provide standing room for the catchers. When more than one strand is being rolled, as in all present-day mills, these floors must be provided with guiding channels and other facilities to prevent the different loops from becoming entangled.

Layouts of Garrett Mills—The arrangement of the roll trains in later looping mills has been subjected to considerable variation. A typical layout is shown in Figure 40—2. As originally planned by Garrett, the three-high billet mill was placed near the heating furnaces, which are now mainly of the continuous end-discharging type with floors sloping downward from the charging end. Two or more of these furnaces may be used to heat the billets, which are conveyed to the mill by roll tables. Following the billet mill, at a distance great enough to permit the piece from the last pass to clear the billet-mill rolls, is the roughing mill which, in present-day mills, may be a looping train of three stands or two or more stands arranged in tandem. Then come, with their looping floors sloping in opposite directions from the narrow level standing, the intermediate and finishing rolls, arranged, usually, in two trains of four or five stands each, lying end to end along two parallel lines in close proximity to each other, and so placed that the first intermediate pass is in line with the last roughing pass and far enough away to give proper clearance for the piece. In some mills especially designed to roll small rods, the finishing and last intermediate stands are coupled together in a third and separate train, which is driven at the highest speeds practicable, to reduce the size of the loops and make it possible to finish the rod at a higher temperature.

Combination Mills—In roughing down the 4-inch by 4-inch billets on the three-high mill, considerable time is consumed in making the necessary five to seven passes back and forth through the rolls. Not only does this delay tend to cool the steel somewhat, but these operations require some heavy hand labor. To overcome these disadvantages as far as possible, some looping mills make use of a group of continuous rolls for roughing purposes. This group usually consists of eight stands, and displaces not only the billet mill but the roughing train as well. With such a group, the work of roughing can be done much faster than the looping trains can dispose of the material even when four strands are rolled at once. Consequently, one continuous roughing mill is used to feed two looping finishing mills, one of which is placed on the right and the other on the left side of the roughing mill. By locating these finishing trains at a suitable distance beyond the roughing mill, the sections from the last roughing stand are carried forward or looped into the first intermediate pass by guides similar to the repeaters previously described. This type of mill is sometimes referred to as the Garrett semi-continuous mill.

The Double Belgian Mill, which is also designated by the name of Boecker's wire mill, represents another attempt to apply the combined continuous and looping methods of rolling, in this case, to the finishing mill. It consists, usually, of seven or nine stands of rolls, six or eight of which are arranged in two parallel lines or trains of three or four stands each, so that the corresponding stands in each line are opposite each other,

thus forming three or four continuous groups of two stands each. The mill is driven from a central shaft lying between the two parallel lines of stands, and from this shaft the power is transmitted to the rolls through three sets of gears. In this way the speed and direction of rotation of the various rolls is so regulated that a rod, passing through the mill, can be looped by catchers or repeaters from one continuous set to another, and from the last continuous set into the single finishing stand, which is two-high. A mill of this design offers some of the advantages of both the looping and continuous types, but also possesses some of the limitations of both. Thus, while it is capable of producing rods that are exceptionally uniform in section, the complicated system of shafting and gearing makes its upkeep expensive and tends to offset its advantages.

Continuous and Looping Mills Compared—A just comparison of the continuous mill and the looping mill is difficult to make. Local conditions and a great number of other factors must all be considered. For example, there is the matter of raw material. The small billet of full standard length, i.e., 30 feet, cannot be rolled on a looping mill because of the long exposure on the looping floor, which cools it below the temperature for hot finishing. On the other hand, the continuous mill is particularly suited to rolling these long billets, and, when combined with the special heating furnace previously referred to, presents a layout by which the rolling can be done at higher and more uniform temperatures, which saves power and minimizes the variation in section of the rod from end to end.

As already pointed out the large, or 4-inch by 4-inch, billet may be rolled on the continuous, the Garrett, or the combination mill. Mills of the Garrett type with looping trains for all except the first roughing, or billet mill, are limited to a billet weight of about 175 pounds for small rod, because, with a larger billet, the last end of the rod becomes so cold that excessive power is required to roll it, and the variation in size of the rod from end to end is too great to be tolerated. Continuous mills and combination mills can roll, without a second reheating, $3\frac{3}{4}$ by $3\frac{3}{4}$ -inch billets weighing up to 1200 pounds. On billets of these weights, the continuous mill requires less power and fewer operators than mills which are chiefly of the looping type; also the repair costs per ton on modern continuous mills are less than on looping mills. The heavier the rod bundle the better, on account of the longer length of the wire that can be drawn from it in one piece, which reduces the handling required and the scrap produced in the drawing and finishing operations.

As to other differences made in the product by these two methods of rolling, these are of such a character as to leave little from which to choose. The tendency exhibited by the continuous-mill rod toward flatness in the middle is offset by the variation in section from end to end of the looping-mill rod when rolled in long lengths. Since the continuous mill cools the rod during the rolling less than the looping mill and uses no hand labor for catching, it permits the use of a greater number of roll stands and passes. This great number of passes makes it possible to use better-shaped passes with smaller reductions from pass to pass, and thus avoid overfills, which frequently cause surface defects in the rod—defects that are of very serious character in many wire products.

Consequently, most mills installed in recent years are either straight continuous mills or employ only two or three loops. However, some of these mills use several motors, to provide more flexibility in rolling a wide range of sizes as well as to keep the loops short.

Rolls for Rod Mills—As to size, the rolls used for rolling rods are subject to considerable variation according to the type of mill and the purpose for which they are used. Thus, in Garrett mills the rolls are long, and vary in diameter from 16 or 18 inches for the first roughing rolls to 9 or 12 inches for the intermediate and finishing rolls, while in continuous mills using $3\frac{1}{4}$ by $3\frac{1}{4}$ -inch billets they vary from about 18 inches for the roughers to about $11\frac{1}{2}$ to 12 inches for the finishing groups. The roughing rolls may be cast steel or cast iron. However, cast steel is only used where it is required for strength because of the poorer pass life obtained. Most mills at present use grain iron rolls in the roughing stands.

In the intermediate and finishing stands, the rolls are either grain iron or chilled iron with the practice being, until very recently, to use chilled iron wherever possible because of the longer pass wear. However, recent development of grain rolls has improved the pass life to the point where they are now being used even in the finishing stands of some mills. As to the roll passes, these are simple in form but of a design to give the necessary reduction without developing defects in the material. In Garrett mills and continuous mills using 4-inch by 4-inch billets, the first roughing passes are rectangular or box passes, or diamond and square passes, but in all other rolls except the finishing, the passes for round rods are arranged to give alternately squares and ovals, etc. For round wire, the last oval feeds the finishing pass which, of course, must be circular. To reduce the number of roll changes otherwise necessary, a number of duplicate grooves are cut in each set or pair of rolls, so that when one set of grooves becomes defective or too badly worn a new set can be made available for use merely by resetting the guides. When all the grooves in a set of rolls have thus been used, they must be replaced by a new set while the worn rolls are being redressed, so that duplicate rolls as well as duplicate grooves are required.

Designing the Passes—Here, the matter of chief concern is the proper regulation of the draft in each pass. The highest drafts are made in the roughers, where the reduction in any one pass may be as high as 45 per cent though a limit of 35 per cent represents better practice. In the intermediate sets of rolls, a maximum draft of about 30 per cent may be attained in the first passes, but as the rod approaches the finishing pass the amount of the reduction permissible gradually diminishes, until in the final pass it is well under 15 per cent. Within the limits mentioned, the drafts will be determined largely by the number of passes provided by the mill, which in turn will depend upon the type of mill, the size of billet used, and also the size of rod to be rolled. For rolling 4-inch by 4-inch billets to No. 5 rod, Garrett mills usually provide from 18 to 20 passes; some continuous mills use 21 passes, while others provided with an intermediate reheating furnace may use as many as 24; and combination and double Belgian mills may use 18 to 24 passes. Nearly all the mills are so arranged that the size of the finished rod can be varied, that is, made coarser than No. 5, either by "opening up the mill," thereby producing larger sections in each pass, or by omitting the use of some of the stands immediately preceding the last. In the latter case the finishing is done on one of the stands used as an intermediate when rolling No. 5 rod.

Housings and Guides—The construction of housings, with their mechanism for making necessary adjustments of rolls and guides, differs in the different mills, but is the same in principle as described elsewhere in this book for corresponding types of billet and mer-

chant mills. The setting and adjustment of the rolls and of the receiving and delivery guides require a deal of experience, and, upon the efficiency of these adjustments depends, in great measure, the quality of the rolled rod as well as the tonnage of the mill.

Rod Reels—The daily output of rod mills in use today varies from 450 to 1200 tons, which tonnages, translated into linear units of No. 5 rod, are equivalent to about 1500 and 4000 miles, respectively. From this statement it is evident that this enormous output would have been impossible without adequate reeling facilities. As previously pointed out, this need caused the early adoption of automatic reels, the first practical development of which was introduced about 1880. The rod reels now in use are mainly of two types, known as the **pouring reel** and the **laying reel**. The pouring reel consists essentially of a horizontal steel disc or pan mounted upon a vertical shaft so that it may be revolved at a speed corresponding to the delivery speed of the rod. Near the circumference of this pan are two circular and concentric rows of pins, or spokes as they are often called. Into the annular space bounded by these spokes the rod pours from the end of a pipe which conducts it from the finishing rolls, and since the rotative speed of the reel is adjusted to the linear speed of the rod, the latter is laid in a neat coil within this space, a single ring of the coil being formed at each revolution of the machine. In the laying reel, the receptacle is stationary, while the end of the delivery pipe, itself, is made to revolve in a circle, thus laying the rod within the annular space provided by a motion similar to that in coiling a long rope by hand, so that the rod is given a twist at each revolution of the pipe, or as each ring of the coil is formed. The laying reel, therefore, can be used only with small round sections; however, pouring reels can only be used up to about 4200 feet per minute. Laying reels provide a better coil on small rod. Hence, most modern mills rolling both small and coarse rod have both laying and pouring reels. In both types the diameters of the coils are determined by the relation between the delivery speed of the rod and the rotative speed of the reel, for the peripheral speed of the coil being formed must equal the rod delivery speed. As these two factors cannot always be kept in exactly the same relation, the diameters of the coils vary somewhat. In all cases the reels are designed to raise the coil or lower the spokes, and deliver the product upon a conveyor, which carries each coil to some designated point where it may be disposed of as desired. In case of wire manufacturers who roll their own rods, the rod mill is located very near the wire mill, and the coils are carried by the conveyor directly into the cleaning or heat treating departments of the latter. Most wire mills, whether they roll their own rods or not, will be provided with covered yards where rods of various kinds of stock may be stored for use as required.

Defects in Rods—To produce a satisfactory rod requires that proper care be exercised in every department concerned with its preparation. To begin with, the steel must be properly made and its composition should be uniform and as near that desired as possible; also, it is essential that the ingot be properly cast and rolled at a suitable temperature, and that the billet be free from pipe, seams, and slivers. Even with perfect billets, considerable care and skill are required to produce satisfactory rods. Assuming that the rod mill, itself, has been properly designed and speeded and equipped with all the necessary accessories, unsatisfactory rod may still be produced by improper heating, by the use of improperly designed ragging on the roughing rolls, by improperly adjusting the rolls and

guides, or by using the grooves too long. In order to finish the rod correctly, every pass in the mill should be made to produce, as near as possible, the section it was originally designed to produce, and to bring about this result all the passes must be kept full but none may be allowed to overfill. Great emphasis is to be laid upon all these features of operation, because, from the point of view of the wire mill it is most essential that

the rod be uniform in composition, and also in section, that it be close to the size and shape required, and that it be free from such surface defects as slivers, seams, and fins. These defects, as well as the composition, are matters of importance to both the consumer and the wire mill, for none of the subsequent wire-drawing operations or finishing processes will eliminate them or reduce their capacity to do harm in the final product.

SECTION 4

OUTLINE OF WIRE-DRAWING PROCESSES

The rolling of the rods is a fairly well standardized process. The primary object of rod rolling is, of course, to put the steel into such shape that it can be most efficiently cold drawn into wire. Using steel of the required composition, the rod is rolled to the desired size and shape by following a standard practice on a standard rod rolling mill. From this point, however, the method for manufacture into wire depends entirely upon the end use to which the wire is to be put. These uses are many and varied, and the wire drawing practices necessary to provide the wide ranges of required wire characteristics vary accordingly. Obviously, it would be impossible to cover all the practices in detail here. However, a brief summary of the various operations necessary to process the rod to finished wire will be outlined.

Preparing the Rod for Drawing—In order to prepare the rod for drawing, it is first given some necessary preliminary treatments. In general, these consist of acid cleaning and coating following a heat treatment when required. The heat-treating process is usually one of the following: patenting, annealing, or normalizing. These processes will be described in more detail later. Low-carbon rods which are to be drawn into wire usually do not require any heat treatment and are cleaned and coated after rolling. In the process of rolling, the rods acquire a mill scale or oxide on the surface. Oftentimes, it is necessary to store the rods for some time before drawing. In storage they may pick up either some additional oxide in the form of rust or just plain dirt. All mill scale, oxide, or dirt must be removed before the rods are drawn into wire. This is accomplished by placing the rods in a solution of hot dilute sulphuric acid for from fifteen to thirty minutes. The action of the acid loosens the scale and frees the rod of all rust or dirt, leaving the surface of the rods perfectly clean. The rods are then removed from the acid and given a thorough rinsing in a spray of high-pressure water. This removes all the acid from the surface and from between the various strands. The next step is to give the rods a suitable coating, usually lime. The purpose of the coating is threefold: first, to protect the surface of the cleaned rods from rusting in the atmosphere; second, to neutralize any traces of acid left from the cleaning; and, third, to serve as a carrier for the lubricant used in drawing the rod to wire.

For many years it was customary to coat rods which were to be drawn into ordinary finished wire with a sull coating. This is accomplished by placing the cleaned rods on a rack or a travelling conveyor and spraying them with a fine mist-like spray of water. The rods are then dipped in a tank containing hot milk of lime. In recent years the practice of sull coating has been discarded, and the rods are coated with the milk of lime directly after the water rinse. Sull coating is used now only on a few kinds of wire; in some instances for manufacture of cold-headed bolts.

Borax is another coating which has been used quite extensively in recent years with good results. After the coating is applied, the rods are baked in an oven or other type of baker to dry the coating. This function will be described later in more detail.

Drawing the Rod—After the rods are properly cleaned, coated, and baked, they are delivered to the wire-drawing equipment. Today, most wire which is drawn three or more drafts is produced on continuous machines. Wire which is to be drawn one or two drafts is produced on single or double-deck motor blocks. Wire in sizes $\frac{3}{8}$ -inch and coarser is drawn on horizontal bull blocks. However, there is still a considerable amount of wire produced on the so-called wire drawing frame. This frame, in the type most generally used for drawing rods, supports a single die and the power driven block for drawing the rod through the die, also a drawbar for drawing the first few feet of the rod. One end of the rod is now pointed, or tapered, so that it may be threaded through the die hole, which is somewhat smaller than the rod in section. Next the die holder, on the entering side of the die, is filled with a specially prepared grease, or some other suitable lubricant, so that in passing through the die the rod must first pass through the lubricant. The pointed end of the rod is now inserted through the proper die hole, where it is grasped by tongs attached to the drawbar, and drawn through far enough to be attached to the draw block. When this block is started revolving, it coils the wire about itself and thus continuously draws the rod through the die, thereby bringing about a fixed decrease in its sectional area and a proportional increase in its length.

Draft, Drawing and Process Wire—The amount of the reduction in the sectional area, as in the case of rolling, is expressed in per cent of the original area and is known as the **draft**, while the operation itself is called **drawing**. In general the draft on the rod varies from 10 to 45 per cent according to the kind of wire to be made. As soon as a rod has been given a draft, it is thereafter designated as a wire, though many more drafts and various other treatments may be necessary to work it into wire of the size, finish and temper desired. In wire-drawing plants, any wire which, following the initial drawing from the rod, is to receive further work or treatment before it is finished is designated as **process wire**. After the first draft from the rod, process wire may be finished in various ways.

Dry Drawing and Wet Drawing—There are two processes for drawing wire. These are designated as dry drawing and wet drawing. Mechanically, the processes are the same; that is, the wire is drawn through a die and wound up on a block. The difference in the processes is in the coating applied to the wire and the lubricant used. All wet-drawn wire is first given one or more dry drafts from the rod. This process wire is then thoroughly cleaned, rinsed, and immersed in a dilute solution of copper or tin sulphate or a mixture of both of these salts.

A chemical reaction takes place which results in the deposition upon the wire of a thin metallic coating from the solution used. After coating, the wire is usually kept under water to protect it from the influence of the atmosphere.

In subsequent wet drawing, the pay-off reel containing the wire is placed in a tub of water. To this water a special type of soap is usually added to act as a lubricant. In recent years special coating solutions have been developed which are applied to the wire after the copper or copper-tin solution treatment. These coatings protect the surface from the atmosphere and are also quick drying, so it is possible to store the wire without keeping it under water and also to permit drawing from a dry reel. In drawing, the copper or copper-tin solution imparts a characteristic metallic color to the wire which is known commercially as **coppered wire** or **liquor-finished wire**. The latter term designates the brass-colored finish obtained from the copper-tin coating mixture.

Types of Wire—For all practical purposes, wire may be described as being low-carbon or high-carbon. Al-

though there are additional classifications in AISI Product Manual Section 16, 0.30 carbon may be considered the dividing point and, broadly speaking, wire under 0.30 carbon is referred to as low-carbon, while that which is 0.30 carbon and higher may be considered as high-carbon. The end uses of the various types of wire require different characteristics in the finished wire as to physical properties, finish, gage tolerance, electrical conductivity and many others. These requirements are met by designing manufacturing practices which employ various amounts of cold work (drawing), various types of heat treatments, or combinations of both. All of these practices are carefully worked out and are designed to provide wire which will adequately meet consumer requirements and at the same time make the most efficient use of producing equipment.

A general discussion of wire manufacture follows which is divided into six sections, namely, "Preparation of Rods and Wire for Drawing," "Wire-Drawing Equipment," "Wire-Drawing Processes and Operations," "Heat Treatment of Wire," "Protective Metallic Coatings for Wire," and "Some Fabricated Wire Products."

SECTION 5

PROCESSES AND EQUIPMENT FOR PREPARING RODS AND WIRE FOR DRAWING

Importance of Cleaning—All of the hard, brittle oxide commonly called mill scale, which forms on hot-rolled rods or on heat-treated rods, and also the slow-forming red rust which forms on long exposure to the air, must be entirely removed before drawing. If these oxides remain on the surface of the rods, they result in very rapid wear on the wire-drawing dies and also cause scratched and off-gage wire. Proper cleaning and coating is largely responsible for success in the wire-drawing operation.

Method of Cleaning—As already stated, the method generally employed for cleaning the material preparatory to drawing consists in dipping the coils into a vat of hot, dilute sulphuric acid. The action by which this acid removes the scale is for the most part mechanical rather than chemical, for ferrous-ferrous oxide, Fe_3O_4 , which is the chief constituent of the scale, is but slightly soluble in sulphuric acid. The acid, however, is able to penetrate to the metal beneath the scale, where it reacts with the iron forming iron sulphate, a soluble neutral salt, and liberating a mixture of gases, mainly composed of hydrogen. This action results in loosening and detaching the scale from the surface of the metal, when it sinks to the bottom of the vat where it accumulates and must be removed at frequent intervals. Unlike the black scale, the red rust (which is a hydrated sesquioxide of iron of the general formula $\text{XFe}_2\text{O}_3 \cdot \text{YH}_2\text{O}$ or a double compound of ferric oxide and ferric hydroxide, $\text{Fe}_2\text{O}_3 \cdot 2\text{Fe}(\text{OH})_3$), is readily soluble in sulphuric acid, and

under the conditions of pickling this action results in the formation of iron sulphate, also. This salt remains in solution, and as concentrated acid is added from time to time to replace that neutralized, the solution eventually becomes saturated to such an extent that it is no longer fit for pickling. The exhausted solution must then be replaced.

Manner of Handling the Material—When the rods are removed from the hook conveyor in the rod mill, they are loaded into standard-gauge gondola cars. The coiled rods are loaded in an upright position to facilitate unloading with a so-called "C" hook (Figures 40—3 and 40—4).

From the rod mill, the rods are transported to the rod storage where they are unloaded by an overhead crane. The crane is equipped with the "C" hook referred to above, which has a capacity of two to three tons. Facilities for storing rods consist of large bins or racks. Each gage and steel composition is stored in a separate bin in order to avoid confusion and possible misapplication.

FIG. 40—3. Open-type "C" hook for handling coiled rods and wire.

FIG. 40—4. Latch-type "C" hook for handling coiled rods and wire.

In modern integrated mills, the rods may be moved directly from the rod storage to the cleaning crane by the rod-storage crane. In other mills, the rods are set down in racks by the rod-storage crane and then moved to the cleaning crane by ram tractor or on rod trucks. In either case, the rod-storage crane sets up the exact amount of rods which the cleaning crane is designed to handle in one lift, so that there is a minimum of handling.

The "C" hook or hairpin hook, as it is sometimes called, is a specially designed device for handling coiled rods and wire. It is designed to lift as a unit the number of coiled rod bundles which the cleaning crane was designed to handle in one lift. There are two types, the open-end type and the latch type. Both are made by using a section of extra-heavy pipe, or I-beam, which is long enough to span the cleaning tank. This pipe has a metal eye attached at the approximate center, or balance point, into which the crane hook is inserted for lifting. From the pipe, a very heavy hanger is suspended. In the open type (Figure 40-3), this hanger is in the form of a large letter "C" with the bottom section straightened horizontally and made long enough to lift the proper number of coils.

In the latch type (Figure 40-4), the hanger is made more in the shape of the letter "L," and the horizontal section is pivoted to the vertical section which allows for a slight movement of the cross piece. At the opposite

end of the pipe, a second hanger is suspended. This hanger is pivoted to the pipe allowing it to swing freely. When the hook has been threaded through a lift of rods, this second hanger is swung down and latched to the free end of the cross piece. This gives support to both ends of the cross piece. All of the parts which come in direct contact with the acid are made of phosphor bronze, aluminum bronze, or other acid-resisting material.

A hook with its load is referred to as a "pin" or "stem" of rods or wire.

Types of Cranes—There are two types of cranes generally used in cleaning, namely, the circle crane and the overhead electric traveling crane. One type of circle crane consists of an upright standard which is set in bearings to allow the upright standard to turn in a complete circle. A horizontal boom is placed on the upper part of the standard. This boom or arm is built long enough to reach the center of the cleaning and coating tanks which are placed in an arc around the base of the standard. Power for lifting the material to be cleaned is supplied by a steam piston which is placed on the boom or standard. Power for turning the standard and boom is supplied by placing a ring gear around the upright standard. This ring gear is then driven by an electric motor which is connected by the proper gearing and shafting. Figure 40-5 shows a variation of this type of crane, in which the standard is fixed.

Use of the circle type of crane requires the cleaning

FIG. 40-5. General view inside a cleaning house showing cleaning and coating tubs arranged around the base of a crane.

and coating tanks to be placed in an arc around the upright standard (Figure 40—5). The number of tanks is then limited by the radius of the boom. Where a large volume of production is required, two circle cranes may be used. Here the first crane handles the work through all the acid cleaning and rinsing, while the second crane handles the work in the stages during which the proper coating is applied.

When the electric overhead traveling crane is used, the cleaning and coating tanks may be placed in a straight line or sometimes two lines are used.

The gantry crane is another type of electric crane in use. This crane requires all the tanks to be in one line as the crane has no cross travel, and the crane hook moves in relatively the same horizontal line at all times. This type of crane has value where there is a large volume of work and few varieties of product.

Construction of Tanks—The rectangular acid tanks are constructed of welded steel plate, and are usually large enough to hold two stems of rods. The bottom is reinforced with channels and angles, and the interior is lined with a $\frac{3}{8}$ -inch thick membrane of rubber or neoprene to protect the steel from the acid. Inside the rubber lining a layer of acid-proof brick is placed com-

pletely covering the sidewalls and bottom of the tank. The brick lining is bonded to the rubber or neoprene with acid-resisting sulphur-base cement. Acid-resisting synthetic-resin cement is used in the brick joints. All unprotected exterior surfaces of the tank are covered with a black vinyl-resin-base acid-resisting paint.

Water-rinse tanks are also usually rectangular and constructed of welded steel plate. Such tanks usually are of one-stem capacity. All surfaces are coated with a black vinyl-resin-base acid-resisting paint. The upper section of a water-rinse tank is provided with a series of high-pressure water nozzles, while the lower part of the tank contains fresh running water for rinsing.

Lime tanks are also rectangular and constructed of welded steel plate, and usually have a capacity of one stem.

Arrangement of Tanks—As already indicated, when a circle crane is employed, the number of tanks is limited by the radius of the boom of the crane. When an overhead traveling crane is used, the number of tanks is unlimited. Figure 40—6 shows a typical arrangement for so-called straight-line cleaning. In general, the acid tanks are used first in the cycle, then the water-rinse tank, and finally the coating tanks. Sull coating today is

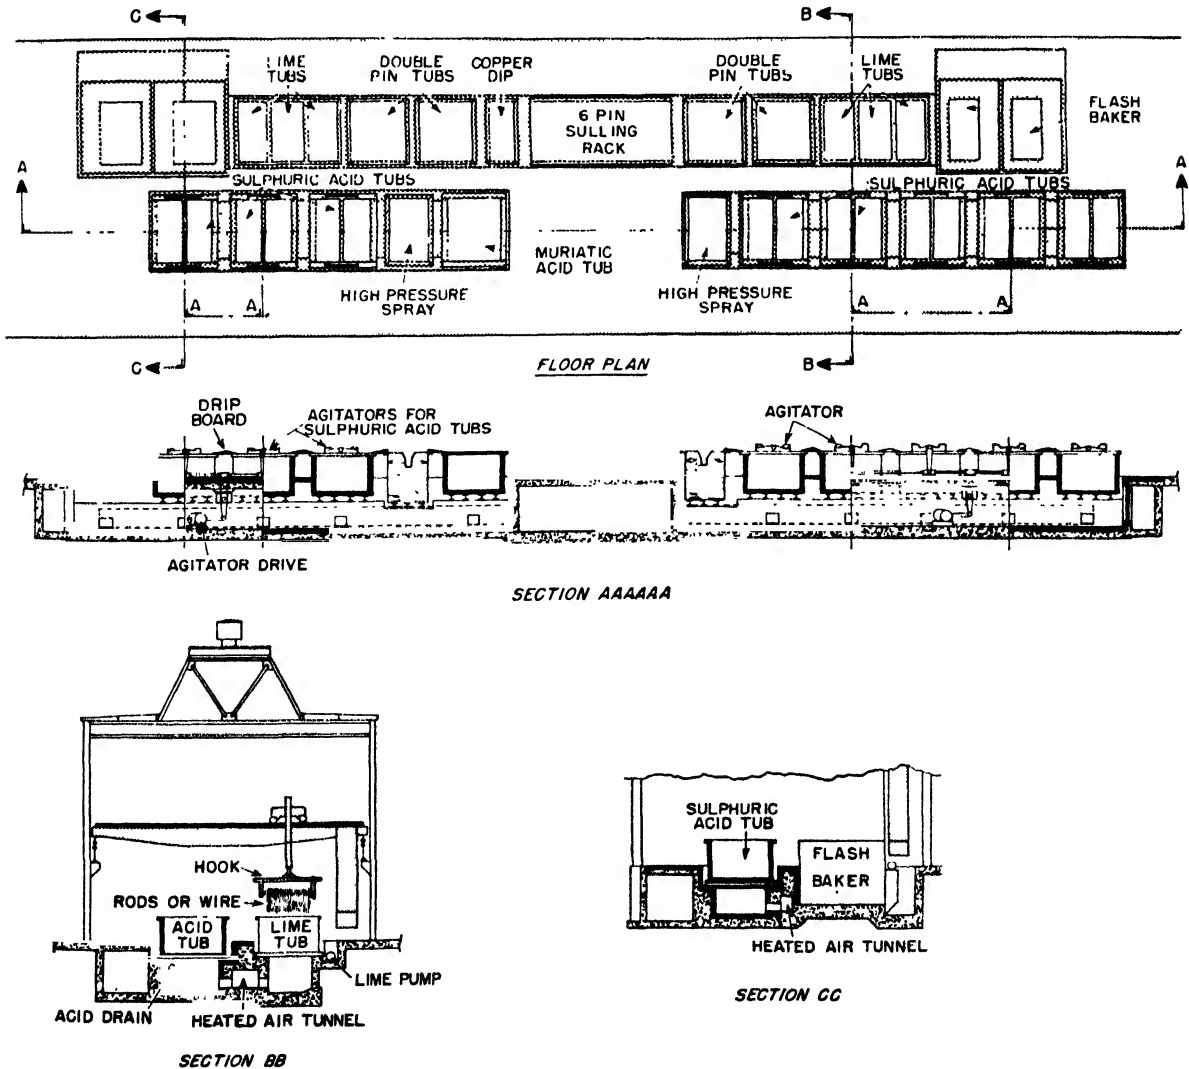

Fig. 40—6. Typical arrangement for so-called straight-line cleaning of rods in preparation for drawing.

in very slight demand, but usually a small section is provided where the rods can be treated for formation of this coating.

Concentration of Acid—There are three factors which affect the cleaning operation, namely, time, temperature, and concentration of acid. In operation, the tanks are first partially filled with water. Then the acid is added in the required amount and the steam for heating the bath is turned on. By the time the tanks are filled by the addition of more water, the steam has raised the temperature to the required point, usually about 180° F, and the acid concentration has been adjusted to the required amount.

Certain kinds of steel require longer time for cleaning than others. Low-carbon rods which may be finished at a high temperature on the rod mill will have a very heavy scale. Also, rod coils which are very compact, as is usually true with the coarser gages, are more difficult to clean. Bessemer and high-carbon steels react much faster to the acid, and the time of cleaning is shorter. This is particularly true of high-carbon patented rods which have the scale broken up by the sheaves on the take-up frame of the patenting furnace. The acid concentration, then, is varied according to the kind of steel being treated, the low-carbon heavily-scaled material requiring a solution having a higher concentration of acid, with the higher-carbon steels and patented material requiring a lower concentration.

Temperature for Cleaning—The control of temperature in the cleaning operation is very important since the rapidity of the reaction between acid and steel is greatly affected by temperature. It is known that the reaction is 100 times as fast at 190° F as at room temperature. Too high a temperature, therefore, can be very wasteful. It causes rapid and high usage of the acid, develops unnecessary fumes which, in turn, can cause excessive corrosive action on the steelwork of the building. What is more important, it causes pitting action on the surface of the steel being treated. The tanks in most modern cleaning houses are equipped with thermostatic controls so that a uniform pickling-solution temperature is maintained.

Inhibitors are used to aid in preventing pitting or over-cleaning. These usually have a nitrogenous hydrocarbon base. The theory of the use of inhibitors is that when the scale has been removed from the steel, the inhibitor forms a protective film on the cleaned surface and minimizes any additional attack by the acid.

Time of Cleaning—The time required for cleaning will vary according to the amount of scale to be removed and the type of steel being treated. This may vary from as little as 10 minutes for high-carbon patented rods to 30 or 35 minutes for low-carbon heavily-scaled rods. When the cleaning facilities serviced by the crane provide enough acid tanks, it is possible to use all tanks for the long-cycle work and reduce the number of tanks in use for short-cycle work. By this means, it is possible to keep the temperature and acidity at a fairly constant point and vary the time. Another factor which affects the time of cleaning is the change in specific gravity of the acid solution. As the work proceeds and more and more scale is removed, the iron content of the bath builds up. This is reflected in a change in specific gravity of the solution, which is usually measured by a hydrometer that provides a Baumé reading. As the Baumé figure increases, the action of the acid is retarded and the cleaning process gradually slows down. When the Baumé reading reaches about 20, the acid in the tanks is discarded, after which the tanks are washed out and refilled. In modern cleaning houses, where the tanks hold from 5000 to 7000 gallons, it is customary to have

one extra acid tank. This tank is filled and heated to temperature, ready to operate when one of the other tanks is being emptied of its spent acid. By rotating the use of the tanks in this way, continuous operation can be maintained.

Rinsing—It is very important to have the cleaned rods or wire thoroughly rinsed after the acid cleaning. The cleaned material is dipped into a tank of fresh running water. There is a series of high-pressure sprays placed around and at the top of the water tank. When the cleaned rods are dipped in the water, a switch automatically turns on a high-pressure pump. As the crane moves the rods up and down, the high-pressure sprays wash them thoroughly and remove all traces of acid or acid residue.

Coatings—After the rods are thoroughly cleaned and rinsed, it is necessary to apply a coating. The purpose of the coating is three-fold: First, it prevents oxidation or rusting of the surface; second, it neutralizes any traces of acid which may be left on the steel; third, and most important, it acts as a carrier for the lubricant used in drawing. For dry drawing, dry slaked lime or hydrated lime have been found to be the best materials for coating. Lime is a low-cost material and is easily applied. Borax is another coating which has been used for dry drawing in recent years. It is a little more costly than lime, but it offers some advantages. It dries very quickly, it does not pick up moisture, and it does not flake off or form a dust in the wire-drawing room, thereby making conditions much cleaner in the mill.

Process for Lime Coating—The lime coating is applied to the rods simply by dipping the cleaned rods into a tank of hot milk of lime. The temperature is kept between 190° F and 200° F. The rods should be kept in the solution long enough to bring them up to bath temperature. This aids in drying the coating and also makes it adhere better to the steel. Formerly, it was customary for the mills to purchase the burned lime and slake and age it before use. In recent years, very good grades of so-called quick-slaking lime and hydrated lime have been developed commercially. These are packaged in paper bags of about 50 pounds each. In using these limes, one end of the bag is cut open, and the lime is dumped directly into the lime tank where it quickly goes into solution.

Another recent practice is to recirculate the lime. This is done by installing a small tank, or section of a tank, alongside of the regular lime tank. A special pump is placed in this small section. One side of the lime tank is cut down so that the lime solution can flow over this low side and into the small section. The pump then forces the overflow back into the large tank, usually through a pipe connected into the bottom of the latter. This keeps the lime solution in constant motion so that there is no settling out. This action also produces a very fine grain lime which is quite adherent.

Coatings for Dry Drawing—In practice, several coating tubs are served by one cleaning crane. There may be three or four lime tubs. In these tubs, the lime is kept at various consistencies. This allows the several coatings which may be required in the wire-drawing operations to be kept in readiness. Rods which are to be drawn one or two drafts to produce a clean bright finish are given a very light lime coating. For three- and four-draft wires, a medium lime coating is applied, and for wires which may be drawn five and six drafts, a very heavy lime coating may be used. In fact, where many drafts are required, it is often customary to give the rod two or three dips in a very heavy lime.

Where borax is used, a separate tank must be provided. This solution is adjusted to a consistency depend-

ing upon the number of drafts the wire is to be given.

Baking—After the rods or wires are properly cleaned and coated, they must be thoroughly dried before drawing. The drying or baking is done in ovens or bakers. In the cleaning process, hydrogen is liberated by action of the acid upon the steel, and sometimes this hydrogen is absorbed by the steel. This can cause the drawn wire to be brittle, a condition known as "acid brittleness." The baking process has two purposes: one, to dry the coating so that it will function properly in dry drawing and, two, to remove any hydrogen that may have been absorbed by the steel.

There are several types of bakers. The **flash type** is the most popular. This is a baker of about the size and shape of a lime tub. One pin of rods is placed in the baker for from five to fifteen minutes, depending upon the weight of coating to be dried. The temperature is usually kept between 450 and 600° F. The **tunnel type** is another baker used. This is a long, rectangular oven with a roll or chain conveyor running through its length. In operation, the rods are placed on the conveyor and pass slowly through the baker. The time may be one or two hours at temperatures from 400 to 500° F. **Compartment-type** bakers are still used to a limited extent. In these bakers, the rods are loaded onto steel buggies which are pushed

into the oven on tracks running throughout its length. The temperature is usually between 250 and 325° F which requires a longer baking time. This may be from three to eight hours. The flash and tunnel bakers are fired with oil or gas and are equipped with high-velocity fans which rapidly recirculate the heated air. Figure 40—7 shows a sketch of a flash baker.

FIG. 40—7. Cross-section of a flash baker for drying rods and wire after cleaning.

SECTION 6

WIRE-DRAWING EQUIPMENT

Dies—The wire-drawing die is one of the most efficient tools used in industry. It has no moving parts; it does not remove any of the metal; yet it uniformly reduces the cross-sectional area of the steel and at the same time improves the finish and physical properties. Over the years many different materials have been used for wire-drawing dies. Chilled iron, steel plates, alloy steel, all have been used, but in the late 1920's tungsten carbide was developed and tried out. This material was an immediate success, and in a comparatively few years it replaced all other materials except the diamond. Diamond dies are still used for very fine sizes of high-carbon and alloy steels but even in this range the tungsten-carbide die can be used. Tungsten carbide is a very hard material and has great wearing characteristics but does not have very great resistance to impact. It must have some outside reinforcing when put to use. This is accomplished by pressing a small section of tungsten carbide, called a "nib," into a cylindrical steel casing, as shown in Figure 40—8.

FIG. 40—8. Schematic cross-section (not to scale) of a single-hole wire-drawing die employing a nib of sintered carbide mounted in a circular steel holder.

Die Holes—The shape of the die has been found to be very important. There are four distinct zones in the die as shown in Figure 40—9. The first zone, on the entering side of the die, is somewhat larger in diameter than the rod or wire to be drawn; its purpose is to afford room for the die lubricant that adheres to the rod or wire to

FIG. 40—9. Enlarged cross-section of die hole showing names of parts.

be drawn into the hole. This is called the **bell** and **entering angle** and gradually tapers into the second zone. The second zone is called the **approach angle** and is the section where most of the actual reduction takes place. The next zone is called the **bearing** zone and it may have a very slight angle of taper. The exit zone or **back relief** is in the form of a countersinking of the back part of the hole. This is done as a strengthening to prevent the circular edge of the hole from breaking away.

Diamond Dies—Diamond dies are frequently used when accuracy and uniformity of section are required in the finer sizes of wire, especially in the process of continuous wet drawing. In the construction of diamond dies, a diminutive flat crystal of diamond is securely fastened in a center opening of a small circular metal disc, then a hole of required diameter is worked through this diamond by special drills and diamond dust. Diamond is one of the hardest substances known and has great wearing qualities. Long lengths of fine wire can, in

consequence, be drawn through these dies with little or no change of sectional area due to wear of the die.

The Block—Wire was first drawn in very short lengths and was merely pulled through the die in straight pieces. As the lengths grew longer, some means of storage became necessary. The wire-drawing block serves this purpose. The block is a steel casting in the form of a cylinder the sides of which have a slight taper. The base of the cast cylinder is solid and there are enough cross members inside the casting to give adequate support to the sides. At the base, there is also a flanged section extending horizontally outward around the cylinder. The juncture of this horizontal flange and the vertical sides of the block is machined to a definite radius. This is called the **fillet** of the block. In the center of the block, a vertical cylindrical hole is left to allow for the drive shaft to be keyed to the block.

In operation, the wire is threaded through the die and attached to the block by a vise or clamp. The block revolves and pulls the wire through the die. As the wire is wound around the fillet of the block it is forced upward. At each revolution of the block the wire moves upward approximately one diameter of the wire being drawn. The sides of the block may be six or eight inches high. At the top of the block four vertical pins are placed.

As the wire feeds upward and reaches the top of the block, it is stored around these four pins. The result is a uniformly wound, compact coil of wire.

DRAWING MACHINES

There are several types of drawing machines. These may be grouped as follows: drawbench, bull block, motor block, multiple-draft machines, drawing frames. These will be briefly described.

Drawbench—A drawbench is a mechanism used to give a single draft to heavy material, which is afterwards usually straightened and cut to a definite length. It handles the largest sizes drawn and is especially adapted for drawing shapes, screw stock and small shafting. The machine itself consists of a horizontal framework 50 to 100 feet long, along the center line of which runs a heavy roller chain driven by heavy sprocket wheels. The die through which the material is drawn is located at the opposite end of the frame from the drive. A carriage mounted on wheels, and arranged to travel along the upper surface of the frame or bench, has suitable jaws for gripping the material and pulling it through the die, and also a heavy hook for connection with the roller chain. This equipment is similar to that used for drawing seamless tubes (see Chapter 41).

STEEL WIRE AND WIRE PRODUCTS

FIG. 40-11. Motor blocks, with vertical spindles, for drawing $\frac{3}{16}$ -inch to $\frac{1}{2}$ -inch wires. (Courtesy of Morgan Construction Co.)

Bull Blocks—Sizes $\frac{1}{2}$ -inch to 1-inch are usually drawn on horizontal blocks called bull blocks. These are very heavy machines built to pull these coarse sizes (Figure 40-10). They are driven by an individual variable-speed motor. The blocks are usually 36 inches in diameter. The horizontal block makes it easier and

safer to handle coils of drawn wire in these coarse sizes.

Motor Blocks—These are also driven by an individual motor, but the blocks have a vertical spindle (Figure 40-11). The size range drawn on these machines is usually $\frac{3}{16}$ -inch to $\frac{1}{2}$ -inch. The blocks may be 26, 30 or 36 inches in diameter. Motor blocks may also be

FIG. 40-12. Overall view of cumulative-type continuous wire-drawing machine. (Courtesy of Morgan Construction Co.)

equipped with double-deck blocks. This is an arrangement whereby one block is placed above the other, both being mounted on a common spindle. The lower block is made smaller in diameter than the upper block. In drawing, the wire is pulled through one die and wound around the lower block several times, then it passes around a sheave and into a second die and onto the second or finishing block. Thus two drafts are drawn on the one spindle. Sizes from $\frac{3}{16}$ -inch to $\frac{1}{8}$ -inch are usually drawn by the double-deck method. Due to the heat developed, only low-carbon wire is drawn in this manner.

Continuous Machines—Wire which requires three drafts or more from the rod is usually drawn on continuous machines. The tungsten-carbide die, due to its long-wearing characteristic, makes it practical and economical to use continuous machines for the so-called multiple-draft work. There are two general types of machines used in dry drawing. These may be described as the cumulative and non-cumulative types.

In the cumulative-type machine, the wire is drawn on a conventional type block and is allowed to build up around the block pins. At the top of the pins a ring is placed. The first end of the wire is threaded through a loop on this ring and then is fed over a dome and down through the center shaft of the block which is hollow. From here it is led around sheaves and into the next die and onto the next block. In another type of cumulative machine the wire passes from the ring up over a sheave, which is mounted above the center of the block, and then down around another sheave and into the next

FIG. 40-13. Closeup view of the blocks of a cumulative-type continuous wire-drawing machine. (Courtesy of Morgan Construction Co.)

die. In this type of machine the blocks are usually geared so that the speed of each block is increased as the diameter of the wire is reduced. In drawing it is customary to lay out the drafting so that each block draws a little more wire than the succeeding block. This results in a gradual buildup on each block. When the blocks are filled up, the machine is shut down and all the blocks, except the finishing block, are de-clutched. The machine is then started again and the finishing block removes the accumulation from the block next to it. The slip ring at the top of this block revolves and keeps the wire paying off uniformly. When this block is nearly empty, the machine is stopped and the nearly empty block is re-clutched. This process is repeated until the build-up is worked down from all blocks. Figure 40-12 shows a

FIG. 40-14. General view of a non-cumulative type of continuous wire-drawing machine. (Courtesy of Vaughn Machinery Co.)

cumulative-type machine and Figure 40-13 shows a closeup of the blocks.

On the non-cumulative type of machine, the wire is drawn through the die and wrapped around a block in the conventional manner. This block will be about six to eight inches in height. When the wire reaches the top of the block, it passes around the sheave. This sheave is mounted at the end of an arm which is attached to a rheostat, which in turn controls the speed of the block. From this sheave, the wire passes to another sheave and into the next die. Each block of this type of machine has its own individual motor. The drafting is usually laid out to meet the nominal speeds for which the machine is designed. If, however, this drafting should get out of line and one block draws more wire than the preceding block supplies, the arm moves forward and actuates the

FIG. 40-15. Closeup view of a block of a non-cumulative type of continuous wire-drawing machine. (Courtesy of Vaughn Machinery Co.)

STEEL WIRE AND WIRE PRODUCTS

reostat so that the speed of the preceding block is increased. By this means the production of each block is kept in balance with all the other blocks and there is no great amount of build-up on the blocks.

Both types of machines are equipped with means for cooling the wire between each draft. In drawing higher-carbon wire (0.30 carbon and over) it has been found that the wire will become brittle if the heat developed in drawing is not removed between drafts. Both types of machines use a blast of air directed at the wire to cool it, but the non-cumulative machine also employs a water spray inside the block. This is necessary because the time the wire is on the block is much shorter than on the cumulative machine. Figure 40-14 shows the non-cumulative machine, and Figure 40-15 a closeup of a block.

Intermediate Machines—It is usually economical to use the continuous machines which draw from the rod for not more than six or seven drafts. This produces sizes down to 0.072-inch or 0.062-inch. For sizes finer than 0.062-inch down to 0.030-inch an intermediate-size machine is used. This machine is usually the same in design principles as the rod machines but its construction is lighter and speeds are usually faster to take care of the smaller-gage wire.

Fine-Wire Machines—Sizes finer than 0.030-inch are usually drawn by the wet process on specially designed machines. There are several types of these machines. The **tandem type** uses horizontal spindles and the drawing blocks are vertical. The wire is drawn through the first die and given a few wraps around the block and passes directly into the next die. The **step-cone type** uses horizontal spindles and has several blocks of different diameters mounted on each spindle, giving the appearance of a cone. The coarser wire is drawn on the smaller block and passes around an idler sheave and into the next die and onto the next larger block. The diameters of the blocks are designed to take care of the normal elongation of the wire. Another type is the **circular tandem type** in which the blocks are arranged in a circle, with a die between each block. Each block is geared to draw enough faster than the preceding block to take up the increase in length. The finishing block is usually eight inches in diameter, but many of

FIG. 40-17. General view of a circular-tandem type of fine-wire drawing machine. (Courtesy of Vaughn Machinery Co.)

these machines are equipped to take up the wire on spools.

In wet drawing, the drawing lubricant is a soap solution diluted with water. This solution is pumped from a tank on the machine or from a central tank supplying several machines. The solution is piped directly to a nozzle which sprays the lubricant into the bell of the drawing die. There is enough surplus to spray the drawing block also. In this manner the die, the wire, and the drawing block are kept well lubricated. The surplus lubricant falls to the bottom of the machine where it drains out to the supply tank or into a filter system for recirculation. Figure 40-16 shows a cone-type machine and Figure 40-17 shows the circular tandem type.

Drawing Frames—Before the development of continuous machines, all wire was drawn on what are known as frames, and a large percentage of wire still is drawn by this method. A frame is equipped with several wire-drawing blocks, all capable of being driven from a common shaft, either singly or in unison. The horizontal shaft extends the length of the machine, usually below floor level. From this shaft, vertical spindles are geared, and at the top of each spindle a drawing block is mounted. A separate clutch for each block permits the individual blocks to be started, operated or stopped without affecting the others on the frame. The blocks are usually 22 or 26 inches in diameter and the spindles set at about 5-foot centers. The blocks are about 25 to 30 inches above the floor level and all gearing and other moving parts are enclosed. Each block has a die holder or die box which also holds the drawing lubricant. Each block is also equipped with a pull-out mechanism, which is geared to the main shaft. In operation, the rod is placed on a pay-off reel and one end is pointed. This pointed end is then threaded through the die. The pointed end is then grasped by a pair of pincer jaws which are attached to the pull-out mech-

FIG. 40-16. General view of a cone-type fine-wire drawing machine.

FIG. 40-18. Plan and elevation sketch of a three-arm pay-off reel. (Courtesy of Morgan Construction Co.)

anism. About three feet of wire is then pulled through the die. The pincer jaws are released and the wire is attached to the block by a clamp on the side of the block. The block is then started by attaching it to the spindle by actuating the jaw clutch which is operated by a foot lever. When the coil has been drawn, the block is declutched and the coil is removed by an overhead hoist. The coil is then placed on another pay-off reel and the process is repeated on another block until the required size is produced.

FIG. 40-19. Stem of rods from the cleaning house being loaded by tractor into the stem-type pay-off.

Obviously, there are disadvantages to this method. Each coil must be handled separately for each draft. All blocks on a given frame turn at the same speed and as the diameter of the wire is reduced, the length of the wire and, consequently, the running time increase, and more blocks must be provided for drawing wire to the smaller sizes in order to keep pace with the blocks drawing coarser wire through the early drafts.

AUXILIARY EQUIPMENT

Pay-Off Reels.—For rods $1\frac{1}{32}$ -inch and smaller, a flipper-type reel is used. This consists of two horizontal arms placed one above the other, both extending from a vertical standard. The arms are hinged so that they may be moved up or down. In use the arms are collapsed and the rod coil is suspended on the upper arm. Both arms are then moved to the horizontal position and the rod is held vertically. In this manner each convolution of the rod coil can be paid off or flipped and pulled up to the die. Some reels are made with three arms set at 120° . While one coil is paying off, the other arms are loaded and the ends are welded so there is no stoppage necessary between rod coils. Figure 40-18 shows a 3-arm reel. Another method is the stem pay-off, Figures 40-19 and 40-20. By this method the full stem of rods from the cleaning operation is placed on a special holder. A long bar or U-shaped rod is placed through the

FIG. 40-20. Battery of wire-drawing machines (left) being fed by stem pay-offs in the right foreground.

STEEL WIRE AND WIRE PRODUCTS

center of the coils and acts as a hold-back to keep the convolutions paying off uniformly. The coils are welded as in the flipper pay-off.

Welders—For continuous drawing, electric butt welders or flash welders are used. These have been developed to perform very well on high- and low-carbon steel. For welding high-carbon steel, the welders are equipped with annealing jaws to give the steel the proper structure for drawing after the weld is made. Grinders are also provided to quickly remove the "burr" or upset formed by the weld.

Safety Stop—All machines and frames are equipped with stops to cut off the power quickly in case of trouble. Between the flipper reel and the first die a snarl stop is placed which will stop the machine or block in case of a tangle or snarl before the rod is broken. All machines are equipped with bars around all working parts. By merely pushing against these bars the machine can be stopped. The motors are also equipped with dynamic brakes so that there is immediate response to the stop signal and there is no tendency for the machine to "coast."

Pointers—Several methods are used for pointing the rods or wire for the initial threading of the dies. The fine sizes are literally pulled apart and the "necking down" forms a point. The intermediate sizes are pointed by means of a "roll pointer" as shown in Figure 40—21. This consists of a pair of oscillating rolls with grooves of varying diameters. The rod end is worked down to smaller sizes by successive rolling in the grooves of decreasing size. The larger sizes are swaged or hammered on rotary swaging machines or are machined by specially designed cutting machines.

"Turks-Head" Shaped-Wire Drawing Machine—Common four-sided shaped wire, such as squares, oblongs or keystone shape, are frequently produced on cold-rolling equipment known as a "Turks-head" machine. This consists of four hardened-steel rolls set in planes at right angles to each other. The narrow face of the rolls, as set in the framework, is adjustable on the same plane so that the assembly of the overlapping roll edges facing each other will project the contour of the opening so formed, into the desired shape of the cross-section of the wire to be made. The process wire, of a size somewhat larger than the finished size desired, is pointed and pulled through the Turks-head, being thus rolled to shape and size, after which it is coiled on a regular wire-drawing take-up block.

Heating Effect in Wire Drawing—The plastic deformation involved in drawing wire will induce internal heat, and this rise in temperature of the wire will be dependent on the composition or hardness of the steel and the amount of cold work or reduction of cross-

FIG. 40—21. "Roll pointer" for pointing rods or wire for initial threading through the dies. (Courtesy of Morgan Construction Co.)

sectional area of the wire. In the ordinary dry drawing of frame or individual drafting, the wire will cool somewhat between successive drafts, but on continuous drafting, the heating of the wire may be cumulative resulting in temperatures frequently detrimental to the quality of the wire. This rise in temperature may be restricted by several methods, such as air or water cooling of the wire-drawing capstans or blocks and the use of water-cooled dies, the latter being more of a secondary rather than a direct effect. The effect of the wire-drawing temperatures is not as detrimental to low-carbon steel wires as to high-carbon wires. The toughness and uniformity are adversely affected, and in drawing high-carbon wire of high tensile-strength requirement, by either single or continuous drafting, the temperature must be controlled and kept as low as possible. The efficiency of lubricants used in the wire-drawing die, and carried on the wire in continuous drafting, is adversely affected by excessive wire-drawing temperatures. Without the cooling devices, the present high wire-drawing speeds could not be attained and die life would be considerably reduced.

SECTION 7

WIRE-DRAWING PROCESSES AND OPERATIONS

Results of Cold Drawing—The results attainable by the wire-drawing process may be summarized as follows:

1. Metal may be elongated and reduced in section to an extent not attainable by other methods.

2. A greater degree of accuracy as to size and section can be attained than is possible by other methods excepting cold rolling, which is not applicable to common sizes of wire.

3. A uniformly smooth and highly polished surface can be produced.

4. The process serves as a test for the detection of hidden flaws in the metal. The fact that a wire has satisfactorily withstood the drawing operation may be taken as an indication that the metal was originally sound and free from defects liable to cause it to fail in service. This statement does not mean that the wire itself is free from all flaws or defects, for it is possible to produce certain flaws by improper drawing.

5. Finally, the process affects the mechanical properties of the metal, which fact, as noted under the heading of tempers, makes it possible, by employing this process in conjunction with heat treatment, to produce

FIG. 40-22. Gain in tensile strength on drafting steels of carbon contents from 0.05 to 1.00 per cent.

many wires from the same steel having different mechanical properties.

Effect of Drawing Upon Mechanical Properties—Wire drawing, like any cold working of metals such as iron or copper, will increase the hardness, stiffness, tensile strength and elastic limit. The ductility, as indicated by the elongation and reduction of area, will be correspondingly decreased. The extent of these changes in

FIG. 40-24. Structure of 0.06 carbon-steel wire after one draft. Longitudinal section. Magnification: 500X.

mechanical properties is not always directly proportional to the amount of drafting or cold work done upon the metal, as it is affected by various factors such as the total amount of drafting, number of drafts, per cent draft per draft and the type of material itself. However, for each set of conditions, the change in mechanical properties has been determined, and the processing necessary to produce the required grade of wire may be regulated accordingly. The gain in tensile strength in drawing of various carbon steels under standard conditions is shown in Figure 40-22 and indicates the hardness increase as the cold reduction of the wire increases.

The Cause of These Changes—These changes in the characteristics of the metal brought about by cold working are to be attributed to the changes in grain

FIG. 40-23. Full-annealed 0.06 carbon-steel wire. Longitudinal section. Magnification: 500X.

FIG. 40-25. Longitudinal section of hard-drawn 0.15 carbon-steel wire. Magnification: 500X.

FIG. 40-26. Structure of 0.15 carbon-steel wire after short-time-cycle sub-critical anneal. Longitudinal section. Magnification: 500X.

structure such working produces. In a hot-rolled rod or in an annealed wire the grains have a polygonal form and are arranged about as shown in Figure 40-23. The microstructure of an annealed low-carbon steel wire is shown in the photomicrographs of Figures 40-26 and 40-27. All photomicrographs shown represent longitudinal sections, parallel to the direction of drafting. Figure 40-23 exhibits grains in the steel before drafting. Figure 40-24 shows the condition of the grains after the material has had one draft. Here it can be seen that, as the wire is being elongated while passing through the die, the grains in the steel actually become elongated, also. The grains elongate in the direction of the drafting and become correspondingly narrower at right angles to that direction. Figure 40-25 shows the

FIG. 40-27. Structure of 0.15 carbon-steel wire, full-annealed after hard drawing. Longitudinal section. Magnification: 500X.

same wire after having had a number of drafts. Here the grains have been elongated to a considerable extent. Due to the stretching of the wire in drawing and the crushing effect produced by the pressure exerted by the die in all directions towards the center of the wire, the structure has become so altered that it is difficult, if not impossible, to locate the exact boundaries of the individual grains in their strained and distorted condition.

Limitations of Drawing—Steel may be drawn several drafts further than the state illustrated by Figure 40-25, but when wire has been put into this highly strained condition by drawing, it loses its ductility to such a degree that it is not practicable to submit it to further drawing, and if required to be reduced in section still more, it becomes necessary first to restore the grains to the form and arrangement characteristic of the unworked (not strained) condition. This changing back of the grains to a non-distorted form simultaneously restores the properties that existed in the wire before it was subjected to drawing. The processes employed for restoring the grain to strain-free formations are annealing and patenting. The effects of these processes will be discussed in the section on "Heat Treatment of Wire." Enough having been said to explain the reasons for them, some of the chief features of wire-drawing practice will now be considered.

DRY DRAWING

Dry Drawing Low-Carbon Coarse Wires—Dry drawn wires may be sub-divided into three groups according to the number of drafts given them. The first group includes all one-draft wire, normally in 8 gage and coarser sizes. These wires may be used for the fabrication of cold-forged parts, such as bolts and rivets, or formed materials as wire screens, chains, etc. The second group consists of two-, three- or four-draft wire in sizes 9 gage to about 14 gage. These sizes are common wire sizes such as usually required for hardware purposes, galvanized wire for fencing and telephone lines as well as bright wire for the manufacturing of coat hangers, nails, steel wool and similar products. Some of this group of wire will be used for process wire to be heat treated and drawn to finer sizes. The third group consists of five-, six- and seven-draft wire in sizes 15 gage to about 18 gage. In addition to being used as manufacturing wire, it is largely used as process wire, for which latter purpose it is annealed for drawing to fine-wire sizes, since 18 gage is usually considered to be the smallest size wire normally drawn from a $\frac{1}{2}$ -inch rod without annealing.

Drawing Single-Draft Coarse Wires—On single-draft wires, as light a coating and lubricant is used as is possible to meet the needs of each case, the exact nature of both coating and lubricant depending upon several conditions, such as size and kind of stock, uses to which the wire is to be put, etc. These wires are generally drawn on 22-inch blocks. Most mills now provide "block strippers" which are small electric or hand-operated hoists erected over the blocks, for lifting the heavy bundles off the blocks and onto buggies. The usual speed of drafting on this class of product is from 25 to 60 r.p.m., or 144 to 346 feet per minute. The reduction in size of this one-draft wire is usually about $\frac{1}{32}$ inch in diameter, and varies according to the purpose to which it is to be put. For bright finish wire, the principal object of the drawing is to remove the inequalities in dimension and finish of the hot-rolled rod and at the same time to retain, as far as possible, the mechanical properties characteristic of the hot-rolled steel. If the light draft necessary to accomplish the first result

renders the wire too hard for the purpose intended, the requisite softness in the finished wire is obtained by using a hot-rolled steel with very low carbon content or an annealed wire as the starting material.

Drawing Two-, Three-, and Four-Draft Wires—In this second group of dry drawn wires are found practically all the process wire for finer sizes and the largest tonnages of finished wire. For the two-draft wire, the rod may be given a medium lime coating with or without sll, according to the finish desired; while for three- and four-draft wires, a medium or heavy lime coating is needed on the rod. The lubricant for the first draft should be of such character and consistency that all succeeding drafts may be effected without damage to the wire or die. The reduction per draft, the speed of drawing, and other such features will vary for this class of wire, as well as for other kinds, with different companies and in different mills, but the following example represents conservative practices: Starting with a $\frac{1}{32}$ -inch low-carbon rod, this would be drawn to a No. 8 $\frac{1}{4}$ wire on the first draft, to a No. 10 $\frac{1}{2}$ wire on the second draft, to a No. 12 on the third draft, and to a No. 13 $\frac{1}{2}$ on the fourth draft—all on 22-inch blocks. The corresponding percentage reductions would be approximately 41, 35, 32 and 34, for each draft.

Drawing Five- and Six-Draft Wires—The third group of wires are given their finish drafts on 16-inch blocks, which run at a peripheral speed of 160 to 272 feet per minute on frame drawing, or about 1200 to 1500 feet per minute on continuous machines, depending on the composition of the steel. In this group are found the hard-drawn wires which have already received three or four drafts on 22-inch blocks, and are to receive one, two or three drafts to No. 15, 16 $\frac{1}{4}$, or 17 $\frac{1}{2}$ gage, as well as wire drawn five or six drafts direct to finished size on the 16-inch continuous machines.

Process wire, which was annealed at 13 or 13 $\frac{1}{2}$ gage, may also be drawn five or more drafts to about 20 gage, finishing on 16-inch blocks.

Drawing No. 14, 15 and 16 Wires—In addition to the wires discussed in the two preceding paragraphs, there is a relatively large tonnage of wires drawn four, five and six drafts from the rod on 22-inch blocks without process annealing. The most important of such wires are No. 14, drawn four drafts from the rod on 22-inch blocks, and five- and six-draft No. 15 and No. 16, drawn the same way.

Drawing High-Carbon, or Special Wires—The class here referred to as high-carbon wires is made up of a great variety of wires used for many different purposes. These wires include the four different grades of rope wire, the various kinds of spring wire, as well as music wire, spoke wire, brush wire, card wire, pile wire, pivot wire, safety pin wire, sewing-machine needle wire, phonograph needle wire, and various other highly specialized products. Because these wires are made to specifications somewhat out of the ordinary, either as to finish or mechanical properties, requiring special treatment at some stage in their manufacture, they are collectively known as special wires. As to the method of drawing, the actual processes for drawing these wires do not differ from those for drawing low-carbon wires except as to details, and such differences as do exist are due to the greater care that must be exercised with the high-carbon wires. These differences may be summarized as follows:

1. In the case of certain products, such as music wire and some grades of rope wire, the rods are patented before they are drawn. This treatment refines the grain structure of the rods, homogenizes the structure, and provides better drafting qualities.

2. The cleaning of high-carbon rods or wire requires greater care to avoid "smutty" surfaces and to prevent acid brittleness, which has a more harmful effect upon high-carbon than upon low-carbon wires.

3. The coating must be heavier and more uniform on the high-carbon stocks in order to prevent scratching of the wire and cutting out of the dies.

4. A longer time of baking is required to counteract the effects of the cleaning acid.

5. As a lubricant for drawing high-carbon wires, a specially prepared soap powder is used, as the very best lubricant possible is necessary for satisfactory results in drawing.

6. The speed of drawing and the amount of reduction per draft must be carefully regulated to prevent the structure of the wire from being harmfully affected by the drawing.

7. High-carbon process wires are usually patented instead of annealed, whenever it is necessary to remove the hardening effect of previous drafting. This special heat treatment (which will be described later) provides, in the case of high-carbon wires, better drawing qualities and produces a much stronger and tougher finished wire than annealing. This treatment, when followed by proper drafting, gives the highest possible strength. High-carbon wire is spheroidized annealed if maximum softness is required.

8. As is well known, the higher carbon steels are more sensitive to heat treatment than the low-carbon steels, hence, they require correspondingly greater care in heating and cooling. Not only must too high temperatures in heating be avoided, but care must be taken to maintain uniformity in temperatures and rate of cooling in order to obtain uniformity in the finished product, which is particularly important and desirable in the case of the uses to which most high-carbon wires are put.

WET DRAWING

As previously stated, wet or liquor-finish drawing is applied to a large percentage of wires smaller than 20 gage and to all coarser wires requiring a liquor finish, and is distinguished from dry drawing by the kind of coating given the wires and the fact that they are drawn wet from a vat of fermented rye-meal liquor or a substitute alkaline soap solution. As to the actual operation of drawing, the wet process does not differ from the dry, except that little or no lubrication is needed other than that furnished by the metallic coatings and the liquor. The percentage reduction per draft, however, is materially less in wet than in dry drawing, and of the two processes, wet drawing is the more expensive. For this reason it is the practice, in the case of coarse wires, to draw the wire dry to within one size or a half size of the finish before coating and drawing wet to finish. The size to which fine wires are drawn dry before coating and drawing wet depends upon the size of the finished wire and the purpose for which it is to be used, but generally the dry drawing will stop at about No. 17 or No. 20 gage, the latter representing the usual limit for dry drawing.

Manner of Handling Material for Wet Drawing—After being cleaned, all wire for wet drawing is delivered to the wet-wire department immersed in water contained in barrels or tubs, where it remains until the mill is ready to draw it. Just before drawing, each coil of wire is removed from the water and dipped into a coating solution of the correct composition to give the kind of coating desired. If the wire is to be finished by single drafts, the coil is then placed on a reel set in a tub containing the fermented rye-meal liquor, from

which it is drawn wet through a die of correct size and kind by a block of proper size and strength. If the wire is to receive several wet drafts, the drawing may be done on a continuous machine. These machines give very satisfactory service in wet drawing, because the drums may be partly submerged in the liquor which keeps the wire cool. While the coating and liquor are generally relied upon to supply the necessary lubrication, tallow occasionally will be rubbed on each coil at one or two places after coating, and large sizes of wire are sometimes dipped in soap water, to supply additional lubrication. As to the composition of the coatings, the brass (copper and tin) coatings give a better wearing or drawing surface than the pure copper coating, and these coatings are, therefore, used in all liquor drawing, especially of high-carbon wires, unless a copper-colored finish is required. The drawing operations have the effect of burnishing the coatings so that the wire has a fine finish, but, while these metallic coatings cover the wire completely, they are extremely thin and cannot be relied upon to give much protection against corrosion.

Number and Sequence of Operations for Fine-Wire Drawing—Previous discussions have indicated that a great number of operations are required to produce a wire of very small size, and also that these operations vary in number, type and sequence according to the size of the wire, the grade of steel, and fabrication requirements. No one kind of wire, therefore, can be taken as typical of all fine wires and space is not here available for describing in detail the manufacture of even a few of the more common wires. However, it seems desirable at least to give some idea of the great amount of work required to produce these wires, and this may best be done by an example. For this purpose, a No. 34 gage (0.0104-inch) low-carbon wire has been selected which, as fine wire goes, is produced in relatively large tonnages. The steel used is usually a low-carbon basic open-hearth steel of a type which lends itself to continued heavy drafting and the severe plastic deformation involved in such section reduction. After this steel has been properly made in the open-hearth furnace, cast into ingots, and soaked, it is rolled into billets, which are reheated and rolled into the standard $\frac{7}{32}$ -inch (0.218-inch) rod, each rod coil weighing around 600 pounds as rolled from the more modern continuous hot mills. This rod is cleaned, lime coated, and baked, after which operation it is dry drawn about five drafts to 14 gage (0.080-inch) on 22-inch blocks, usually on continuous-drawing machines, at 1500 feet per minute. It may be annealed or not, depending on further processing, drawn six drafts to 20 gage (0.0348-inch) on 16-inch blocks, usually at 1500 feet per minute on continuous machines. Coils may be split at the machines and then are bright annealed in pots under controlled atmosphere, cleaned and metal coated, placed on pay-off reels and drawn wet about twelve drafts on cone-type continuous drawing machines to 34-gage.

Tungsten carbide dies are used on all of the twenty-three drafts. The wire, in 25-pound coils, is next inspected and tested, when it may be shipped as bright wire without further work, or be tinned, galvanized, or annealed as required by the purpose for which it is intended. Low-carbon wires much coarser than No. 34 gage, may be given but a single anneal in process, usually between the dry and wet drawing, or the two annealings may be located at different points from those cited above, while wires much finer than No. 34 size may be given three annealings in process.

Drawing Copper Wire—While this chapter is concerned only with the drawing of steel wire, a few words

concerning the drawing of copper wire should be included, perhaps, especially since many of the wire manufacturers regularly draw wire from both of these metals. As to the actual drawing operation, the drawing of copper wire differs from that of steel wire only in minor details. Copper rod or wire is never coated. It is merely dip-cleaned in sulphuric acid to remove the oxide, then washed with a hose and dipped into hot water, the last operation being employed so that it will dry quickly. Fine sizes in coils, however, may require an additional operation, as they are usually dried in bake ovens. As the lubricant for the dry drawing of copper wire, tallow or tallow mixed with a drawing compound is used. To anneal copper wire after hard drawing it is heated to redness and cooled either rapidly or slowly. Most of the copper-oxide scale can be removed by quenching red-hot copper wire in cold water.

Precautions in Drawing—Proper Alignment of the Die—The correct setting of a die is an important part of a wire-drawer's work, to which too much attention cannot be paid. As indicated in Figure 40—28, the die holder is fastened to the frame by a bolt allowing a lateral swinging movement. The pull of the wire is on a line from the center of the bolt to the fillet at the base of the block, and the face of the die should be at right angles to this center line. The hole through which the wire is drawn should be so in line that the center line of the hole will coincide with the pull of the wire, or with a line drawn from the center of the bolt holding the die box at a tangent to the block. Suppose the wire-drawer carelessly uses a hole at one side of the center. The die box swings around, but if the center line of the hole does not coincide with the pull of the wire, off-sized or scratched wire will be produced, and the die will speedily wear out. The sketches of Figure 40—28 show these two conditions. The upper sketch shows two positions of the die holder. The position shown by the solid line is assumed when wire is being drawn through

FIG. 40—28. Sketches illustrating the importance of proper alignment of the die in wire drawing.

a hole of a die which is placed correctly in the holder. The line CD represents the center line of another hole in the same die. If the wire drawer starts to draw a piece of wire through hole CD without moving the die to bring it into a central position in the holder, the holder will assume the position shown in dotted lines and its center line will not be tangent to the block and center line CD will then not be tangent to the wire-drawing block. The effect upon the wire is illustrated in the larger scale drawing. The wire is there shown drawing off the lower edge of the die, and thus off-sized wire will be produced, and the life of the die will be shortened. The die should also be set in an upright position. Sometimes the clamping screw is not in just the proper position, and a bar of steel is used to shim it up, which is allowable only if properly used. The die should be lined up a little below the fillet of the block. This will permit the leading of the wire on the block in such a way as to cause it to slide up properly. Some die holders are equipped with a hinged joint to permit a motion in a

nearly vertical plane. This is to overcome the tendency to pull hard on the upper side of the hole when the block is first started. This tendency is due to the fact that the vise is usually on the top of the block and the pull is upward.

Drawing Limits and Tolerances—Although every effort is made to draw the wire as true to the required shape and size as possible, exactness in these respects is almost impossible under commercial conditions, and all wire produced under such conditions will vary somewhat in diameter and section. These variations may be due to a varying degree of hardness in the metal being drawn, to somewhat rapid wearing of the die, or, in the case of wet-drawn wires, to unsuitable or imperfect coatings. Some tolerance is necessary therefore, but it is important that these tolerances be kept within certain limits defined by the use to which the wire is to be put. The tolerances used by the wire industry are divided into four groups of allowable variations in the diameter of the common grades of round wire, other than special grades, and designated as **standard**, **semi-special**, **special**, and **extra special drawing**. Each of these sets of tolerances contains the variations allowable, which are adjusted to the size of the wire as indicated in Table 40—III. The standard tolerances are those adopted by the American Iron and Steel Institute (AISI) and are given in their Steel Products Manual, Carbon-Steel Wire, Section 16.

All wire is gaged carefully in two or three places around the circumference, just after the first end of the coil is pulled through the die and at the finished end to insure that it is of the correct size and shape. Wire ordered by gage number, by decimal, or by fraction of an inch, is gaged with a micrometer gage.

Table 40—III. Standard Size Tolerances for Wire

Size Tolerances for Uncoated Coarse Round Wire in Coils

Size, in.	Tolerance, Plus and Minus
0.500 and larger	0.003
Under 0.500 to 0.076, incl.	0.002
Under 0.076 to 0.035, incl.	0.001

Out-of-round is customarily one-half the total gauge tolerance.

Size Tolerances for Coarse Round Galvanized Wire in Coils

* These tolerances do not apply to special wires which have been annealed as a separate operation following cold drawing or immediately prior to coating.

SPECIAL FINISHING OPERATIONS

Straightening and Cutting Wire—With the exception of the largest sizes, all wire, both round and shape, is drawn on a block and, therefore, at the finished size, is still in the form of a coil. But for certain purposes it is desired to have the wire furnished in short straight lengths, rather than in coils. This straightening and cutting work is usually done on some type of machine.

Whirls—For common round wire, automatic machines are employed for straightening and cutting the wire. These machines are required to perform three operations simultaneously or in very rapid succession, namely, pull the wire forward, straighten it, and cut it into the lengths desired. The mechanism for straightening the wire is known as a **head or whirl**. It contains a number of staggered dies which bend the wire slightly, as it passes through, in reverse directions so as to remove the bends and kinks and leave it straight. The wire to be straightened is automatically fed through the whirl and onto an apron, where it actuates a mechanically or electrically driven cutting tool which cuts the wire into uniform short pieces of the length desired.

Roll Straighteners—For shapes and flats the roll straightener is used. This machine consists of a set of vertical and also of horizontal rolls which can be so adjusted that pressure can be brought to bear on the sides, top and bottom of the wire. On these machines the first sets of rolls put a considerable bend in the material to remove the kinks, and succeeding sets of rolls reverse this bend just enough to leave the wire perfectly straight. Squares, rectangles and hexagons, narrow flats that are not too thin, most shape wires, and also very fine wires, can be straightened on this type of machine provided the machine is properly designed for them.

Stretching Machines—A process of straightening by

stretching is used on some fine soft annealed wire. The usual products straightened in this manner are copper wire, which may be as coarse as No. 15; tinned tag and florist wires, from No. 20 to No. 35 gage; and soft annealed wire. To straighten such wire, it is wound onto a wheel about 8 feet in diameter, and the coil is then slipped off and placed over two lugs on a hydraulic machine. When the ram of the machine is set in motion one of the lugs moves away from the other, first drawing the coils out straight, then stretching the strands some three or four inches. The stretched and straightened strands, which may number as high as 1,000 on the smaller sizes, are then cut to length. This process does not produce wires that are so straight or that are so exact and uniform in length as the other methods.

INSPECTION AND TESTING

Importance of Inspection—Of equal importance with the various processes in making wire is the thorough system of inspection and testing to which the material is subjected during its progress through the mill and after finishing. Beginning with the hot-rolled rod, the material undergoes frequent and careful inspection during manufacture and is subjected to whatever tests are needful to determine its fitness for the service required.

Final Tests on Wires—Wire for shipment to customers is regularly inspected and tested at both ends of each bundle for size, finish and temper. For temper, small sizes are tested by a kink test, medium sizes by a bending test, large sizes by a nick-and-break test. The better grades of wire are subjected to a machine test for tensile strength and elongation, and some of it may be given severe torsion tests. All telephone and telegraph stock is tested also for conductivity. All exact-weight bundles are net weight of wire, excluding wrapping material. Wet-drawn wires are invariably prepared; that is, bundles are covered with paper, but they may also be wrapped in burlap when so ordered.

Defects in Wire—After the wire has been drawn, it may be found defective or unsuitable for the purpose for which it was intended, and every effort is made to detect and discard all such wire. The chief sources of trouble can usually be placed under one of the following headings: off size or shape, internal defects, surface defects, and improper mechanical properties.

Size and Shape—The reasons for wires being off size or shape have been already given. While every effort is made to draw the wire to the tolerances given, the tolerances themselves may be too great to permit use of the wire in an exacting application. Where extreme dimensional accuracy is needed, proper specifications should be established before the wire is drawn so that product can be made to suit the special requirements.

Internal Defects—If the steel from which the wire is made contains pipe or seams, these will remain in the wire, but are usually so minute that they cannot be found by any of the ordinary means of inspection. Any slight segregation in the steel will also induce defects in the wire. This segregation causes uneven temper and is also thought to induce, at times, a defect known as "cupping." A "cupped" wire is one the fracture of which exhibits the cup and cone form. This defect, it is believed, may also be caused by improper drafting. Such hidden defects are very difficult to detect and frequently cannot be found except by actual use of the wire.

Surface Defects—Sometimes the finish of the wire does not meet requirements. If the finish is not satisfactory it may be due to poor cleaning, to the use of improper coatings or other causes. In the case of liquor-finished wires, especially, the color may not be of the particular shade desired, or it may vary too much in different bundles. When these features are of special importance, they should be stated on the order, so that special attention may be given to meeting requirements in this respect. Other surface defects in wire are scratches, slivers, and seams. Scratches are caused by using a die in poor condition, or they may result from improper lubrication or from pieces of metal or other gritty substances being drawn into the die with the wire. Slivers, as the name indicates, are sharp pointed projections of metal that rise from the surface of the wire. They may be caused from any one of a great number of sources, including the ingot and rolling practice. Seams are longitudinal cracks in the surface of the wire and are generally traceable to lack of proper care in rolling. Therefore, in the wire they are very small, and are sometimes very difficult to detect.

Mechanical Properties—The mechanical properties of any wire will depend upon the chemical composition and quality of the steel as well as the exact nature of the drafting practice and of the heat treatment it has undergone. The particular application or method of fabrication determines the grade of wire necessary. A finished wire taken at random will not be suitable for all purposes, as the strength and ductility may vary from a 50,000 lb. per sq. in. tensile strength for an annealed low-carbon tie wire to 350,000 lb. per sq. in. tensile strength for a high-carbon music wire. If the wire manufacturer is fully informed both as to the desired properties of the wire and its application, the requirements can be met by proper selection of composition, heat treatment and predetermined amount of hardening by cold working in wire drawing. Many products such as upholstery springs, rope, telegraph wire, etc., are recognized in the industry as regular grades of wire for standard applications, being covered by standard industry specifications, and may be ordered as such.

SECTION 8

HEAT TREATMENT OF WIRE

Heat-Treating Processes used in the wire industry include subcritical or process annealing, patenting, and hardening and tempering. Of these, patenting may be described as a special toughening process used only in the wire industry, while annealing, hardening, and tempering play such an important role in the industry and the methods of applying these processes have become so highly specialized that, although their general principles and their application to other branches of the steel industry have been thoroughly discussed in other chapters of this book, a brief account of their

specific application to the wire industry is included in this chapter. These processes are briefly described and discussed in the order of their importance, which is the order in which they were first mentioned above.

Importance and Purposes of Annealing—Of the three wire heat treatments mentioned above, subcritical or process annealing is the most common, and it is practically the only heat treatment given to the soft, or low-carbon, steel wires, which constitute by far the bulk of wire production. In general the process is employed in the wire industry to accomplish any one of the following

objectives: (1) to refine, soften, and make uniform the grain structure of rods or wire; (2) to obtain a specific structure in, and thus impart special properties to, process wire or the finished material, and (3) to soften the wire after cold-working, i.e., drawing or cold-rolling.

Normalizing (Cycle Annealing)—Normalizing consists of heating the rods or wire to above the transformation temperature and cooling in still air at room temperature. This practice is usually followed when treating medium-carbon steels of about 0.25 to 0.45 per cent carbon to obtain uniformity of structure and hardness. Normalizing imparts the proper ductility or flowability as required for certain cold upsetting and forging applications, and much of the medium-carbon bolt wire is therefore normalized in the regular course of manufacture. This normalizing process consists of passing full coils of rods or wire on a moving conveyor through a furnace made up of three zones, "preheating," "soaking" and "cooling" zones, the temperatures of which are automatically controlled. In the soaking zone, a temperature of approximately 1600° F is maintained. Combinations of several variables permit variations in the heating and cooling cycles and the cooling rate is usually retarded. By the use of controlled atmospheres in the furnace, decarburization and scaling may be held to a minimum.

Annealing for Definite Structures—This type of annealing is applied to the higher carbon steel wires, i.e., those with a carbon content of 0.40 per cent or more, in order to obtain certain definite structures, and is similar to the treatment given carbon tool steels and other high-carbon steels in order to make them easy to machine. If steel having a pearlitic (lamellar) structure is heated to 1300° F (704° C), and is held at that temperature for a sufficiently long period of time, the iron carbides slowly coalesce, changing from a platelike form to a granular, globular, or spheroidal form. By properly regulating the temperature of the treatment, structures intermediate between these two extremes and best suited to the purpose for which the wire is to be used may be obtained with temperatures in excess of 1330° F yielding a correspondingly greater percentage of pearlite as the temperature increases. These structures are sought in high-carbon wires mainly to enhance their machinability. Close regulation of the temperature is imperative in this type of annealing, for in heating the steel to a point so near the critical range, a difference of 50° F in the temperature often means the difference between obtaining the spheroidized carbide structure sought and the lamellar (pearlitic) structure which it is desired to efface.

Process Annealing to Soften Hard-Drawn Wires—In the previous section, it was pointed out that each successive draft in drawing a wire has a certain hardening effect upon the metal; that the grains become elongated in the direction of drafting; that, as the drafts are repeated and the wire becomes progressively harder, a point is reached at which the wire will break if subjected to further drafting; and that well before such a condition of brittleness is reached, it is necessary to heat-treat the wire in order to put it in a condition that will permit further processing without injury. For reasons which have already been stated or will be made apparent in the discussions to follow, high-carbon wires are generally patented, while low-carbon wires are annealed.

Process Annealing—For softening wires in process of manufacture, process annealing at sub-critical temperatures is usually employed. This type of annealing is used mainly to restore the ductility of hard-drawn low-carbon wires at process size so that they may be

drawn to finer sizes, although it is also employed to adjust the mechanical properties of some wires at finished size as required by their application. To accomplish these results, it is only necessary to heat the wire to below the lower critical range, as a temperature between 1000° F and 1250° F is sufficient to soften the steel to such an extent that the material is almost as ductile as it was before any drafting was done. The reason for this is illustrated by a comparison of the photomicrographs of hard-drawn and annealed wire in Figures 40—23 to 40—27. Figure 40—23 shows the form, arrangement, and size of the grains in the full annealed steel. In this condition, this steel exhibits a tensile strength of approximately 48,000 lb. per sq. in. and an elongation of approximately 33 per cent in 10 inches. Figure 40—24 shows the structure after a single draft; the grains are somewhat elongated in the direction of drafting. Figure 40—25 shows the structure of the wire after it has had about five drafts, and it will be observed that the grains have been generally elongated into a stringer-like or fibrous structure, greatly changed from the original equiaxed grains of Figure 40—23. This wire would have a tensile strength of about 125,000 lb. per

FIG. 40—29. Curves showing changes in mechanical properties of hard-drawn low-carbon steel wire after annealing at various temperatures up to 1200° F.

sq. in. and an elongation of about one per cent. At an elevated temperature, such as 1000° F, the grains recrystallize, thereby forming new grains. The greater the amount of plastic deformation, the lower the recrystallization temperature. Such incipient recrystallization or forming of new grains is indicated in Figure 40—30. Grain size is shown in the photomicrographs to increase as the temperature of annealing and the time the wire is held at temperature increase. The grain size obtained after the long time annealing cycle and recrystallization at 1200° F is similar to that of the original structure, although certain remnants of the structure produced by drawing still remain, with some residual directional properties.

The mechanical properties obtained by annealing hard-drawn low-carbon wires at various temperatures up to 1200° F are shown in the graphs of Figure 40—29.

Size of Grains—While the preceding paragraph shows the effect of grain distortion upon the mechanical properties of steel, nothing is said about the effect of grain size on these properties, and in all annealing, as well as other forms of heat treatment, the matter of grain size is of considerable importance. Large grains lower

the tensile properties of the metal somewhat, while small grains make it not only stronger but tougher. The reasons for this, as well as the effects of cold working, are to be found in the structure of the grains themselves. Structurally, each grain is in reality a small crystal in which the atoms of which it is composed are arranged in regular rows and "layers," as described on pages 11 through 15. Crystals deform through movement of adjacent parts along definite planes, called slip planes, whose location and direction within the crystal are determined by the positions of the atoms within the space lattice. Anything that interferes with this movement will make the metal more resistant to deformation, while anything that promotes slip will lower its resistance to deformation. Small grains offer greater interference to slip than large grains, because the slip planes in different grains lie at different angles, and in any one of such small grains the slip cannot progress far before it is stopped by an adjacent grain. Each grain offers considerable resistance to the force causing the slip, because the direction of possible slip movement may differ greatly from the direction of the applied force. In a small section, such as a wire, where the ratio of the diameter of the wire itself to that of the crystals is relatively small, the effect of large grains on lowering the tensile properties is likely to be very noticeable. The increase of strength due to drawing may also be explained from the standpoint of slip interference, for, as the grains are distorted, the slip interference becomes greater and greater until most of the grains have been drawn into parallel stringers and there are no more planes of easy slip on which further motion can take place. In this condition, the force required to pull the wire apart should approach the force of attraction of

the molecules or atoms themselves, since the wire no longer can adjust itself to the load by deforming, but it never does because some of the grains begin to break before the others. The resulting ferrite grain size is referred to as "structural grain size," and is not to be confused with austenitic grain size.

The Conditions for Process Annealing involve three factors, namely, strain, time, and temperature. Without strain no change in the crystalline structure takes place on heating below the critical range. As to the effect of the amount of the strain in causing grain growth, or rearrangement, below the critical range, Sauveur has shown that, in the case of steel containing from 0.04 to 0.12 per cent carbon, very slight straining followed by annealing at 1200° F for 7 hours produces no grain growth, but that moderate straining (approximately 15 per cent), such as might be effected by a single light draft, and annealing cause the grains to grow to very large size resulting in "orange peel" surface if the wire is deformed; over-straining, or severe distortion, and annealing at the same temperature and for the same length of time produce grains of small size, comparable with the structures shown in Figures 40—23 and 40—24. The condition of strain producing large grains is seldom met with in process annealing of wire, because the grains of such wires are usually distorted far beyond that point. However, when a consumer expects to anneal wire, this fact should be made known to the manufacturer; it will then be possible, except in a few cases, to supply wire that will not form large grains under any annealing conditions. In the case of pure or almost pure iron, and steel containing more than 0.12 or 0.15 per cent carbon, the amount of strain, according to Sauveur, has no effect in producing large grains on an-

Fig. 40—31. Curves showing approximate effect of carbon content and heat treatment on tensile strength of steel wire.

nealing, but others have shown that the same tendency persists in 0.20 to 0.30 per cent carbon steel.

Time and Temperature for Annealing—From what has already been said, and the evidence supplied by Figure 40—30, it is evident that, for the best results in annealing, careful regulation and adjustment of the time and temperature are necessary. In all types of annealing, sufficient time must be allowed for the whole charge to reach the required temperature, and in low-temperature annealing additional time is required for the development of the structure desired. Process annealing requires careful adjustment of time and temperature in order to avoid the formation of large grains, and, at the same time, eliminate the effects of the cold working, because at a low temperature the atoms or molecules move at a slower rate, and more time is required for their adjustment than at higher temperatures. As to temperature, the fact that full control and careful regulation of this factor in all annealing is necessary to satisfactory results cannot be too highly emphasized. If the temperature is too low, it may fail entirely to accomplish the results desired in process annealing. In some cases adjustment of the temperature to the size of the wire is also necessary. Fine wire in coils, for example, is generally annealed at as low a temperature as practicable, in order to avoid the sticking of the wire in the coils. After these remarks it is scarcely necessary to say that accurate and carefully standardized pyrometers form an essential part of any equipment for the proper annealing of wire.

The tensile strength (at various carbon levels) of wire full-annealed or recrystallized by annealing above the upper critical point, followed by slow cooling, is shown in Figure 40—31, as well as that of wire subjected to annealing in a molten lead bath (one form of a "sub-critical anneal" involving a short time cycle of heating and cooling). It should be noted that it is possible for sub-critical annealing to produce approximately the same tensile strength values obtained by full annealing, providing the long time cycle of heating and cooling used in the former treatment is observed. A comparison of the effects of full annealing on recrystallization and grain size with short time sub-critical annealing of hard-drawn wire is indicated by the photomicrographs of Figures 40—26 and 40—27. These differences in structure are reflected in the lower tensile properties of full-annealed wire shown in Figure 40—31.

METHODS OF ANNEALING WIRE

While it is possible, theoretically at least, to anneal wire in any apparatus in which the proper conditions of time and temperature can be maintained, the efficient handling of the material calls for, and some of the finishes and conditions to be met demand, equipment specially designed for the purpose in mind. These conditions, in general, call for differences in the time of annealing, and differences in the methods of applying the heat, and usually require that the material be protected against oxidation. To meet these conditions, four different methods requiring entirely different apparatus and equipment are used. These are known as **muffle annealing, pot annealing, continuous lead annealing and tube annealing.**

Muffle Annealing represents the crudest form of annealing used in the wire industry and must not be confused with heat treatments carried out in modern muffle furnaces of the type described in Chapter 21. The common muffle furnace consists of a brick-lined chamber about 12 feet long, 8 to 12 feet wide and 2 to 2½ feet high. At the back of the chamber and separated from the muffle proper by a baffle wall is a grate for

burning the fuel which heats the furnace. At the opposite end of the muffle chamber is a hanging door spanning the width of the furnace, through which, when open, the wire is charged and discharged. The bottom of the chamber is provided with a grating of iron rails or castings known as "muffle ladders," the object of which is to form a support for the wire so that the furnace gases will be free to circulate beneath it. The wire is seriously oxidized on its surface by being in contact with the open flame, which passes over the fire wall into the muffle proper and then out of the flues to the stack. For this reason, muffle annealing is generally employed only to meet unusual conditions.

Salt-Bath Annealing—Molten salt-bath annealing is sometimes practiced for process annealing of common sizes of wire. The wire, in coils, is immersed for one-half hour to one hour in gas-fired pots containing molten salt which is held at some predetermined temperature between 1000° and 1300° F, depending on steel composition and structure or physical properties desired. Advantages over other methods are that small amounts of wire may be quickly annealed at closely controlled temperatures without scaling the surface on the wire. Such annealing is somewhat limited as to its application in wire processing.

Pot Annealing—This method of annealing is identical in principle with that known as box annealing, the material being placed in a sealed container, or pot, and thus protected from the air and furnace gases during the entire process of annealing. The method is largely used for annealing steel process wire, but a considerable amount of copper wire is also pot annealed.

Equipment for Pot Annealing—The older pot-annealing equipment consists of pit furnaces, annealing pots and power cranes. The pit furnace is constructed of fire-brick and is direct fired with coal burned on a grate at the bottom of the pit below the pots, and the flame is circulated up and around the pots. The pots are cylindrical and are made of cast iron or cast steel. The wire coils are loaded within the pots, covers are sealed thereon, and the pots are lowered into place in the pit furnace, which is then closed with a fire-brick cover. As the coal-fired furnaces were not always adapted to provide uniformity of temperature throughout the pot, they have been largely superseded by the bell type of annealing furnace, either electrically heated or gas fired. In the bell type of furnace, the wire coils are placed one on top of the other on stems, forming a cylindrical stack or pile on a refractory-brick or cast alloy-iron base. A cylindrical cover or hood of thin sheet steel is placed over the stem of wire and a second cover or hood, somewhat larger in diameter, is then set in place. This outer cover may carry the heating equipment, either the electric resistance heating elements or radiant-tube gas-fired heaters; in some of the latter types, the gas-fired flame may circulate in the space between the inner and outer covers or hoods. Thermocouples are placed within the inner hood to indicate, record and control temperatures of the top and bottom of the stem of wire. To aid in attaining the desired temperature uniformity throughout the mass of wire, fans are placed in the base of the furnace to circulate the heated non-oxidizing or reducing gas atmosphere which is maintained within the inner cover throughout the heating and cooling cycle. The covers containing the heat sources are interchangeable and are moved from one base to another as required. This allows one charge which has been annealed to cool slowly under cover of the inner hood only, while the outer hood is placed over a new charge to begin its heating cycle.

Advantages of Pot Annealing—The chief advantages

of pot annealing are the following: The furnace gases do not contact the wire being treated and, if desired, air may be excluded from the inner covers to such an extent that a bright clean surface may be obtained on the annealed wire. Also, as compared with muffle annealing, pot annealing makes possible a greater uniformity of temperature throughout a load of wire coils and a more exact knowledge of the actual temperature attained by different parts of the load, providing thermocouples are used to best advantage. Another advantage is that when the wire is cooled in the pot, the rate of cooling may be comparatively slow, resulting in a softer product; this is especially advantageous in the annealing of the high-carbon steels. Most of the heavy work of handling coils in pot-annealing departments may be done with cranes. Also in pot annealing, there is little snarling of wire. With proper appliances, bright annealing is possible, and in general the loss due to scaling is comparatively slight in any pot-annealing apparatus, because there is little opportunity for scale formation. The lighter coating of scale also means that less acid is needed for cleaning. Furthermore, various finishes may be produced on steel in pot annealing, the results obtained depending largely on how the wire is prepared and how the pot is sealed and cooled. If the air is allowed to come in contact with the wire when it is at high temperature, oxidation will occur, of course. But by controlling the air admitted to the pots, and by retarding the cooling, it is feasible to obtain wire that is black, blue, or bright, while liquor-finished wire may be annealed "white" by entirely excluding air.

Continuous Lead Annealing consists merely in drawing the wire through a bath of molten lead heated to the proper temperature. The molten lead is contained in a shallow rectangular steel pan, some 10 to 15 inches deep, 3 to 4 feet wide, and 15 to 25 feet long, the exact dimensions depending upon conditions. (Sometimes two pans are used, the first known as the cold pan and the second as the hot pan, and the wire is drawn through each in succession.) The pan is heated from below usually by gases from an oil or gas fire and is supported by a brick setting adapted to the method of heating. In practice several strands of wire are drawn through the bath in parallel. For this purpose the coils of wire to be annealed are placed on free-running reels before the annealing furnace, and the wire from each coil is drawn through the bath by a take-up block placed at a convenient distance from the other end. For keeping the wires immersed in the molten lead, devices of various forms, known as sinkers, are used. To obtain bright annealing by this process, it is necessary to cool the wires without their being in contact with the air. Consequently, when such a finish is desired, the wires from the hot lead bath are conducted directly into long tubes which are kept as nearly sealed as possible.

The Advantages of Lead Annealing are obvious. In addition to protecting the material from the air, the bath of molten metal is readily maintained at a uniform temperature throughout its mass, and its temperature can be accurately ascertained at any time by a pyrometer. Also, since the process is continuous, it eliminates much handling of the material.

The Principal Use of Lead Annealing is in connection with galvanizing plants, where it is employed to anneal process wire. In these plants, layouts are provided that permit the wire to be annealed, cooled, cleaned, washed and dried, or dried and galvanized or tinned, all in one continuous operation. In continuous annealing and cleaning, when the wire is not to be galvanized or tinned, the wire, after passing through the lead bath, is conducted through crushed coal or sand banked at the end

of the lead pan; this bank of coal or sand is known as a header. The wire then passes successively through a water bath, a weak acid bath, a cold water bath, and a hot water bath, thence to the take-up blocks, which are located several yards beyond the hot water bath to permit the wire to dry. This elimination of the customary process of dip-cleaning with cranes is very desirable in the case of process wire.

PATENTING

Patenting is a heat treatment applied to rods and wire having a carbon content of 0.25 per cent and higher, the term being peculiar to the wire industry. The object of patenting is to obtain a structure which combines high tensile strength with high ductility and thus impart to the wire the ability to withstand hard drafting to produce the desired finished sizes possessing a combination of high tensile strength and good toughness.

Methods of Patenting—Patenting is always conducted as a continuous process and consists in first heating the material to a point well above the upper critical temperature, then cooling through the critical temperature at a comparatively rapid rate to a predetermined temperature level at which the transformation will yield the desired microstructure and mechanical properties. In practice, there are three ways of carrying out the treatment. Thus, the wire may be heated by passing it through alloy-steel tubes arranged in an open muffle or in an open flame without tubes and be cooled by pulling it from the furnace into the open air, which method is now referred to as "O.P." (old process or air) patenting. In a second method, the wire may be heated as in the first method, then cooled by passing it into a lead bath held at a relatively low temperature; this process is known as the **metallic hardening process**. The wire, in the third process, can be heated in a bath of very hot lead and cooled in another bath of lead at a lower temperature, as in the **double lead process**. In this last process the temperatures of both baths can be readily controlled and accurately measured. These features make it possible to obtain any desired structure even in wires of highest carbon content, a condition not easily attainable in "O.P." patenting. The third method is also more advantageous in that less scale is formed than in the other two methods. In the wire industry, both the metallic-hardening process and the double-lead process are generally referred to as "lead patenting."

Properties of Patented Wires—The structure obtained by patenting is extremely tough and possesses the best characteristics for drawing to high tensile strengths. As indicated in Figure 40-31, the tensile strengths of air- or lead-patented rods or wire are considerably higher than the same steels in the annealed condition. The lead patenting process is definitely required in the production of any exceedingly high strength and tough wire such as music wire. As an illustration, by properly patenting and drawing 0.75-carbon steel, a wire is produced having a tensile strength of 375,000 lb. per sq. in. or over. In spite of the great amount of drafting required to raise the tensile strength to this point, such wire will be tough enough to wrap around itself (i.e., can be wound around a pin of the same diameter as the wire) or can be hammered flat to one-half its original thickness without cracking.

HARDENING AND TEMPERING

In other branches of the steel industry, hardening and tempering are usually considered as separate operations, but in wire-making they are more often conducted in a single continuous operation. As in the case of tools and other products of steel, the object in hardening and

tempering wire is to control the hardness, or "temper," in order to adapt the material to the use for which it is intended. Hardening and tempering are applied to a great variety of wires, such as typewriter wire, umbrella wire, dress-stay wire, curtain spring wire, and wires for measuring tapes, clock and watch springs, automobile-engine valve springs, door-check springs, etc. Wires for such purposes are generally treated in wire form by a continuous process, but many kinds of springs, tools, and miscellaneous special products, are heat-treated after the wire has been formed into the article desired, when it is not always possible to use a continuous hardening and tempering process.

Methods of Hardening and Tempering Wire—For greatest efficiency in hardening and tempering, it is necessary to adapt the method of treatment to the nature of the material and the size and form of the article. Therefore, because of the great variety of steels and of articles produced by the wire industry, various methods of treatment involving the use of various kinds of apparatus and of various heating and cooling media, are employed. Thus, for hardening, the material may be heated in muffle, tube or electric furnaces, or in molten lead, and be quenched in water, oil, molten lead, or some other liquid. For tempering, the material may

be reheated in open furnaces, in baths of molten lead or hot oil, or by bringing it in contact with hot sand or with hot plates or discs of iron or steel. In continuous hardening and tempering, the heating for hardening may be accomplished in a manner similar to that for patenting, and the quenching may be accomplished by passing it quickly into a tank of water or oil; in the tempering operation, the material may then be drawn through a suitable bath, such as molten lead, the wire being in continuous motion throughout the process.

AUSTEMPERING

Austempering, described in Chapter 42 on "Heat Treatment," is a method adapted to the heat treatment of wire, and particularly formed parts. It is employed to develop the highest combination of strength and toughness in certain kinds of wire, particularly for fabrication into springs. In this process the transformation of austenite is effected at some preselected and constant subcritical temperature, which usually requires a longer time than does the regular continuous oil tempering operation; consequently this process is preferably used for batch or semi-continuous operation on high-carbon springs or small articles made of steel of $\frac{1}{4}$ -inch maximum thickness or diameter.

SECTION 9

PROTECTIVE METALLIC COATINGS

Kinds of Coatings—Probably more than one-third of all the steel wire drawn is given some kind of metallic coating, either for decorative or protective purposes. This phase of the industry has reached huge proportions and is of great importance. As already indicated, appreciably large quantities of the medium and larger sizes of wire are given a light coating or "liquor finish," varying in color from that of copper through the various shades of brass to the color of tin, for decorative purposes only, and practically all soft fine wires have to be given this coating for lubricating purposes. This coating, which may consist of copper or tin or a combination of the two, is very thin and has but little value as a protection against corrosion. As is well known, all of the common grades of steel will rust sooner or later when exposed to atmospheric conditions unless their surface is covered with some substance that will protect it from moisture and air. To afford such protection, it is the practice to galvanize wire, i.e., coat it with zinc, or to tin it, or to coat it with aluminum, or, for certain purposes, to give it a coating of paint, lacquer or japan. While it is also possible to coat steel wire with copper, lead, nickel, and the precious metals, these metals are seldom used for coating wire, except in a few particular cases, so they need not receive any further consideration here. The remainder of this section will, therefore, be devoted to galvanizing, tinning, and aluminum coating.

WIRE GALVANIZING

Advantages of Galvanizing—As a protective coating, zinc offers several advantages over other metals: (a) Zinc is electropositive to iron, which means that if the steel of a galvanized wire should be exposed to corrosive influences, owing to defective or damaged coating, the zinc will corrode first, and its presence will protect the iron from corrosion until after a considerable area has been exposed. Just the opposite reactions might occur with other metals, such as tin, which are electronegative to iron. The presence of tin alone under the

same conditions would hasten the corrosion of the iron, but, for specific purposes, tin is added in small amounts to zinc for galvanizing to improve adherence of the metallic coating, and the size and appearance of the spangle, without affecting corrosion resistance. (b) Zinc may be obtained in a comparatively pure state at a relatively low cost. (c) With zinc, it is easy to obtain a hard, smooth coating comparatively resistant to abrasion. (d) The color of the zinc coating is satisfactory for general purposes.

Methods of Galvanizing—There are two common methods in use for galvanizing wire, known as (1) the hot galvanizing process and (2) the electro-galvanizing process, but the second is the less widely used. In both processes, some 30 (more or less) parallel strands of wire pass first through certain preparatory processes, thence through the galvanizing bath to take-up frames on which each strand of wire is separately coiled, all these operations being made by attaching the tail end of each coil to the head end of the succeeding one. As the wires pass through the various baths required to clean and coat them, they are submerged by suitable forms of sinkers (either of the stationary or rotary type) or, in the case of electro-galvanizing, under contact fingers in the electrolytic or plating solution.

Processes Preliminary to Hot Galvanizing—In nearly all cases, wire to be galvanized must be annealed to remove the effects of cold working, and, in order to minimize handling of the wire, it is common practice to do this work in conjunction with the galvanizing operations by one of the continuous annealing processes. For this purpose a hot lead furnace will be built in front of the cleaning and galvanizing apparatus. Since the rate of cooling in process annealing has little effect upon the physical properties of the wire, the wires are cooled in air, or, if the space is limited, low-carbon wires will be cooled by conducting them from the annealing furnace into a vat of water. Following annealing, the next step is cleaning, for which purpose the wire is conducted into a bath of hot muriatic (hydro-

FIG. 40—32. Overall view of the apparatus employed in the continuous hot-dip galvanizing of steel wire.

chloric) acid at predetermined concentration. This acid is used instead of sulphuric, which is the acid commonly employed for cleaning in the galvanizing of sheets and tubes, because it acts much more quickly than sulphuric, and is much more effective in removing traces of lime remaining from the drawing operations. The iron chloride formed by the action of the acid, as well as any particles of loosely adhering scale, must next be removed and these objectives are accomplished by passing the wire through a bath of hot water.

While the wire is now perfectly clean, it must also be perfectly dry before it is brought into contact with the molten zinc, but in drying, any exposure to the air, which in practice it is impossible to avoid, results in the formation of a light coat of oxide, or rust. This difficulty is overcome by the use of a flux. In galvanizing sheets, tubes, and various wire products, this flux consists of fused ammonium chloride, commonly known as sal ammoniac, which lies upon the surface of the zinc bath, but for the continuous galvanizing of wire, better results are obtained by passing the cleaned and thoroughly washed wires directly through a hot solution of zinc chloride or zinc ammonium chloride flux at predetermined concentration or Baumé; and then through or over a dryer into the molten zinc. The wire thus becomes coated with a thin film of zinc chloride, which tends to protect it from oxidation during drying and also removes any traces of rust that may be formed.

Apparatus for Hot Galvanizing—From the dryer, the wires are drawn at once into the molten zinc, or spelter, as it is commonly called. This molten metal is contained in a spelter pan, which is usually made of boiler plate and is supported by a brick setting of suitable construction for firing with the most satisfactory fuel available. Figure 40—32 shows the general form of the pan and the furnace commonly used. The dimensions of these pans are subject to much variation, and depend upon several conditions. Thus, the width will vary according to the number of strands it is desired to galvanize at once, which is usually about 30. The length

is dependent upon the size of the wires, the speed of travel, and the thickness of the coating desired. Pans designed for galvanizing coarse sizes of wire may reach a length of thirty feet. The depth of the pan must be sufficient to prevent the wires from coming into contact with the dross which settles and collects upon the bottom. This dross is an alloy of iron and zinc containing from 3 to 7 per cent iron, which is solid at the temperature of molten spelter, forms a pastelike mixture, and is very harmful to the coating. As molten zinc oxidizes rapidly, the pan is provided with some form of covering medium which rests upon the molten spelter and protects it from the air, except at the ends where the wires enter and leave the bath. Here, the surface of the metal must be kept free from oxide by frequent skimming. The mixture of zinc and zinc oxide thus obtained is known as zinc skimmings; these skimmings, together with the dross, represent a considerable loss, for the proportion of these waste products to the total zinc used is relatively large, and, although both are refined, the cost of recovering the zinc they contain is relatively high.

Wiping the Wire—As the wires emerge from the galvanizing pan, some of the zinc they carry remains in the molten state for a brief period, and, unless prevented from doing so, tends to flow downward on the surface of each wire, making the coating rough and uneven. Such a coating makes the wire hard to handle, and renders it unsuitable for many purposes, especially when it is to be fabricated by machinery. Further, such a coating represents an actual waste of zinc, for the durability of an unevenly applied coating is determined by the thinnest part of the coating, not by the thickest parts. It is plain, therefore, that the removal of this excess zinc is a matter not only of economy, but of expediency as well. It is also evident that in order to form a smooth, evenly distributed coating, the surplus zinc must be removed while it is still in a fluid state. This is accomplished by passing the wire, just after it emerges from the zinc bath, through either one of two

devices known as **wipes and headers**. In the case of wipes, the parts in contact with the wire are made of asbestos, and the type most commonly used is known as the **split wipe**. It consists essentially of two balls, or molds, of asbestos fibers held together by some suitable binding material, or stranded asbestos rope of suitable diameter formed into wiping pads. In service, these two balls are pressed lightly against and about the wire, and are held securely in place by cup-shaped holders. The aim in the split wipe is to make it possible for the operators to separate the two halves in order to permit the splices joining two coils of wire to pass, as otherwise the wipe is torn out entirely or badly damaged. Headers are employed for wiping only when extra heavy coatings are desired. A header consists of crushed charcoal of definite mesh, blended with a certain wax, beef tallow or certain oils and arranged so that the wires shall pass upward through it. In any of these cases the wipe thus artificially provided acts as such only for a short time, for a hollow cone of solidified spelter soon forms about the wire, either within or in front of the wipe, and this cone of zinc then becomes the real wipe.

Cooling the Coated Wire—After passing the wipes, the coating of the wire is completed, but the manner in which it is cooled should also be given some consideration. If the wire is allowed to cool naturally in the air, the coating, because of the formation of a thin film of zinc oxide on the surface, will be dull and lusterless in appearance, known as air-cooled galvanized wire, but if the coating is cooled suddenly, as by immersing the wire in cold water as soon as possible after leaving the wipes, it will have a bright lustrous surface. However, since the real value of the coating as a protection against corrosion depends upon the thickness of the coat and the completeness with which it excludes moisture from the iron, it is clear that the luster, which is a characteristic of suddenly cooled coatings, is no indication of the quality of the coating, and since this luster can be preserved only for a short time in any natural atmosphere, its attractive appearance is of little value.

Coiling the Wire—The wire, which is delivered to the galvanizing department in coils, is drawn through the annealing, cleaning and galvanizing apparatus by blocks, which form it into coiled bundles again (Figure 40—32). The blocks commonly used for this purpose are of the so-called continuous type, and are similar to a wire-drawing block except that their spindles are mounted in a horizontal position. With these blocks, bundles of wire may be removed at any time without stopping the blocks, so that the speed of travel of the wire through the annealing and galvanizing baths may be uniformly maintained.

Some Features of the Operations for Hot Galvanizing—To the novice the galvanizing of wire may appear to be a simple process. The wires being drawn through the various pieces of equipment and recoiled on the blocks apparently require little attention from the operator. As a matter of fact, however, the process demands considerable experience and skill in order to obtain uniformly good results. For example, the firing of such long shallow pans requires not only a properly designed furnace, but constant care and observation on the part of the operator to keep the temperature of the spelter uniform and constant and to avoid injury to the pan. Similar statements apply also to the annealing and cleaning equipment. Some of the factors that determine the quality of the zinc coat are as follows:

The Quality of the Zinc Coat, by which is meant its effectiveness in protecting the wire from corrosion and its adaptability to the intended use of the wire, de-

pends upon the completeness with which the zinc covers the iron, the thickness, uniformity, physical properties, structure, and chemical composition of the coat. The completeness with which the iron is covered by the zinc depends upon the thoroughness of cleaning and fluxing and also upon the aftertreatment of the wire. Attention has already been called to the effects of the manner of cooling the wire as it is leaving the spelter bath. It should also be noted that the coating may be injured in fabricating the wire. If the cooled wire is bent at sharp angles or otherwise severely deformed, the coating is likely to be cracked or peeled off, especially if the coating is a heavy one. As to the thickness of the coat and the uniformity with which the spelter is distributed over any given wire and adherence of the zinc coating, these features depend upon the type of steel used, thoroughness of cleaning, the methods of wiping, the temperature of the molten spelter, and the time of immersion of the wire in the spelter bath. Up to certain limits, the thickness of the spelter coat increases as the temperature of the bath increases and as the time of immersion is prolonged. The time of immersion is controlled by the length of the spelter pan and the speed of travel of the wire through the bath. In this connection it should be pointed out that the thickest coat is not always the best, for, as the thickness of the coat increases, its brittleness and its tendency to peel or crack also increase. Some of the brittleness is to be attributed to the fact that zinc itself is a comparatively brittle metal. This brittleness might be lessened somewhat by alloying with other metals, but as these might decrease the resistance of the zinc to corrosion or otherwise affect it adversely, it is the practice to keep the spelter as pure as possible. The composition of the spelter is checked repeatedly by chemical analysis, and close limits are fixed for all the impurities it may contain. Another reason why the brittleness increases with the thickness of the coat is the fact that the conditions necessary to produce a heavy coat are also likely to affect the structure of the coat itself, for the coat obtained by hot galvanizing is not wholly composed of pure zinc.

The Structure of the Zinc Coat—The structure of the zinc coating as obtained on hot-dipped galvanized wire is shown in the photomicrograph of Figure 40—33. It will be seen that the spelter coating is made up of three different layers. The lower portion of the photomicrograph represents a section of the steel base, and the zinc layer represents the outer layer of spelter, which may be considered pure zinc. The alloy layer is made up of two different alloys of iron and zinc, the one next the steel base containing slightly more iron in solution than the other. Formerly it was thought that when iron is brought in contact with molten spelter, two compounds, having the formulas FeZn_2 and FeZn , are always formed. More recent studies indicate that the constitution of these coating layers is not precisely represented by these formulas. Assuming for the present that the formulas are substantially correct, however, the alloy next to the steel base consists of the compound FeZn_2 , while the remainder of the alloy layer is composed of the compound FeZn . The dark lines separating different areas in the photomicrographs are not cracks, but the result of grain boundary effect in etching, similar to that observed in developing the structure of pure metals.

Electro galvanizing—Electro galvanizing is the name applied to the process of covering any metal with a coating of zinc by means of an electric current. It is sometimes termed "cold" or "wet" galvanizing to distinguish it from the more common method of hot

FIG. 40-33. Structure of the zinc coating on a steel wire galvanized by immersion in molten zinc. Magnification: 250X.

galvanizing. For galvanizing flat wire and also strip steel, this cold process has certain advantages over hot galvanizing. For example, in hot galvanizing such materials, the edges, especially of strip steel, tend to destroy wipers, and special care is required to secure a smooth uniform coating, whereas the thickness of the zinc coating may be readily controlled in electrogalvanizing. The thickness of an electrodeposited coating depends primarily on two factors, namely, current density and time. By current density is meant the number of amperes flowing per unit of surface of the metal exposed in the electrolyte. The coating, when well applied, adheres firmly to the metal and will stand severe bending without flaking off. But many features of the process require special attention, because the quality of the coat depends upon the condition of the electrolyte, the cleanliness of the surface, and on general working conditions.

The Equipment for Electrogalvanizing consists of a long shallow horizontal vat, known as the plating vat, which is usually made of steel lined with rubber or a synthetic mixture. Attached to one outer side of this vat are the positive bus bars, or feeders, connected to the plating generator, while on the other side are similar negative feeders. As considerable time is required for suitable electroplating, the vats are usually from 100 to 200 feet long in order that the speed of the wires or strips through the vats can be maintained at a reasonable rate for production and still remain submerged in the electrolyte long enough to receive the desired coating. Since the working voltage is low and the amperage high, the conductors consist of heavy copper bars. In addition, there are needed a low-voltage direct-current supply source, and means for making and storing fresh electrolyte.

Operation of the Process—The vat is nearly filled with the plating liquid, called the electrolyte, consisting of a solution of some zinc salt, such as zinc sulphate. This solution must be continually agitated to maintain a uniform density, and it must also be kept clean and at a fairly constant and suitable temperature. For anodes, slabs of zinc are submerged at selected locations in the electrolyte and are electrically attached to the positive bus bars. Alternating with the anodes are strong copper contact bars which are placed across the vat, immersed a few inches below the surface of the electrolyte, and con-

nected with the negative bus bars outside the vat. These contact bars support the wires being plated, which collectively form the cathode. The wires to be electrogalvanized are generally annealed, thoroughly cleaned in acid, then rinsed before they pass through the plating vat. From the vat the wires pass through or over some simple form of wipe and onto take-up blocks placed far enough away from the wipe to permit the wires to dry in air.

Factors in Controlling the Thickness of the Coat—Theoretically, about 2.5 pounds of zinc can be deposited per hour per 1000 amperes of current. In practice, the amount of zinc deposited will be somewhat less, as no electrochemical operation can be carried on at 100 per cent efficiency. The practical maximum current density varies and must be determined experimentally for each set of working conditions. Having determined this and also the efficiency to be expected, it will be possible to calculate the required total current needed to deposit a required amount of zinc in a given time. The current flowing from the zinc anodes through the electrolyte into the cathode wires causes the zinc to dissolve into the solution at the same rate that the zinc is deposited on the wires, so that the solution, if it is continually and correctly agitated, will remain at a uniform density, and only pure zinc will be deposited, although the slabs used usually contain some impurities. As the zinc ions traveling through the electrolyte actually carry the current, the amount deposited will be directly proportional to the current strength and to the time of current flow. Since the former factor is fixed, the latter must be increased as the required weight of coating becomes greater.

Tests for Galvanized Coatings—The whole galvanizing process is placed in the hands of experienced operators, who keep constant watch over each phase of the process and at frequent intervals make certain tests to determine the fitness of the material for the purpose for which it is to be used. With respect to the galvanized coatings, these tests are both physical and chemical. The more common of the physical tests are known as the button test and the mandrel test, each being applied to different classes of wire to meet different requirements. In the button test, the wire is wound tightly about its own diameter, while in the mandrel test the wire is similarly wound about a smooth mandrel having a diameter that

is some multiple of its own diameter. The object in both these tests is to determine if the coating will crack or flake under these conditions and, if so, to what extent. For determining the thickness of the coat and whether or not the zinc has been uniformly distributed, two chemical tests are employed. One of these, called the **antimony hydrochloride test**, is a laboratory test used chiefly for determining the exact quantity of zinc per unit of surface galvanized. The other, known as the **Preece or copper sulphate test**, though only qualitative, is the best known and most generally used chemical test for galvanized coatings. This test, when made under properly standardized conditions, will determine whether or not the coating is uniform in thickness and whether the thinnest portion will dissolve in a certain solution of copper sulphate in one, two, three, four or more minutes. The terms "one minute wire," "two minute wire," etc., are based on this test, and mean that the coating will successfully withstand immersion in a standard neutral copper sulphate solution for one, two, or more minutes.

Methods of Carrying Out the Copper Sulphate Test—The standard solution used in the test is prepared by dissolving approximately 36 parts of crystallized commercial copper sulphate in 100 parts of distilled water, adding an excess of pure cupric oxide (CuO), and filtering. The concentration of the solution is then adjusted, by adding water or a stronger solution, so that its specific gravity is exactly 1.186 at 65°F . The samples to be tested are thoroughly cleaned before making the test by dipping in benzene or gasoline, or rinsing in water, and wiping with clean white cotton waste or cloth. A clean test jar, 5 inches high and 2 inches in diameter, is then filled to within one inch of the top with the standard solution at a temperature between 62°F and 68°F , which temperature must be maintained throughout the test. The sample is now immersed in the solution by lowering it endwise into the jar, where it is allowed to remain for exactly one minute; it is then removed, rinsed immediately in water of the same temperature, and wiped until dry with the clean cotton waste or cloth, so as to remove the dark deposit of copper which forms on the surface. These operations are then repeated, the wire being immersed for exactly one minute at each trial, until traces of bright metallic copper begin to appear on the surface of the steel, indicating removal of the zinc, or until the number of one-minute immersions exceeds the number required by the specifications. In case more than one wire is tested at the same time, the samples, numbering not more than seven, are immersed simultaneously in the same jar, and these must be kept well separated. The lower inch of each sample, being adjacent to the cut exposing the iron, is disregarded in the test. A fresh portion of the standard solution must be used after each complete test of seven wires or less.

Principles of the Test—The principles upon which the copper sulphate test depend may be explained as follows: The copper sulphate dissolves both zinc and iron, these two elements displacing the copper in the solution of copper sulphate according to the following reactions:

From these reactions it will be seen that copper is precipitated, or thrown out of solution, in each case. Since the reaction can take place only where the wire is in contact with the solution, this liberated copper is deposited upon the surface of the wire, and the test depends wholly upon the difference in the manner in which this deposit is made upon zinc and upon iron. In the case of zinc, the deposited copper is in a finely

divided form, and appears as a black flocculent coating completely covering the wire. As this coating increases in thickness, it tends to shield the wire from the solution, thus retarding the reaction, hence the necessity for removing the wire from the test jar and cleaning its surface at regular intervals of one minute. In the case of iron, however, the copper, if all the conditions of the test are properly observed, is deposited upon the surface in the form of a bright metallic coating which cannot be wiped off and is similar in appearance to that obtained in electroplating. Thus, as soon as the zinc has been removed from any part of the surface of the wire, this bright coating appears on that spot.

Value of the Copper Sulphate Test—The chief merit of the copper sulphate test is that it reveals any unevenness in the thickness of the coat. Although the test is not directly quantitative, it provides a relative measure of the amount of zinc at the thinnest point of the coating, provided the surface condition, composition and structure of the coatings being compared are the same. This information is important, for the corrosion resistance of the coat depends not only upon the weight of the zinc on a given surface but also upon the evenness with which it is distributed. In service, corrosion of the steel begins where the zinc coating first disappears, so that for a given total weight of zinc applied, the best protection to the steel is offered by the most uniform distribution of zinc. The test can be quickly made with simple apparatus, and the effect is very apparent, but each phase of the test must be carefully performed under standard conditions to obtain fair comparative results. The latter fact is not generally recognized, the impression being that almost anyone can make the test without instruction as to the points to be observed. In this connection it should be noted that the copper will plate out upon an alloy of zinc and iron as well as upon pure iron or steel, but the coat of copper on the former does not adhere firmly to the surface and may be brushed off with a fine steel brush.

WIRE TINNING

Because of the high cost of tin, and of the difficulty of entirely avoiding pin holes in tinning steel wire, only a small amount of steel wire is tinned, and that largely for decorative purposes. As already explained, tin is cathodic to iron. Consequently, in the case of steel wire coated with tin and exposed to the atmosphere, the destruction of the steel base will be accelerated by the presence of tin when corrosion begins. The tinning process is very similar in principle to the hot galvanizing process and need not be described at length. The wire has to be thoroughly cleaned and fluxed before entering the bath of tin, and as it emerges from this bath it passes through a wipe of wicking wound about the wire, after which it goes to the take-up blocks, either with or without an intermediate water cooling. The tin must be maintained at a fairly constant temperature (500° to 550°F), for if the bath temperature is too low, the coating will be rough and uneven, and if too high, it will be discolored by the yellowish tin oxide formed on the surface.

ALUMINUM COATINGS

In recent years aluminum coatings have been applied to steel products for resistance to corrosion in marine, industrial and the usual environments. The aluminum is applied to steel wires by the hot-dip process, where the cold-drawn wires are cleaned prior to immersion into a molten aluminum bath. Aluminum forms alloys with steel in a manner similar to zinc, and the process must be carefully controlled; otherwise, a brittle alloy layer

will form which will cause cracking and spalling during subsequent forming operations.

The aluminum bath is operated at a temperature of approximately 1225 to 1250° F. This temperature is sufficient to soften carbon steels with a corresponding loss in tensile strength. Aluminum-coated wire can be cold drawn after coating to improve or raise the tensile

strength. Also, by drawing after coating, very bright finishes can be produced which make the wire suitable for many decorative applications.

Wire which can be coated with aluminum for corrosion protection includes: field fence, barbed wire, broom wire, netting wire, paper-clip wire, spiral-binding wire, tie wire and welding wire.

SECTION 10

TYPICAL FINISHED WIRES FOR MANUFACTURING PURPOSES

The object of this section is to list according to their common trade names the different kinds and grades of wire used for manufacturing purposes and indicate the uses of each.

COMMON WIRES

Bright Bessemer Wire—Wire of this grade is hard or stiff wire, ordinarily drawn from a rod to finished size without an intermediate annealing. It is not well suited for purposes involving special finishes or specific mechanical properties.

Bright Basic Wire or Bright Hard Basic Wire—Wire of this classification receives the same treatment as Bright Bessemer, is slightly softer wire than Bright Bessemer Wire, has a finish obtained by regular dry drawing and is used in applications not requiring specific physical properties.

Bright Soft Basic Wire is a soft grade of bright wire for manufacturing purposes, and is adapted to difficult forming, severe twisting, swaging, crimping, etc. Wire of this classification is also suitable for severe upsetting.

Medium Classifications—Medium hard and medium soft Bessemer and basic wires are finer gradations between the "bright" and "bright soft" grades. They are common only to the finer sizes, 8¼ gage (0.152-inch) and finer, and their use depends upon the severity of the bending and forming operations which are to be performed.

Annealed Wires—Annealed wire is the softest grade that can be produced. Because of differences in chemical composition (assuming the carbon content is the same), annealed basic wire is softer than annealed Bessemer wire of the same size. In producing annealed wire, the coarser sizes must be given a special draft before annealing, otherwise brittle wire known as "crystallized wire" will be obtained after the annealing. The finer sizes are drawn the same as the bright (hard) grade and then annealed. "Annealed," or "annealed, cleaned and limed basic" Cold-Heading Quality wire is used largely for extremely severe upsetting, such as special bolts, certain kinds of rivets and for any purpose in which the wire is severely deformed by pressing or heading operations. If maximum softness is essential, the use of annealed basic wire is indicated.

Cold-Heading Wire—Wire for cold heading or cold forging has become one of the large production items in the wire industry. Wire of this grade is used for bolts, rivets, screws, and similar applications requiring, in many instances, severe plastic deformation. For common fabrication, low-carbon steel may be used, but with the advent of highly stressed parts as in automobile and aviation applications, higher carbon, low-alloy and stainless steels are now required. As upsetting the head on the bolt or screw will readily accentuate surface defects of the wire such as seams or slivers, bolt wire must necessarily be a high quality product with great uniformity of structure and composition. Production of higher carbon and alloy wire for heat-treated bolts requires close control at all stages: melting

the steel, rolling the rod, heat treating and drawing the wire. In addition to the above prerequisites, the surface coating of the wire, which is controlled primarily by the wire-drawing lubricant, is important as a factor in the cold-heading operation. The type of upsetting die and whether or not the bolt shank is extruded in the operation determine the type of wire coating required; the coating, in turn, has a significant bearing on the life of the heading die and the quality of the finished bolt. The finished hardness and chemical composition of bolt wire both are definitely controlled according to the severity of the deformation required in forming the bolt. As the hardness increases with increasing carbon and/or alloy content of the steel, the final hardness will be regulated by normalizing, process annealing, or spheroidizing the steel. Machinability requirements and the ability of the wire to respond to heat treatment may also be factors influencing selection of the manufacturing processes to produce wire having the proper microstructure and hardness, particularly in steels over 0.35 carbon. The finished product is rigidly inspected, and includes adequate mechanical, chemical and metallographic testing.

Liquor-Finished Fine and Weaving Wire—Some of this grade of wire, which may be used for weaving household window-screen cloth, is made in very fine sizes, 0.0118 inches and 0.0104 inches being the common sizes. Wire for this purpose is usually made from low-carbon basic steel and to reduce the wire from a ¾-inch rod (0.218-inch) to such fine sizes may require two annealings in process and 22 to 24 drafts, depending on composition and requirements.

Welding Wire—Various steels, both carbon and alloy, are used to produce welding wire for the manufacture of electrodes and rods for electric and gas welding, and these range from 0.05 carbon to about 1.0 per cent carbon. While considerable gas welding is still employed, by far the greater proportion of welding operations are performed by the electric-arc process. Wire for gas welding is copper coated and used in straight lengths, composition being governed by properties required in the weld metal.

Electric-arc welding is divided into two classifications: manual welding and automatic welding.

Wire for manual welding is furnished in straightened and cut lengths with surface as free from wire-drawing lubricant as possible to enable electrode manufacturers to apply a flux coating by an extrusion method. Welding steels are made especially for this application, and selection of heats or portions of heats is mandatory to conform to required composition limits and ranges. Low sulphur, not exceeding 0.035 per cent, is generally preferred. Most of the grades of steel made for welding electrodes are of the rimming type, with carbon in the neighborhood of 0.10 to 0.15 per cent. However, there is also some demand for rimming-type steel with 0.31 per cent carbon as the maximum of the range. Killed steels of 0.55 to 0.65 per cent carbon and 0.90 to 1.10 per cent carbon are also used to some extent, along with some alloy grades for special purposes such as resistance to abrasion. Composition of

Bessemer wire.	Nails, flat-head wood screws, tie wires, stove rods, brace rods, low-grade furniture springs, etc.
Bright soft	
Bessemer wire.	Pail bails, double-pointed tacks, jack chains, trace chains, weldless chain, heavy window screens, shelf brackets, staples, market wires, etc.
Bright basic wire	Round-head wood screws, bolts and rivets, large head nails, caster pins, stove bolts, link fabric, cork-screws, electric-welded chain, chaplets, etc.
Bright soft basic steel	Weldless chain, buckle tongues, buckles, electric welding, fine rivets, special screws, link fabric, etc.
Coppered or liquor-finish Bessemer wire.	Common grade furniture springs, tire wires, button hooks, chairs, chair rods, curtain rods, carpet beaters, etc.
Coppered or liquor-finish basic wire.	Pail bails, link fabric, reeds, transom rods, cork-screws, damper rods for pianos, piano pedal rods, etc.
Coppered or liquor-finish soft Bessemer wire	Pail bails, bird cages, buckles, button eyes, spring seat supports, jack chains, piano actions, chairs, coat and hat hooks, garment hangers, hog rings, rapid tag fasteners, rat traps, and similar purposes.
Tinned	
Bessemer wire...	Link fabric, lantern handles, etc.
Tinned soft	
Bessemer wire...	Pail bails, lanterns, bird cages, buckles, card racks, egg beaters, etc.
Tinned basic wire.	Link fabric, bird cages, buckles, lanterns, skewers, cork-screws, etc.
Tinned soft basic wire	Link fabric, buckles, and similar articles.
Annealed wires ...	Bundling, bail ties, rims for wash boilers, check rowers, etc.
Annealed and cleaned basic wire	Balls for bearings, bolts and rivets, toe calks, electric welding, drawer pulls (pressed), and other purposes requiring soft ductile wire.
Annealed and cleaned Bessemer wire	Pump chain, etc.
Galvanized wire ...	Fences, pail bails, rose stakes, clothes lines, bottle stoppers, eave trough hangers, staples, clothes pins, and other uses requiring corrosion resistance at minimum cost.

the steel is governed by composition of the flux coating, the combination being designed to provide certain welding characteristics and specific properties in the deposit metal.

The wire thus serves as the core of the coated electrode and is expected to provide good welding characteristics and a dense, sound deposit. Wire sizes in popular demand are $\frac{1}{8}$ -inch, $\frac{3}{32}$ -inch, $\frac{1}{16}$ -inch, and $\frac{1}{4}$ -inch. Tolerances for diameter, length, camber, and burrs in the straightened and cut wire are listed in the AISI Products Manual for Wire.

The flux coating on the electrode provides a blanket which surrounds the arc during welding and serves as a protection against oxidation from the atmosphere. In automatic electric-arc welding, there are two main processes: submerged-arc and inert-gas. In the former, the welding is shielded by a blanket of fusible material, usually referred to as flux which is fed on to the work. In the latter, shielding is obtained from inert gas such as argon or helium. Both automatic and semi-automatic equipment is used for each process.

Wire compositions vary for submerged-arc welding according to requirements in the deposit metal. The wire is produced with a bright copper finish to improve the contact surfaces and so facilitate the introduction of the relatively high currents used. It is important that the surface of the wire be as free as possible from wire-drawing lubricant which would tend to clog the nozzle through which the wire is fed. Wire for submerged-arc welding is furnished in layer-wound coils with cardboard cores. Dimensions of these coils are designed for insertion into a reel from which the wire is fed through the welding machine. Wire sizes in demand range from about $\frac{3}{32}$ -inch up to about $\frac{1}{16}$ -inch.

The inert-gas welding process calls for smaller wires ranging from 0.045-inch to around 0.125-inch. Wire for this application is furnished with a bright, clean copper coating for the same reason as mentioned above and is wound on spools of the dimensions necessary for insertion in the welding equipment. The required wire compositions vary according to requirements of consumers.

Scratch Brush Wire—This grade of brush wire is produced in sizes from 0.0045-inch to 0.0025-inch. Bessemer stock is used for the production of the wire, and annealings at three different process sizes are required in reducing it to the finish size. The wire is drawn dry to the second annealing, at which point it is bright annealed and drawn wet to the final annealing size; then it is bright annealed and drawn wet to the finish size. As in drawing liquor-finished weaving wire, all drawing from the rod to finish size is performed on continuous machines. This wire is used for jewelers' brushes and other fine wire brushes.

Market Wire—Market wire is a term applied to exact-weight bundles supplied to the jobbing trade. The quality, if not otherwise specified, is a soft basic or Bessemer grade. The standard weight of bundle is 100 pounds, but it is also put up in 63-pound bundles, when so specified.

Uses of Common Wire—The wires described in the preceding section are applied for many purposes, some of the more common are listed in Table 40—IV.

HIGH-CARBON OR SPECIAL WIRES

To select the proper grade of wire for any given purpose, it is necessary to know the mechanical properties required to meet the demands of that particular service. As a result of work correlating a large number of experiments in the wire mills with data collected from

actual experience, it is now possible to supply wire meeting various combinations of mechanical properties, including tensile strength, torsional strength, toughness, etc. These studies have led to the discovery of the principles governing the behavior of high-carbon stocks, and these principles determine the processes to which the wire must be subjected to obtain the desired results. Other elements of uncertainty have been removed by careful standardization, so far as possible, of the manufacturing practices for producing the various classifications and grades of high-carbon steel wires.

Rope Wire—The stock used for manufacturing high-carbon rope wire varies in carbon content from 0.20 to 0.90 per cent. The coarser the finish size and the higher the tensile strength required, the higher must be the carbon content of the stock from which the wire is produced. At least one and as many as three patentings are necessary to produce the various grades and sizes of rope wires. The finer the size and the higher the tensile strength of the finished wire, the greater the number of patentings in the process of manufacture in order to reduce the wire and obtain the proper mechanical properties at the finished size. The finer the size and the higher the carbon content of the wire, the lighter must be the reduction in cross-sectional area per draft. Practically every size and grade of rope wire must be produced from a different final patenting size in order to obtain the proper mechanical properties in the finished size.

Music Wire—Music wire is the term applied to wire having the physical requisites necessary for use in musical string instruments. Although commonly known as music wires, these wires are generally referred to as piano wire, harp wire and mandolin wire, depending upon the purpose for which it is used. In conjunction with the manufacture of music wire, there is a grade of wire manufactured known as music spring wire. This wire is not quite as high in quality as piano wire and is used for high-grade, cold-wound, high-tensile-strength springs.

Piano Wire—Piano wire has rightly been called the "specialty of specialties." It represents the highest attainment in the art of wire manufacture. The wire possesses the highest tensile strength of any form in which carbon steel is used for purely stress-resisting purposes. It is made from the finest quality of steel, having a carbon content of from 0.80 to 0.95 per cent. Different grades and sizes require varying drafting and heat-treating practices to develop the proper tensile strength and toughness.

In addition to the mechanical properties required, piano wire must possess acoustic properties. Attainment of this requirement is dependent upon the accuracy of the size, the soundness of the steel and the finish of the wire. Furthermore, the tension required for different pitches and lengths means that high elastic limit with uniform tensile strength is imperative for a given wire. The toughness must be developed to a maximum for the tensile strength to permit forming the wire into loops or eyes by the bass-string manufacturers. The bass strings must also be flattened locally on the ends to form an anchor for the covering wire. Tensile strengths for the highest grades of piano wire are given below, from which data it should be noted that the higher strengths are obtained in the finer sizes.

Kind of Wire	Diameter in Inches	Tensile Strength (Lb. Per Sq. In.)
Bass Strings	0.035 to 0.067	290,000 to 351,000
Treble Strings	0.029 to 0.049	319,000 to 390,000

Tinned and Liquor-Finish P.S.R. Tire Wire—Tinned P.S.R. (Plow-Steel Rope) Tire Wire is used in the manufacture of automobile tires, the initials P.S.R. indicating the grade of steel used. This product receives special care at every stage of its manufacture to be sure it will meet requirements, which are very exacting. It therefore receives a rigid inspection. It must be perfectly round and true to gage, and possess the proper tensile strength, torsion and elongation qualities. Practically all consumers require this wire to stand a torsion test of ten twists per inch under tension of a five pound weight, usually in a length of six to eight inches. Some demand only a minimum breaking weight while others specify both a maximum and a minimum. A wire having the high tensile strength demanded, that will withstand a minimum of 80 twists in 8 inches, must be free from all steel defects, such as pipe, seams, and segregation.

Spoke Wire—Satisfactory spoke wire to be used in the manufacture of automobile wire wheels must possess special mechanical properties. It is made from sound stock, free from all imperfections, so that a good finish can be obtained on the final product. The method of manufacturing spokes requires that the wire shall be capable of being swaged, headed and threaded. It is stiff enough to withstand the loads to which it is subjected and yet it possesses considerable toughness and ability to withstand the shocks and vibration that are imposed on it in service. The increase in strength obtained by heat treatment, plus that developed in the wire by drawing to the finished size, results in a tensile strength ranging from 140,000 to 160,000 pounds per square inch. It is furnished in sizes ranging from 0.0645 to 0.2045 inch, either in bright or liquor-finished grades. Bicycle-spoke wire (usually 0.0795 inch in diameter), also follows this general requirement, but is normally supplied with a drawn galvanized finish.

Baby carriage and similar types of wire wheels do not require the high tensile strength developed in the wire for automotive wheels. A bright or tinned low-carbon basic wire, drawn direct to finished size from the rod without any intermediate heat treatment, is furnished for this purpose. It has a tensile strength of 90,000 to 110,000 pounds per square inch and is usually supplied in sizes ranging from 0.0625 to 0.162 inch.

Valve Spring Wire—Formerly, automobile engine speeds averaged about 2200 r.p.m., but this speed has since been increased up to 3800 to 4200 r.p.m. Ordinarily, any good commercial oil-tempered wire with a carbon content of from 0.60 to 0.80 per cent would make a satisfactory valve spring capable of giving dependable service at 2400 r.p.m. At 3300 to 4200 r.p.m., however, there is a terrific increase in the fatigue stresses so that failures of ordinary wire frequently take place in less than 1000 miles of operation. But by careful selection of material at each stage in the manufacture of the wire, all the requirements of the high-speed valve spring have been met. Some of the precautions taken with this material are: (1) Use of basic steel of exceptional cleanliness. (2) Generous cropping from both top and bottom of the ingot. (3) Inspection and conditioning of billets. (4) Pyrometric control of rod temperatures. (5) Extra heat treatments from rod to finished wire. (6) Special heat treatment on finished wire. (7) Special tests, including sharp right angle bend tests in four directions. (8) Tensile tests to destruction from each end of every bundle. (9) Spring winding and extension tests for uniformity of temper. (10) Vibration tests of sample springs on motors.

Tempered Wire—Tempered wire is made in rounds, flats and rectangles. The most important feature of this class of material is its temper, which depends upon both

the composition and heat treatment. The tensile strength of this product may ordinarily be required to range from as low as 160,000 pounds per square inch to as high as 300,000 pounds per square inch. Occasionally, strengths in excess of 300,000 pounds per square inch are required. The tempering is accomplished by passing the wire through a continuous tempering furnace in which the wire passes successively through a heated muffle or heated tubes or a hot lead pan, an oil quenching bath and a cold lead pan.

The temperatures of the muffle, tubes and lead pans are controlled automatically by pyrometers which hold each of these at a very uniform temperature and consequently give uniform temper to the wire within very close limits.

Tinned armature-binding wire is another specialty wire. It is made in several grades, which differ in tensile strength. The specifications require a product having high elastic limit and high elongation combined with toughness. To obtain this combination, important essentials are: first, steel of the proper composition; second, proper heat treatment; third, a uniform drafting practice; fourth, a tinning temperature which will give a good finish and will aid in obtaining the desired physical properties in the finished wire.

Metal-Stitching Wire was developed for fastening non-stressed parts in automotive assembly operations and is now also used in the assembly of non-stressed aircraft structures as well as in a multitude of other types of assemblies. In this application, the wire is fed from a spool through a stitching machine which cuts the wire to length, forms it into a staple and drives the legs of the staple through the material to be fastened. In most cases, the legs are folded back or clinched after penetrating the two or more layers being assembled. This wire is frequently used to unite metal to metal or metal and non-metal parts, such as rubber, fiber, felt or plywood. The tensile strength of wire for these applications may range from 200,000 to 330,000 pounds per square inch, depending on the thickness and type of metal required to be penetrated by the fasteners. For this purpose, it is evident that the wire must be very uniform in temper and possess great toughness. Metal-stitching wire is made with several different finishes, according to whether a protective or decorative finish is desired.

Other Special Wires—Besides those already mentioned, there are numerous other grades of drawn high-carbon wires produced. In practically every case, the various grades differ from each other in one or more respects, such as stock, temper, quality of toughness, finish and coating. Practically all of the high-carbon wires are classified as "special wires." By special wires is meant wires made to uncommon specifications, either as to finish or mechanical properties. The range of stocks used for special wires may include basic open-hearth steel from the lowest carbon steel up to a steel having a content of 1.20 per cent carbon. There are at least twenty-five different carbon grades, and these are further increased by variations in manganese and other elements. Following selection and rolling of the stock, preliminary testing of the rods is usually necessary to prevent unnecessary work on stock which will not give the desired qualities in the finished wire. Extreme care must be used in the cleaning, coating, and every step of the manufacture. Special drafting, various heat treatments, both before and after the complex drawing processes, special testing and extraordinary precautions must be followed to secure the unusual properties and degree of uniformity that may be required.

STAINLESS-STEEL WIRE

Stainless-steel wire has become an established commodity for many purposes because of its utilitarian nature, its stainless and heat resisting characteristics, and its ability to withstand a variety of forming operations. Among the established products are cold-heading wires for the manufacture of bolts, rivet pins, and screws; tinned non-magnetic armature-binding wire for use in highly-powered motors for Diesel engines, and other motors which require a high-tensile non-magnetic wire; welding wires furnished for all methods of welding; spring wires to be used where resistance to chemical solutions and atmospheres is a necessity; weaving wires for a wide range of screens from very fine mesh flour sifters to coal and coke screens and continuous high-temperature conveyor belts; rope wires for specialized purposes such as mine sweeping, aircraft-control cables and strands for yachts and ships. The unusual properties of stainless steel which permit a lasting bright finish to be developed, combined with its utilitarian nature, give it great intrinsic value when used as display racks, dishwasher and refrigerator racks.

While Types 430, 410, 302, 304, and 305 may be considered the more popular grades, almost the entire list is drawn to wire for a great variety of uses.

The processing and drawing of these steels are similar, in general, to that of the carbon-steel wires. They will differ somewhat in individual practices because of the inherent nature of the alloys, such as resistance to some acids and activation by others, all of which combine to make the coating and lubricating problems in drawing stainless-steel wires one of meticulous control.

STAINLESS COLD-ROLLED STRIP STEEL

Stainless cold-rolled strip steel is manufactured from hot-rolled annealed and pickled strip by cold rolling in mills equipped with ground or ground and polished rolls, depending upon the surface finish requirements. Strip steel is normally supplied up to and including 23 $\frac{1}{16}$ -inches wide in a great many of the more common types of stainless steels.

A range of mechanical properties can be provided by taking advantage of the possibilities offered by combining the influences of chemical composition, cold work (cold rolling), and heat treatment. These are varied according to the mechanical properties desired. Physical properties developed in this manner are referred to as tempers and are associated with the capacity each temper level possesses in regard to resistance to cold deformation. In the straight chromium grade (400 series), only three tempers are generally recognized by the industry, viz., full hard (Rockwell C 20 minimum), No. 4 Temper (approximately Rockwell B 89-90), and No. 5 Temper (approximately Rockwell B 83 maximum). In the chromium-nickel steels (300 series), No. 4 Temper will show approximately 80-90 Rockwell B and No. 5 approximately Rockwell B 83 maximum. In addition to these soft tempers, a variety of hard tempers is available classed as $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ hard and full hard. These are based on minimum values for tensile strength or yield strength or both.

Finishes—Various surface finishes are possible in cold-rolled stainless strip steel although they are gradations. For example, a dull finish without luster can be produced by rolling on rolls roughened by chemical or mechanical means. A luster finish can be produced by rolling on rolls having a moderately high finish. For the very best or high luster, all of the treatments must be carefully done and the rolling performed on highly-polished rolls.

Basically only two finishes are recognized in the stainless steel strip industry:

- No. 1 Finish, which is cold rolled, annealed, and pickled, and
- No. 2 Finish, which is cold rolled, annealed, pickled, and rerolled.

Because of the difference in the alloy contents between the straight chromium and the chromium-nickel steels, it is possible to anneal the former so that a bright finish results, while the annealed and pickled chromium-nickel steel will be dull. In the chromium-nickel steels, No. 1 Finish is classed as dull, while the hard tempers are relatively bright as will be the No. 2 Finish, No. 4 Temper.

Since the annealed and pickled straight chromium steels result in a bright No. 1 Finish, it is possible to change the processes to enhance this finish in making a No. 2 so that it is even brighter. Dull finishes are also available in these grades where the requirements are necessary.

There are three edges available in stainless strip depending upon the width and thickness:

- No. 1 Edge is a rolled edge, either round or square as specified, and is recommended when a very uniform width is required. It is limited to strip of approximately 5 inches in width and under.
- No. 3 Edge is an approximately square edge produced by slitting. This edge is not burr free. Width is not a limiting factor in furnishing this edge.
- No. 5 Edge is an approximately square edge produced by rolling or filing for the primary purpose of removing burr originating in the slitting operation. Width is not a limiting factor in furnishing this edge.

COLD-ROLLED CARBON-STEEL STRIP

Cold-rolled carbon-steel strip is manufactured in a variety of finishes, tempers, and edges, all depending upon the end use. By common custom, cold-rolled carbon-steel strip is made in a width range of over $\frac{1}{2}$ inch to $23\frac{1}{16}$ inches and up to 0.2499 inch thick. It may have a carbon content of 0.25 per cent maximum; material of this form containing more than this amount of carbon is considered as flat carbon spring steel.

Cold-rolled strip is produced in coils on any of the conventional reversing mills, tandem mills, or by single-stand rolling. While the strip may be supplied in coils, it can be furnished in cut lengths by the straighten-and-cut process.

Before cold rolling, the mill scale is removed from the hot-rolled strip by pickling. From this point, the strip may be cold reduced to final thickness or to some intermediate gage where it is annealed and further cold reduced to obtain the desired temper and gage.

Temper—Many degrees of temper are possible in the manufacture of cold-rolled strip by controlling the combinations of cold rolling and annealing. However, many years of use have brought certain ranges of temper into common usage, and these have come to be recognized by number, as follows:

Temper	Maximum Carbon Content (Per Cent)*	Rockwell Hardness	
		Minimum	Maximum**
No. 1 (Hard Temper)	0.25	B-84 ^a	
		B-90 ^b	
No. 2 (Half Hard)	0.25	B-70	B-85

No. 3 (Quarter Hard)	0.25	B-60	B-75
No. 4 (Skin Rolled)	0.15	—	B-65
No. 5 (Dead Soft)	0.15	—	B-55

- Ladle analysis
- Approximate
 - * For thicknesses 0.070 inch and greater
 - * For thicknesses less than 0.070 inch.

No. 1 Hard Temper is a very stiff springy strip intended only for flat work where no bending is required.

No. 2 Half Hard Temper is less stiff than No. 1, but is intended for limited cold forming and will only withstand 90 degree bends made across the direction of rolling.

No. 3 Quarter Hard Temper is intended for limited bending and cold forming and can be bent 90 degrees in the direction of rolling and 180 degrees across the direction of rolling over its own thickness.

No. 4 Skin-Rolled Temper is intended for cold forming such as bending flat upon itself in any direction and for deep drawing. The purpose of the skin pass is to prevent the formation of stretcher strains.

No. 5 Dead Soft Temper or annealed temper is intended for severe cold forming and deep drawing where the formation of stretcher strains are not objectionable.

Three finishes have come to be recognized as standard within the industry, again by common usage.

No. 1 Dull Finish does not have any luster and is actually made rough intentionally by rolling on rolls roughened either mechanically or chemically. This finish is suitable where paint adherence is desired, or in deep drawing since the lubricant will stick to it.

No. 2 Regular Bright Finish is cold rolled on rolls having a moderately smooth finish. It is suitable for many requirements, although it is not generally applicable to plating.

No. 3 Best Bright Finish is the highest luster finish produced by cold rolling and is particularly suited for electroplating.

Cold-rolled carbon-steel strip in No. 1 Dull Finish, No. 2 Regular Bright Finish, and No. 3 Best Bright Finish is also available with "rolled-in" designs produced through the use of embossed rolls.

Six types of edges have become recognized as standard.

No. 1 Edge is a prepared edge of a specified contour (round, square, or beveled) which is produced when a very accurate width or edge finish is required.

No. 2 Edge is a natural mill edge carried throughout the cold rolling from the hot mill without additional processing of the edge.

No. 3 Edge is an approximately square edge produced by slitting.

No. 4 Edge is a rounded edge produced by edge rolling either the natural edge of the hot-rolled strip or the slit-edge strip. This edge is produced when an approximate round edge is desired and when the finish of the edge is not important.

No. 5 Edge is an approximately square edge produced by rolling or filing of a slit edge to remove the burr.

No. 6 Edge is a square edge produced by edge rolling the natural edge of the hot-rolled strip or slit-edge strip when the width tolerance and finish required are not so exacting as for No. 1 Edge.

FLAT WIRE

Flat wire is ordinarily cold rolled from a drawn round wire, properly annealed and treated to permit additional reduction in rolling and to produce a reasonably bright

surface. Natural round, smooth edges are produced by this method of manufacture. Flat wire can be made up to $\frac{1}{2}$ inch wide, with ratio of width to thickness being in accord with good manufacturing practices. Normally, flat wire is best produced in sizes up to $\frac{3}{8}$ inch in width with roughly a 5-to-1 ratio in thickness. However, this ratio can in some instances be as high as 10-to-1 or 15-to-1. Flat wire is available or can be made to include soft or medium or hard rolled tempers. This material has a variety of uses: some typical applications are in window-shade roller springs (Curtain Spring Wire), leaf-

type feeler (thickness) gauges (Feeler Gauge Steel), electricians' tools for "fishing" wires between walls and through conduits (Fish Tape Wire) and staples for many fastening operations involving stapling machines (Flat-Preformed Staple Wire). Flat wire can be formed into flat wound springs. It also is used in miscellaneous products where spot welding is required in assemblies. Types 302 and 430 are grades of stainless steel which have been most commonly furnished in the form of flat wire, although flat wire can be produced from many of the other grades.

SECTION 11

SOME FABRICATED STEEL-WIRE PRODUCTS

Importance of Fabricated Wire Products—Steel wire is fabricated into thousands of different kinds of articles, which are used for a great variety of purposes. In a list of such articles will be found many items of common use, such as automobile and bicycle wheel spokes, hoops, rivets, bolts, chains, buckles, cotterpins, sifting screens, wire netting, wire cloth, and a host of others, each of which consumes large amounts of wire. Since even the briefest description of the fabrication of all these articles would require a great deal of space, only a few of the more important commodities, in the fabrication of which great tonnages of steel wire are consumed annually, are briefly discussed here.

WIRE NAILS

The wire nail has almost entirely displaced the old-style cut nail, being better in all respects and much cheaper. A review of any modern nail catalogue will show that there are many varieties as to length, size and style, ranging all the way from the tiniest tack to the long heavy spikes. The common finish on nails is obtained by tumbling, though large quantities are galvanized, tinned, blued by oxidation, or cement coated. In the last named process the nails are given a light coating of some compound of a resinous nature which greatly increases their holding capacity.

Nail Machines—All steel-wire nails are made in automatic machines. These machines differ greatly in size and in design, but the principle of operation is much the same in all of them. Nails are made on a machine by five distinct operations; namely, (1) forming the head, (2) feeding the wire, (3) pinching the wire, (4) cutting off the wire and forming the point, (5) expelling the nail.

The head of the nail is formed by compressing and flattening against a die the portion of the wire which projects beyond this die and remains after the previously-formed nail has been cut from the wire. This compressing and flattening is done by a hammer which is attached to a reciprocating member, called a hammer stock, which in turn is actuated usually by a crank and pitman. The amount of wire which projects beyond the die governs the size and thickness of the head and is regulated by adjusting the cutting knives to the proper distance from this die. The various shapes of heads are obtained by cutting the desired depression in the die. This die is split, that is, made in two parts, one fixed or stationary and the other movable.

Feeding—After the head is formed, the hammer moves away from the die, and the die opens up and allows the feed mechanism to push the wire, with a nail head on the end, the correct distance through the die to give a nail of the length required. The feeding mechanism is driven by an adjustable crank on the flywheel of the machine, and, by adjusting this crank, various lengths

of nails can be obtained. This feed mechanism also pulls the wire through a series of staggered rolls, as it leaves the reel, to straighten it.

Pinching—When the hammer has reached the end of the stroke, the wire has been fed the correct amount for the nail required and the die closes to pinch the wire. This pinching action is motivated by a cam on the crankshaft.

Cutting—Immediately after the wire is pinched, two knives, each attached to a lever, move together and cut the wire. These cutting knives are ground to form the point on the nail at the same time that the cut is made. This point is formed by pressing the wire into the shape required, and, in doing so, some of the metal is squeezed out or protrudes between the knives and is cut off by them. These cutoff particles are called whiskers. The cutting levers to which the knives are attached are actuated by various forms of mechanisms deriving their motion from the crankshaft.

Expelling—Sometimes, because of dull knives or insufficiently close adjustment, the nail will still adhere to the wire when the cutting knives open up. The cutting knives open up on the return stroke of the hammer, and, in order to remove this adhering nail, an expeller comes into action, knocking the nail downward out of the path of the hammer and breaking it off. The hammer on the return stroke forms another head on the wire for the next nail, the wire being pinched during this stroke. The finished nails drop into a pan placed on the floor beneath this mechanism.

Finishing Common Nails—The nails in these pans are collected and placed in a tumbler, care being taken to have nails of only one kind in the tumbler at a time in order to avoid mixing. Into this tumbler some sawdust is also placed. The tumbler has projections on the inside, causing the nails to be churned when it is rotated. This churning polishes the nails and removes any whiskers which may have adhered to the nail by a thin fin of metal. The sawdust absorbs the grease and oil which the nails collected during their manufacture. The cover of the tumbler has perforations or a screen which allows the whiskers and sawdust to pass through but holds back the nails. After the nails are tumbled sufficiently they are packed in kegs ready for shipment.

WIRE FENCE

An increasing amount of steel wire is used for fence purposes. Today an enormous tonnage of galvanized steel wire is fabricated into woven-wire fence and barbed-wire fence.

Woven-Wire Fence—There are a great many types of woven-wire fence, varying in style or design, and each may be made up in many different sizes. In a general way, the various styles resemble one another in that

FIG. 40-34. Battery of machines producing various types of woven wire fence.

they have several horizontal or lateral wires which are secured in position with vertical or diagonal stay wires, the former being stronger and stiffer than the latter and provided at frequent intervals with tension curves, to take care of expansion and contraction due to temperature changes. The crossing of stay wires, with the horizontals, form the meshes, which may be quite large, as in cattle fences, or very small, as in poultry netting, and may be of any one of four forms, namely, triangular, rectangular, hexagonal, or diamond-shaped. They are also fastened together in various ways. In the cut-stay fence there is a short piece of stay wire for each space, having its ends twisted about the laterals. The stays may be electrically welded to them, or the two wires may be woven together. In any case, the work is done by specially constructed and rather complex machines from which the coils of fence will emerge all ready for the market (Figure 40-34). In the making of these fences, a most rigid system of inspection and tests is maintained, not only in the drawing and galvanizing of the wire, but also in the weaving room, in order to turn out as perfect a product as possible. These same fences made of extra-strong wire constitute exceptionally good reinforcement for concrete work. The leading fence manufacturers also produce a line of gates, special fittings, steel posts, and other articles used in fencing.

Barbed-Wire Fence—In this fence, two wires, usually galvanized, and known as line wires, are twisted together, and, at regular and frequent intervals (3 to 6 inches apart) either two or four barbs, which may be round, flat or oval in section, are wound about one or both of these line wires. The barbs are diagonally cut so as to produce a long sharp point extending at right angles to the line wires. Here again, a great variety of styles and sizes of fence are made by fast-running and rather complex machines. The bulk of barbed wire, however, has the two line wires of No. 12½ wire, while the barbs are usually made of No. 14 wire. The fence is furnished to the market in 80-rod, or in "catch-weight," spools.

CONCRETE REINFORCEMENT

Concrete reinforcement is a steel fabric which, as the name implies, is used to reinforce concrete work in its numerous applications. Although concrete offers great resistance to compressive stress, it is lacking in tensile and bending strength unless reinforced by some material which possesses these characteristics to a marked degree. In this respect steel excels, particularly cold drawn steel, because of its high tensile strength and high yield point. Concrete-reinforcing wire fabric is electric welded: the longitudinal and transverse wires are fixed in position by an electric-welding machine designed to space the wires accurately and weld them together at the contact points.

The accurate spacing of the longitudinal and transverse members is important, since it not only enhances the reinforcing value of the fabric by placing the steel exactly where it is designed to be, but also facilitates handling of the material. Furthermore, each welded intersection develops a positive anchor in the concrete.

Electric-welded wire-fabric reinforcement has a varied application. It is used to reinforce concrete roads, buildings, dams, etc. As a matter of fact, every type of concrete construction should be reinforced. This fabric is used in such precast concrete products as pipe, posts, and slabs. It is supplied in flat sheets or rolls of desired length and width. Standard rolls are 60 inches wide by 150 feet long. Welded wire fabric which is too heavy to be rolled must of necessity be supplied as flat sheets.

PRESTRESSED CONCRETE

Prestressing of concrete is the introduction of desirable compressive forces into a concrete member. These compressive forces are designed to offset or neutralize any subsequent tensile forces which occur when the concrete member is loaded. Since concrete has very little tensile strength, prestressing permits a concrete member to withstand tensile forces without cracking.

Prestressing is done by two general methods:

(a) *Pretensioning.* Steel wire or strand is tensioned on a precasting bed and then concrete mix is poured around the steel. When the concrete has attained full strength, the strand or wire is released from its tensioning apparatus, and the tensile forces of the steel induce equal and opposite compressive forces in the concrete. The bond between the concrete and steel continues to hold the steel in tension and the concrete in compression.

(b) *Posttensioning.* Steel wire or strand is threaded through ducts in a precast concrete member and tensioned by means of end fittings. The tensile forces of the steel induce equal and opposite compressive forces in the concrete members.

Wire and strand for prestressed concrete must have high tensile strength—usually on the order of 250,000 lb. per sq. in. Both wire and strand are furnished from cold-drawn wire, and after the final draft or stranding they are stress-relieved by immersion in molten lead at temperatures of about 800° F. Stress relieving improves the elastic properties and ductility of the product and also burns the surface clean of any residual matter on the wire or strand.

The greatest use of prestressed concrete to date has been in bridge and tank construction and in the manufacture of pressure pipe.

BALE TIES

Large quantities of wire are used annually for tying or bundling bales, bundles, boxes, or packages of every description. While there are several styles of bale ties, each, however, is made of wire that is high in tensile strength and fairly pliable, a goodly percentage of this commodity being made of annealed medium-carbon steel having a light oxide finish. The wires are cut to length, and one end is fabricated to form a means of fastening the two ends together. Lengths and sizes vary between wide limits, but tie wires are made of sizes No. 13 to 16½, inclusive, plain or galvanized. They are put up and sold in bundles of 250 and 500 per bundle, the ends of the bundles being wrapped in burlap.

WIRE ROPE

A single, solid bar of steel, for example a bar one inch in diameter, is very stiff and will stand relatively little "back-and-forth" bending before breaking, but if this same bar of steel is drawn and then formed into a twisted bundle, or "strand," of small wires having the same aggregate sectional area of metal, it will be found to have gained greatly both in flexibility and life, and usually, also, in tensile strength. These reasons account for the large amount of steel-strand wire rope that is used as haulage rope, hoisting rope, hawsers, guys, etc., and for such purposes as oil-well drilling, ships' rigging, tramways, elevators, and so on. These ropes consist of iron or steel wires ranging in tensile strength from 85,000 to 280,000 pounds per square inch or even more, the wire of very high strength being made from high-carbon steel. Wire for ropes used for guy or standing purposes is generally galvanized.

Fabrication of Wire Rope—A full description of the fabrication of wire to form the various types and kinds of rope would be very lengthy, indeed. Consequently, only a few of the simplest examples can be cited here to illustrate a few of the principles involved in steel wire ropemaking. The first wire rope was made of straight wires held together by fine wires which were wrapped about them at intervals, but this construction was unsatisfactory for obvious reasons. The first great improvement consisted in twisting a number of wires together to form what was called a strand, and then twisting a

number of these strands together to form a rope. At first both the strands and the rope consisted only of wire, and the strands in the rope were few in number, with the result that it lacked flexibility and wearing qualities. But this lack was soon remedied by the introduction of the hemp core, which, together with an increase in the number of strands and the number of wires in a strand, marked the beginning of really successful wire rope manufacture—from the standpoint of the user, at least. So, a steel wire rope, as it is made today, may be defined as a group of strands, usually in one layer, twisted together helically and symmetrically, with a uniform pitch and direction, around a central core of hemp or wire, each strand in turn consisting of a group of steel wires similarly twisted, in one or more layers, around a central core of wire or hemp. The principal operations of ropemaking are two in number and are known as **stranding** and **laying**.

Stranding—Stranding consists of bringing the individual wires together in a predetermined pattern, and twisting or "stranding" them uniformly in concentric rings about a central wire, in either a clockwise or counterclockwise direction, to form the completed strand (Figure 40—35).

FIG. 40—35. Arrangement of wires in a galvanized bridge strand. Note the increasing number of wires, starting at the right, are 1, 7, 19, and 37, respectively.

Many types and geometrical patterns of wire-rope strands are possible and are made for special uses. Most wire-rope strands, however, fall into three classifications or basic types: 7-wire, 19-wire, and 37-wire. The 7-wire strand is made by covering a center wire with a layer of 6 wires stranded or twisted about it in uniform helices. Strands of this kind made of uncoated wires are closed about a fiber core to form a 6x7 haulage rope (Figure 40—36, Diagram A). When made of galvanized wires, this construction is a 6x7 guy or standing rope. If a cover of twelve wires is twisted about a 7-wire strand, a 19-wire strand is formed. There are several modifications of the basic 19-wire strand used in the fabrication of 6x19 hoisting ropes, the most widely used of all wire ropes. Adding another cover of 18 wires to the 19-wire strand produces the 37-wire strand, which is also fundamental in design. Modifications of this basic pattern are used by manufacturers in wire ropes of special flexibility, such as crane ropes and other wire ropes which operate over relatively small sheaves.

Laying or Closing—The final operation in rope making is the closing of the strands around the core. More wire ropes are composed of six strands than all the others combined, as the 6x19 and 6x37 classifications are the most common types. Eight-strand ropes, 8x19 classification, are extensively used on passenger elevators. There are ropes of three, five, and other numbers of strands, but these are comparatively few in number. The largest number of strands in any standard wire rope is eighteen in 18x7 non-rotating hoisting rope.

The cores around which the strands are closed are usually either fiber or wire. Fiber cores are standard for wire ropes which are not subjected to heat, crushing and/or heavy loads. Wire cores, usually independent wire-rope cores, are employed where greater strength or greater resistance to distortion and/or heat are required. Other substances, such as plastics, are used to very

A. 6 x 7 Classification Haulage Rope, consisting of 6 strands of 7 wires in each strand and one fiber core.

B. 6 x 19 Classification Hoisting Rope, with 6 strands of 19 main wires in each strand and one main fiber core.

C. 8 x 19 Seale Elevator Hoisting Rope, consisting of 8 strands of 19 wires in each strand - arranged in Seale construction - and one fiber core.

D. 8 x 19 Classification Hoisting Rope, consisting of 8 strands of 19 main wires in each strand - plus 6 filler wires and one fiber core.

E. 6 x 37 Classification Hoisting Rope, with 6 strands of 37 main wires in each strand and one fiber core.

F. 6 x 25 Type B Flattened Strand Lang Lay Hoisting Rope consisting of 6 strands, each containing a single triangular-shaped core wire and 24 round wires and one fiber core.

G. 18 x 7 Non-Rotating Hoisting Rope consisting of 12 strands of 7 wires each over a core of 6 strands of 7 wires each and one fiber core.

FIG. 40-36. Different types of steel wire rope.

limited extents to meet specific service requirements.

The direction of lay of a wire rope may be either right or left, although practically all wire ropes are right lay. In a right lay wire rope, the strands form a helix about the core similar to the threads on a right-hand screw. If the direction of the lay of the wire in the strands is opposite to the direction of lay of the strands in the rope, that rope is regular lay. If the lay of the wires in the strands and the strands in the rope are of the same direction, that rope is Lang lay. Regular lay ropes are in greater demand than are the Lang lay ropes because of greater inherent stability. Lang lay ropes, however, possess greater resistance to abrasion than do regular lay ropes because of the greater distance that each outer wire in a Lang lay rope is exposed to surface wear.

Types of Wire Rope—By changing the number and arrangement of wires in each strand, by varying the number of strands in the finished rope, by making ropes both with fiber cores and with independent wire-rope cores, by closing the ropes so that they are regular lay and Lang lay, right lay and left lay, by producing wire ropes in several grades of steel and in sizes from $\frac{1}{16}$ -inch diameter through 4 inches in diameter, the number of possible wire ropes becomes legion. However, only a small fraction of the possible constructions are sufficient for industrial purposes.

WIRE SPRINGS

There is a wide diversity in types, shapes and sizes of springs, ranging from the tiny watch hairspring to the large buffer springs used for railroad equipment. The majority of springs are manufactured from medium-

carbon or high-carbon steel; such springs are furnished in the annealed, hard-drawn or pretempered state. As to shape, they may be round, flat or rectangular. Special applications may require stainless steel, and many non-ferrous metals such as brass, phosphor bronze and the nickel alloys are likewise employed for certain classes of use. The following classifications indicate the springs in most common use.

1. **Compression Springs**—These springs are open wound with varying space between the coils and are provided with the ends plain, plain and ground, squared, or squared and ground. They are furnished in a wide range of wire sizes, diameters, lengths, shapes and each and every one must be designed to meet certain load requirements. Figure 40—27 illustrates typical springs of this class.

2. **Extension Springs**—Generally, extension springs are close wound, usually with specified initial tension and, as they are used to resist pulling forces, they are provided with hook or loop ends to fit their varied applications (Figure 40—38). These ends may be an integral part of the spring itself, or may be specially inserted forgings, castings or wire forms to meet individual requirements.

3. **Helical Springs**—The term "helical" springs, although literally applying to any spring which is helically wound, is generally considered as a trade name for extension springs used in great volume by manufacturers of spring beds, couches, and cushions. Many sizes and shapes of this particular category are in general usage.

Any one of the three foregoing types of spiral springs may be strengthened by increasing the wire size, or by decreasing the mean diameter of the helix, but in any case the ability of the material to withstand the load must be of prime consideration.

4. **Torsion Springs**—This type of spring (Figure 40—39) is one in which work is required to wind up the spring about its own axis—never to unwind it. The ends may be finished in a number of ways, the type of end being generally dependent upon the particular requirements.

5. **Upholstery Springs**—These are used to serve as cushion or bed springs. They are normally made in two styles, known as full springs and half-springs and, in

either, one or both ends may be "knotted," that is twisted about the wire at the beginning of the second coil.

6. **Clock and Motor Flat Springs**—These springs are made of cold-rolled high carbon strip steel of proper width and thickness to meet specifications and are tempered, tempered and polished, or tempered, polished and colored. The ends are formed as desired, and the coils are wound spirally and held in compact shape by a retaining clip or ring.

7. **Jig Springs and Specially-Formed Wires**—These represent a group, covering an endless variety of odd shapes and sizes, made or formed in jigs, on automatic wire-forming equipment, or with small hand tools. Springs of this type are generally used to serve as more or less simple parts of mechanisms.

SPRING TERMS

The manufacturers of springs, in common with every other industry, have used terms frequently misunderstood. The most common of these are:

Bluing—A low-temperature heat treatment of springs after fabrication, to relieve the cold-working strains created by coiling and forming.

Tested Spring—A spring which has had its set removed as a result of one or more compressions to solid height.

Scale Testing—A spring which has been tested for load at a given height or heights.

Pitch—Center to center distance between adjacent coils at free height.

Active and Inactive Coils—Two types of coils are present in compression springs, namely, active and inactive. This is prevalent in squared springs where the end coil squared on the next adjacent coil becomes inactive due to its contact with said coil and, consequently, the inactive coils are omitted when computing spring load and stress data.

Initial Tension—Indicates the force or load necessary to cause the coils to start to open. This force or load must be considered as part of the total spring load for stress calculations. This initial tension factor applies only to the close-wound extension type of spring.

BRIDGE WIRE

Bridge wire is the term commonly applied to high-grade rope wire used in the construction of cable sus-

pension bridges, in which the main cables consist of parallel wires compacted to act as a unit. These bridges are remarkable for their graceful beauty, the absence of heavy superstructures, and their extraordinarily long spans. Some of the largest bridges in the world are of this type, including the George Washington Bridge, New York, and the Golden Gate and San Francisco-Oakland Bay Bridges, California. Interesting data on the cable wire used in the San Francisco-Oakland Bay Bridge are: Length of longest spans (West Bay) center, 2,310 ft.; side, 1,160 ft.; vertical clearance, 200 ft.; number of cables, 2; diameter of cables, 28¾ in.; number of wires in each cable, 17,464; diameter of each wire, 0.195 in.; total length of cable wire, 70,815 miles; total length of suspender ropes, 43 miles. Total tonnage of wire in both crossings amounted to 18,200 tons.

Bridge wire requires steel of high quality and extreme care in every step of its manufacture from melt to finished wire. Specifications for the finished wire have required: (1) The wire to be heavily coated with zinc to protect it from corrosion—galvanized to withstand 5 immersions in the standard Preece test. (2) A minimum tensile strength of 225,000 lb. per sq. in. (3) A minimum elongation of 4 per cent in 10 inches. (4) A coating that will permit wrapping without peeling about a round mandrel of a diameter equal to 1½ times the diameter of the wire.

At one time, specifications required the steel to be made by the acid open-hearth or the crucible processes, but it is now generally accepted that steel equally as satisfactory or better can be made by the basic open-hearth process. The wire is made from selected high-carbon steel, the composition of which is held within close limits. The composition of the steel used heretofore has usually been held within the following limits: carbon, 0.75 to 0.85 per cent; manganese, 0.55 to 0.75 per cent; phosphorus, under 0.03 per cent; sulphur, under 0.03 per cent; silicon, 0.15 to 0.30 per cent, with maximum limits for other elements that may be present in small amounts. Some of the more important requirements of the manufacturing practice are listed as follows: The manufacturing processes in the production of bridge wire are very closely controlled in order to produce the required mechanical properties of high tensile strength, toughness, and resistance to fatigue. The bright wire is produced in two common wire sizes, No. 6 and No. 8, the former being more frequently used. The bright wire is usually hot galvanized. In order to prevent undue bending, and to supply wire which is straight, as required for the subsequent spinning of the cables, the wire is finished in five-foot diameter coils. Coils are coupled together to form long, continuous lengths of wire, and are shipped to the bridge site on large reels, from which the wire is unreel during the process of spinning the cables.

The following notes cite one example of metallurgical, rolling, drawing and coating practice. Heats must be kept separate, from casting of the ingots to the finished wire. The steel should be made in heats of about 150 tons or less, cast into hot-top ingot molds, and held till completely solidified before stripping. The ingots should be soaked to a uniform temperature throughout, and rolled on the blooming mill at a temperature of 2200° F, with reduction in each pass limited to avoid cracks and other rolling defects. The crop from the top of the bloom should not be less than 12 per cent, and billets (usually 2 in. by 2 in. by 30 ft.) should be carefully inspected on the ends for pipe and segregation and on the surface for other defects and chipped and surfaced to remove seams, laps, slivers, etc. The billets should be rolled at temper-

atures between 1900° F and 2000° F to a rod of specified diameter with a minimum amount of water used on the rolls and none on the reels, to avoid hard spots on the rod. The rod should be carefully inspected before it is treated. For the latter operation, the rod is uncoiled continuously and passed through a 50-foot or longer continuous furnace held at 1625° F to 1675° F to heat the rod above the critical temperature of 1325° F, after which it is passed into an 18-foot lead pan held between 900° F and 950° F, the exact temperature to give the desired structure being determined by preliminary tests on each heat. Lead adhering to the rod must be removed, a result usually accomplished by a header of coke breeze on the exit end of the lead bath.

To clean the rod, it is pickled in a bath, the acidity of which is maintained between 5 and 8 per cent with 66° Baumé sulphuric acid, and the temperature of which is held at not over 110° F to avoid acid embrittlement that cannot be removed by the subsequent baking. A suitable inhibitor is used to reduce the amount of acid consumed, prevent overpickling, or pitting, and help avoid acid embrittlement.

The rod is then washed with water, and sprayed 30 or 40 minutes to obtain a complete silt coat; submerged repeatedly in a water suspension of slaked lime; and baked 10 to 12 hours at 400° F to 450° F.

The rod is then drawn on a specially-built 6-draft continuous machine or on powerful 30-inch diameter blocks at a speed of 16.5 r.p.m. or 130 feet per minute, using powdered soap mixed with grit-free hydrated lime as a lubricant and uniform light-reduction drafts of 0.384, 0.334, 0.290, 0.252, 0.219, and 0.192. Each wire should be inspected front and back and tested. Requirements are: minimum tensile strength, 240,000 lb. per sq. in., 40 per cent reduction of area; and 2 per cent elongation in 10 inches. It has been demonstrated that wire cold drawn to finish in this way is far superior for bridges than a heat-treated wire of about the same strength.

Galvanizing operations are continuous, the wire passing through the following baths: (1) molten lead at 850° F, momentarily, to remove lubricants, (2) a cleaning box containing a 4 to 6 per cent solution of hydrochloric acid at 150° F to 170° F, (3) a hot water wash at 200° F, (4) a flux box of zinc chloride (ZnCl₂) or 1 per cent hydrochloric acid at 150° F to 175° F, (5) the galvanizing tank filled with especially pure zinc at 880° F to 900° F, equipped with an exit sinker of the roller type and a charcoal header filled with a mixture of charcoal and beef tallow.

Bridge Strands—For cable suspension bridges where the size of the main cables does not justify the stringing of individual wires, parallel bridge strands are used to form the main cables. These strands are compacted in the same manner as are the main cables composed of individual, parallel bridge wires.

Chapter 41

MANUFACTURE OF STEEL TUBULAR PRODUCTS

SECTION 1

HISTORY AND CLASSIFICATION OF STEEL TUBULAR PRODUCTS

Events Leading to Development of the Butt-Weld Process—About the year 1815, William Murdock, a Scottish inventor, introduced at London the use of coal gas for lighting purposes. For conveying this gas, Murdock collected old musket barrels and screwed them together to form continuous tubes. The popularity of this lighting system created a demand for tubes, and stimulated inventors to seek some means of producing the tubes more rapidly and at a lower cost. The first to succeed in this undertaking was James Russell, who filed patent papers describing his process as "an improvement in the manufacture of tubes for gas and other purposes" in 1824. In his method, the tube was formed by butting the white-hot edges of a bent plate together. The initial welding was done with a tilt-hammer provided with round grooves in the head, and the rough tube thus formed was finished by reheating it and passing it through a round groove in a rolling mill and over a mandrel which was supported in the pass, or opening, between these rolls. The next year, however, Russell's work was overshadowed by the invention of Cornelius Whitehouse, who succeeded in forming a commercially perfect tube by merely drawing the flat plate, heated to a proper temperature, through a "bell" or die. This invention, which became the basis of one of the present-day butt-weld processes, made it possible to produce tubes of superior quality much more cheaply than before. Shortly after this invention, about 1832, the first shop for making butt-weld pipe in the United States was established in Philadelphia by Morris, Tasker and Morris. Four years later, this firm built the works afterwards known as the Pascal Iron Works. Following their success, other plants appeared in Eastern Pennsylvania, Eastern New York, New Jersey and Massachusetts, but no plants were built west of the Allegheny Mountains until after 1860. The idea that pipe could be butt-welded continuously was conceived by John Moon in 1911. Later, with S. F. Fretz, Jr., he built the first experimental mill. This equipment proved successful and in 1921 and 1922 the Fretz-Moon Tube Company was formed and continuously butt-welded pipe was made on a production basis.

First Seamless Tubes—Following these developments in making welded tubes, inventors turned their attention to the production of seamless tubes. At first they attempted to duplicate with iron or steel the method (extrusion) used to produce tubes of lead and other ductile metals, namely, forcing the hot metal through an orifice formed by a mandrel or punch located and supported in the center of a circular die. In 1836 such a process was patented by Hanson in England, but this method proved impracticable. Two other methods were brought out in 1840 and 1845. They involved the cupping of a plate or the piercing of a round billet in a press, and subsequently elongating the rough tube thus formed by drawing or rolling. While practicable, these methods were costly,

and for fifty years the use of seamless tubes was restricted on that account. The modern developments beginning about 1890 are described in Section 5.

Innovations by Briggs and Riverside Iron—Besides these developments in methods of manufacture, two other events should be mentioned because of their far-reaching effects on the industry as a whole. About 1862 Robert Briggs, then superintendent of the Pascal Iron Works, formulated the dimensions of pipe (tube) threads, and compiled a table giving the nominal sizes, the exact diameters and the number of threads per inch for all sizes of pipe and tubes up to 10 inches. These formulae and tables were subsequently adopted as standard for the manufacture of all tubes and pipes up to 15 inches in size and are widely known as "Briggs Standards," but the name now officially adopted is American Standard (A.S.A.) Pipe Thread. In 1887 the Riverside Iron Works, Wheeling, W. Va., began making butt- and lap-welded pipe of soft Bessemer steel. Up to that time, wrought iron had been the only material used for welded pipe and tubes. Riverside proved that steel was not only equal to wrought iron for this purpose, but actually superior to it in many respects.

The Present Importance of the Steel Tubular Industry and of steel tubular products is apparent to all observers. This growth was due to many things, chief of which is the diversity of uses to which steel tubular products may be and are applied. The mere mentioning of the names, oil, gas, air, water, plumbing, heating, ammonia, dry-kiln, greenhouse, boiler tubes and bedstead tubing are sufficient to call to mind industries almost wholly dependent upon steel pipe or tubing. In addition to these uses, we find it in service as trolley poles, flag poles, lighting poles, telephone and telegraph poles, columns, conduits, automobile axle housings, airplane fuselage, motor mounts, and many other items too numerous to list here.

Classification of Steel Tubular Products—The many uses to which steel tubular products have been applied have led to a great variety of products and to the use of a large number of more or less descriptive terms in designating the products used for different purposes. Use, therefore, may form a basis for classifying steel tubular products, as shown in Table 41—I.

Another classification is based on methods of manufacture. On this basis all steel tubular products may be classified under the two main headings of welded and seamless, with subclasses, as shown in Table 41—II.

Modern Methods of Manufacturing Welded Tubular Products—A butt-weld pipe or tube is made from a hot-rolled strip, with square or slightly beveled edges, called skelp, the width of which corresponds to the circumference of the pipe, and the gage to the thickness of the wall. By heating this skelp to the welding temperature and drawing it through a suitable die or

Table 41—II. Steel Tubular Products Classified According to Methods of Manufacture

A. Welding Processes.

- I. Butt-Weld Process. This process is used in the manufacture of pipe, $\frac{1}{8}$ inch to 4 inches, nominal diameter.
- II. Lap-Weld Process. This process is used to produce pipe and tubes, $\frac{1}{4}$ inch to 30 inches, nominal diameter.
- III. Electric-Weld Process. This process is employed to produce pipe and containers in practically all sizes.

B. Seamless Processes.

- I. Piercing Processes—Roll-Piercing and Disc-Piercing. These processes are used to make pipe and tubes up to 26 inches in outside diameter.
 - a. Hot Finished
($1\frac{1}{2}$ inches to 26 inches, outside diameter)
 - b. Cold Drawn
(Any size up to 10 $\frac{3}{4}$ inches outside diameter)
- II. Cupping Process. This process is applied in the manufacture of tubes and cylinders 3 inches to 20 inches outside diameter.
 - a. Hot Drawn (Finish)
(3 inches to 20 inches)

roll pass while at this temperature, the skelp is bent into cylindrical shape and its edges pressed firmly together into a **butt-weld** or **jump-weld**, thus forming a pipe. Recent innovations which have improved this weld are described in Section 2.

In the **electric-weld** process, hot-rolled strip or plate, of a gage corresponding to the thickness of the wall of the pipe desired, but of an overall width slightly greater than its circumference, is first edge-trimmed to insure parallelism and accurate width. To produce **fusion-welded pipe**, the plate is then bent into cylindrical shape with the beveled edges abutting to form a "V" into which the electrode is melted. Fusion welding, which is particularly applicable to large-diameter pipe, is a term used to distinguish this method from electric-resistance welding used in the manufacture of smaller sizes of tubing. By the latter process union of the seam is effected by the application of pressure and heat, the heat being generated by the resistance to current flow (either transformed or induced) across the seam during the welding.

Seamless Tubular Products are made by two basic processes, known as the **piercing** and the **cupping** processes. The piercing process, in which a solid round bar or billet is heated, pierced and afterwards wrought to the desired diameter and thickness of wall, is employed generally on sizes up to 26 inches, outside diameter,

while the cupping process, in which the tubing is formed by pressing a preheated solid round plate through cup-shaped dies, may be employed for all sizes between three and twenty inches. The reasons for these restrictions in the use of the five methods cited will be made apparent in the detailed descriptions that are reserved for succeeding sections.

Pipe—Applied in a general sense, pipe is a term used to designate any long hollow body used for conducting gases or liquids, and may be of clay, cement, wood, lead, brass, cast iron, or steel. Restricted to the steel industry, the term is one that is applied to all tubular products intended for the purposes for which such products are ordinarily used, as for conducting water, fuel, gas, steam, air, oil, etc. The term "wrought" distinguishes forged iron or steel pipe from cast-iron pipe.

Varieties of Pipe—Since the pipe should be adapted to the kind of service it is expected to give, there are different varieties of pipe. Thus, welded pipe is regularly made in three separate classes, which are distinguishable by characteristic differences in the wall thickness of each class of pipe as a class. These classes of pipe are known as **standard weight**, **extra strong**, and **double extra strong**. **Standard weight pipe** is pipe made and threaded to the American Standard (A.S.A.). The weights or wall thicknesses of this pipe are suitable for all ordinary purposes, such as water and gas lines for plumbing and heating, etc. **Extra strong pipe** is characterized by heavier walls in all sizes than the standard weight pipe, and is used where higher internal pressures or greater column loads are to be sustained. **Double extra strong pipe** is used for extremely high-pressure purposes, such as hydraulic lines for operating hydraulic machinery or apparatus. **Line pipe**, used for the higher pressure oil, gas and water lines, and **drive pipe**, used in drilling oil

and water wells, differ from each other and from standard pipe mainly in the manner in which the different sections of pipe are coupled together. **Air-line pipe**, used for steam train and electric car air-brakes, and **drill pipe**, used for oil-, gas- and water-well drilling, are further examples of the different varieties of pipe. In addition to these varieties, pipe is also made to conform to the British Standards. Pipe may be used for many structural purposes, such as columns, railings, piling and poles for telegraph, telephone and electric power lines, also railway signal and safety devices.

Sizes of Pipe—As a whole, pipe is made in sizes that range from $\frac{1}{8}$ -inch nominal inside diameter to 96 inches outside diameter. Up to a diameter of 12 inches, pipe is commonly known by the inside diameters, and is spoken of as three-quarter-inch pipe, one-inch pipe, two-inch pipe, etc. These terms are but nominal, because, in order that different pieces of pipe may be coupled together conveniently, the outside diameters must be standardized, and any variation due to differences in gage, or thickness of the wall, occurs in the bore. However, care is taken to make these differences for any one kind of pipe as small as possible, so that in the case of standard pipe these nominal diameters approximate as closely as possible the inside diameters. Exceptions may be cited in the case of 8-inch, 10-inch, and 12-inch standard line pipe, which are made in different weights to adapt the pipe to different purposes. For example, 8-inch standard line pipe is made in two standard weights, namely 24.696 pounds per foot and 28.554 pounds per foot, the difference in weight being represented by a difference in the wall thicknesses. Standard line pipe, drive pipe and pipe over 12 inches internal diameter, and practically all pipe over $12\frac{3}{4}$ inches in diameter, are known by their outside diameters

SECTION 2

BUTT-WELDED PIPE

The National Tube Division of United States Steel manufactures butt-welded pipe by the furnace-weld and continuous butt-weld methods. Following is a description of these two processes.

BUTT-WELD PROCESS (FURNACE-WELD)

Rolling the Skelp—Skelp for butt-welded pipe may be rolled on any mill adapted to the rolling of long thin flats. For the smaller sizes of pipe, $\frac{1}{8}$ inch to $\frac{1}{2}$ inch, the skelp sizes will range from about $1\frac{1}{8}$ inch to $2\frac{3}{4}$ inches in width and from 0.068 inch to 0.109 inch in thickness. For the larger sizes of butt-welded pipe, the skelp will range in width from $3\frac{1}{8}$ inches to 12 inches, and in gage from 0.113 inch to 0.216 inch for the standard, or from 0.154 inch to 0.300 inch for extra strong pipe. While it is evident that this material may be rolled by tongue and groove passes and plain rolls, much in the same manner that sheet bar is rolled, on many different types of mill, yet, on account of the introduction of special features aiming at improvements in the quality of pipe, skelp is best rolled on a mill specially designed for the purpose.

Example of a Skelp Mill—As an example of a modern skelp mill, the No. 5, 13-inch mill at the Lorain Works of National Tube Division may be cited. This mill consists of thirteen stands of horizontal rolls and one stand of vertical rolls arranged on the continuous plan, but the roll stands are so placed that the piece will clear the first, second, fifth, seventh, and eleventh passes before it enters the next succeeding passes, respectively. In order to secure this arrangement, the first ten stands

are set up in four tandem groups composed of two, three, two, and three stands, in the order named. The stands in each group are geared together and driven through one shaft. The eleventh stand, in which the rolls are vertical, and the twelfth, thirteenth and fourteenth stands, which are horizontal rolls, are separately driven. The mill is served by two continuous heating furnaces and is provided with a hot shear between the fifth and sixth passes, that is, between the second and third groups of rolls. Its product is received on a two-way cooling bed. An end-cutting shear is located at each of the two delivery corners of the cooling bed, and between these two shears are two other shears, known as the clipping shears.

Operation of the Mill—The bloom, which is rectangular in shape and of the proper dimensions to produce skelp of the desired size, is heated in the continuous furnace to a rolling heat. The first stand of rolls is placed far enough from the furnace to permit the switching of the bloom to the mill floor in case there should be a rolling accident on the mill or the bloom should be overheated or underheated. The first two or four stands in the mill, corresponding to roughing rolls in other mills, are used to spellerize the metal. In the usual manner of carrying out the spellerizing process, the working surfaces of the first and second stands, called **knobbling rolls**, are provided with regularly shaped projections and depressions, while the surfaces of the other passes are plain. When the bloom passes through these rolls, the roll-knobbling, or kneading, process to which its sur-

FIG. 41—1. Showing how the skelp is bent and welded as it is drawn through the welding bell.

faces are subjected is said to give a pipe surface that is better adapted to resist corrosion in the form known as pitting than that of skelp rolled on plain rolls only. Upon leaving the third set of rolls, the bloom, now much reduced in thickness, is edged by a twisting guide in the second group of rolls, in order to control the width. Next, the bloom is cut into two or more pieces by the hot shear, to adjust the length of the finished strip to the cooling bed. These pieces then pass flat-wise, or flat-and-edgewise, if desired, through the next five stands to the vertical rolls. These rolls are grooved to roll the edges of the skelp, which must be slightly beveled, so that, when the skelp is bent to form the pipe, they will fit squarely together and form a perfect joint. In this way, the defects in pipe, known as a *falling*, or *sunken*, seam, a depression along the weld on the outside of the pipe, and a *deep seam*, a depression on both the outside and inside, are avoided, for both may be due to round edges on the skelp. To secure the required edge on the finished skelp, the bottom of the grooves in the vertical rolls are made slightly convex, thus forming concave edges on the skelp, so that the spreading of the steel in the succeeding passes through the three stands of plain rolls will be just sufficient to fill the concave surface.

Shearing the Skelp—From the finishing rolls of the mill, the skelp passes over the cooling bed to the shears, where the crop ends are cut off, and the remainder of the strip is cut into the lengths desired, the standard lengths being approximately twenty-one feet for single lengths and forty feet for double lengths. The skelp is then passed to the *clipper*, a machine that performs the

double function of a shear and a press. It (1) shears two small triangular shaped pieces from one end of the skelp, one from each corner, (2) shapes, or cups, the pointed end to start the curve for welding, and (3) bends the skelp transversely just back of the curve, so that when the skelp lies on the flat surface of the welding furnace hearth the pointed end will be elevated, thus making it easier to grasp with the welding tongs. Care is required in adjusting the end of each strip in this machine, so that the clipping and cupping will be symmetrical, as otherwise the skelp will be liable to stick in the welding bell, which will be described later. The skelp is now stacked in a small pile, loaded on railroad cars with a crane, and then taken to the butt-welding furnaces.

The Butt-Welding Furnace—In the pipe mill, the skelp is charged directly into a reheating furnace preparatory to welding. To obtain uniform heating of the material (a condition absolutely necessary to effect good welding) and economize in time and labor (factors that vitally affect the cost of pipe) the heating furnace, charging apparatus, welding appliances, and finishing machines must be of special design, and constitute a single unit. The heating furnace is the central figure in this unit. These furnaces are of the gas-fired regenerative type, and, depending upon whether they are designed for single or double lengths, are 22 or 40½ feet long inside, but vary in width to suit the different sizes of pipe, in order to accommodate a certain number of skelp strips, which lie side by side upon the hearth, or bottom, of the furnace. Special care must be taken

FIG. 41—2. Butt-welding furnace, showing a pipe in the process of being welded.

in making up the hearths of these furnaces to prevent the material of the bottom from sticking to the hot skelp and thus ruining the pipe. The materials used for this purpose are high-grade sand and gravel. The gas and air for combustion are admitted through ports arranged along the sides of the furnace, so that the flame must pass transversely over the hearth, which is covered with a low, arched roof. The ends of the furnaces are constructed so that only narrow openings, one extending across each end just above the level of the floor, remain to provide an inlet and outlet for charging and drawing the skelp and repairing the hearth. When the furnace is in operation, these openings are partially closed by adjustable shields suspended by proper supports from above. Opposite the inlet is placed the charging machine, while the welding machine is opposite the outlet. Both machines are mounted on wheels. Those under the charging machine run on tracks laid across in front of the furnace, and the machine is propelled by electricity back and forth as desired. Usually, only the end of the welding machine next to the furnace is movable, and it is moved back and forth by a steam or air cylinder. The charging machine for the larger sizes of pipe is provided with a platform for the operator to stand upon, a table for supporting a pile of skelp at a convenient level, and, alongside, an electrically-operated endless chain pusher or magnetic rollers for charging the skelp into the furnace.

The Welding Machine very much resembles a draw bench, with the end next to the furnace mounted on wheels and the farther end pivoted. It consists of a carriage, on which is mounted an endless chain for drawing the skelp from the furnace through the welding die, and a stop for holding the welding die as the skelp is drawn through it. The draw chain is actuated by a motor-driven sprocket wheel on the pivoted end. The

welding die, called a welding bell on account of its form, is so shaped inside that, as the skelp is pulled through it, the strip is gradually bent into the form of a tube, and its edges are forced together, thus forming the weld. The bells are made of a special grade of copper alloy.

Operation of the Butt-Welding Furnace—The skelp from the rolling mills, in either single or double lengths, depending upon the size of the furnace, and of a width and gage to make the pipe desired, is unloaded from the flat car, bundle by bundle, and placed upon the charging machine by an overhead crane. Starting at one side of the furnace, the skelp is slid by hand from the pile to the charging table with the clipped ends foremost, one strip at a time, and charged into the furnace by the charging machine with the convex side of the clipped end up. After charging each strip, the machine is moved over a distance corresponding to the width of the strip before pushing in another. In this way, the bottom of the furnace is soon covered with the strips lying side by side, and the charging machine is ready to repeat the cycle. Since the size of the furnace and the rate of charging are so regulated that, when the last strip has been charged, the first one charged will have reached the welding temperature of about 2600° F, the welder now begins drawing the skelp in the same order it was charged. This he does with specially-designed tongs, having short jaws for grasping the pointed end of the skelp and very long handles with a locking bend in the middle and a knob on the end for engaging with the lugs, or the dog, on the draw-chain. No section of these tongs can be larger than the outside diameter of the pipe, as they must pass through the welding bell. Preparatory to drawing each strip of skelp, the welder grasps the pointed end of the skelp with the jaws of the tongs. He then slips, large end first, a welding bell of the proper size over the handles of the tongs and drops the handles

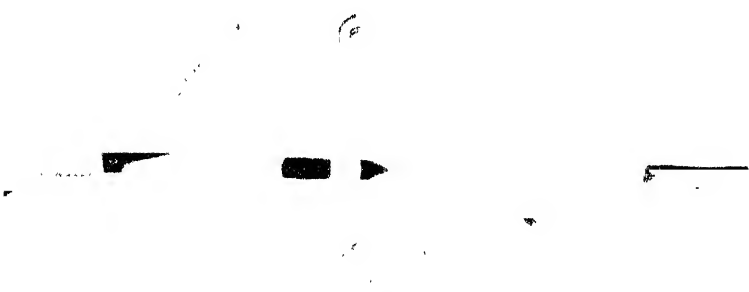

FIG. 41—3. Pipe passing through the sizing rolls.

FIG. 41-4. Sizing rolls. Illustrating how the size of the pipe is reduced to the diameter desired.

between the two prongs of the bell stop in such a manner that the dog on the draw-chain will engage the knob on the handle. Then, the chain, traveling continuously away from the furnace, draws the tongs, bell and skelp out of the furnace. When the bell reaches the stop, it is held there until the skelp has been drawn through for its full length, when the bell drops from the stop by its own weight. The flat skelp is thus bent into the form of a pipe, and its edges are forced together and welded, all in the one operation. In this way the welding requires but little time: one-inch pipe, for example, may be welded at the rate of 750 twenty-one-foot lengths per hour. For the larger sizes of standard pipe, two welding bells, instead of one, are employed.

Although the metallurgical features and mechanical principles used in manufacturing butt-weld pipe from skelp have remained the same for over fifty years, there have been numerous slight changes and innovations introduced with the idea of improving the weld made. Since the temperature of the skelp edges to be welded must be very closely controlled, various means have been developed for regulating this temperature after the skelp leaves the furnace and before it enters the welding bell. The use of a strong air blast on the edges of the skelp just before it enters the bell was practiced for many years and is still in use. An improvement on the air blast resulted from the application of an air blast enriched with oxygen which, impinging on the edges of the skelp, raises the surface temperature and acts more effectively in maintaining the skelp edges to be butted together at the proper welding heat. This process is still used in many plants. A further application of this same principle consists in applying an oxy-acetylene jet to the skelp edges, and this method of local heating has two distinct advantages. In the first place, the temperature of the skelp edge can be better controlled by the adjustment of the oxy-acetylene flame, making it possible to maintain a definite welding temperature which will produce a uniform and superior weld. The second advantage of the oxy-acetylene gas flame is that it may be made reducing and thus decrease the formation of an oxide film on the skelp edges just prior to welding.

While the control of all these adjuncts must be very precise, equipment and adjustments have been gradually developed, which have led to improvement in the quality of weld made. In fact, pipe now being made with the oxy-acetylene gas-welding practice has produced welds which may be justly placed in the fusion class, enabling the use of welded pipe in applications to which the ordinary furnace-welded pipe is not adaptable.

The Hot Finishing of Pipe—The Sizing Rolls—When the pipe has been drawn through the welding die, the tongs are removed, and the pipe at once moves down a slightly-inclined table in front of the sizing rolls. These are electrically driven horizontal rolls of cast alloy iron, 18 inches to 24 inches in diameter, depending upon the size of the pipe to be made. They are grooved to form a perfect round, when properly adjusted. The rolls contain usually but a single groove, hence are very short and are supported in a single two-high housing. In passing through these rolls the pipe, which was purposely drawn slightly oversize, is compressed and elongated to an exact uniform outside diameter, and the weld is also improved to some extent thereby.

The Stretch-Reducing Mill—As the name implies, this mill is used for reducing the diameter of and simultaneously applying tension to the tube being produced. By this method and without the use of supporting mandrels, the wall thickness of a tube can be maintained or even decreased while the diameter is being reduced. The finished tube is considerably lengthened by this process. It can be used in the manufacture of both welded and seamless tubes.

The mill (Figure 41-5) consists of a series of pairs of rolls, mounted in housings which are spaced as close to one another as design considerations will permit. Each consecutive pair of rolls is driven at a speed in excess of that required to deliver an equal volume of metal per unit of time from each roll stand. Tension is thereby developed in the tube between stands, which permits larger diameter reductions than can be obtained without tension and, under certain conditions, a reduction of wall thickness. The close spacing of the housings is necessary to minimize the so-called "end-effect" or

FIG. 41—5. Stretch-reducing mill.

thickening of the wall at both ends of the pipe, where no tension can be applied.

The proper speed relationships are obtained either by selecting suitable change gears on mills driven by one motor or by adjusting the motor speeds on mills having individually driven housings.

The number of pairs of rolls used ranges from eight to sixteen, varying with the design and purpose of the mill.

Straightening Rolls—From the stretch-reducing mill, the pipe is transferred over a cooling table and allowed to drop into a rack. In the case of double-length furnaces, the pipe is middle-cut by a hot-saw while on the cooling table, before dropping into the racks. After being quenched in a water bosh to complete the cooling, the

pipe is then transferred to the straightening machines.

Two types of straightening machines are used. One type, known as "cross-rolls," consists of two electrically driven rolls, from two to four feet long and from ten to twenty inches in diameter, depending upon the size of the pipe to be straightened, set with their axes askew so that they cross each other to form an angle of about 30° , their center points being directly opposite each other. The body of these rolls is machined with a concave surface so that a pipe lying between them will be in contact with the rolls for their entire length. The end of a pipe that is to be straightened is inserted between the rapidly-revolving rolls which move it forward between the rolls, as it rotates, due to the axes of the rolls

FIG. 41—6. Pipe passing to cooling bed. This bed is designed to cause the pipe to cool practically straight.

TYPICAL CONTINUOUS WELD PIPE MILL

FIG. 41-7. Schematic plan of the layout of a typical continuous butt-weld pipe mill. Details of the uncoiling box are shown schematically in Figure 41-8. Figure 41-9 illustrates diagrammatically the steps performed in the operation of the flash welder. The furnace threading machine is shown schematically in Figure 41-10. Section D-D of the heating furnace is given in Figure 41-11. Operation of various parts of the forming and welding mill is explained in Figure 41-12.

FIG. 41-8. Schematic elevation of coiled-skelp handling equipment at the entry end of a continuous butt-weld pipe mill.

being askew. When the straightened pipe emerges from the straightener, it moves forward a short distance and is discharged laterally into a cradle or rack. From the cradle, the pipe is transferred by an overhead crane to the finishing equipment. The other type of straightening machine, known as the "rotary" straightener will be discussed under the seamless process.

BUTT-WELD PROCESS (CONTINUOUS)

The continuous butt-weld mill is a true continuous process starting with the coiled skelp and ending with finished pipe. Figure 41-7 shows an arrangement which is typical of many of the continuous butt-weld mills in use today.

Production of Skelp—Skelp for the continuous butt-weld process may be produced in the same manner as skelp for the conventional butt-weld process described previously. However, instead of shearing the strip into twenty-one and forty-foot lengths, only the leading and trailing ends of each strip are trimmed square and the skelp is coiled on vertical-type reels.

Uncolling the Skelp—Coiled skelp is loaded onto the uncoiler feed table and advanced by the coil pusher to the uncoiler (Figure 41-8). The end of the coil is fed into a pinch roll which is released after the skelp enters the roller leveler. The function of the roller leveler is to straighten or flatten the skelp for further processing. A typical roller leveler consists of two entering pinch rolls and five to nine leveling rolls. As the trailing end of one skelp coil is reached, the leading end of the next coil is being made ready for welding to form a continuous strip. Before the welding can be undertaken, both ends of the skelp must be trimmed square and true. If this has not been done at the skelp mill, or if the ends have become damaged, they are cut on an upcut shear which is provided ahead of the end welder (Figure 41-7). The shear is provided with incoming and outgoing guides to align the skelp properly for cutting. When the ends have been properly prepared, they are advanced through the end welder.

Welding Unit for Joining Ends of Coils—The leading end of the coil is fed into the flash welder where it is welded to the trailing end of the preceding coil to deliver an endless piece of skelp to the mills. The welding unit consists of a flash welder, stripper, pulling and gripping mechanism, side trimmers, skelp-centering device and side guides. The welding cycle for a typical end welder is shown in Figure 41-9. During the welding cycle, the ends of the skelp are, of course, held stationary.

"Looping" the Skelp—Upon completion of the welding cycle, the skelp is guided to the floor (on its edge) and formed into a large skelp loop. This loop provides sufficient skelp storage to assure continuous operation of the mill while the uncoiling unit is stopped and the front end and trailing end of the two coils are welded to-

gether. Four magnetic-roll units are provided to assist the leveler in feeding the skelp into the storage loop.

Furnace "Threading"—Vertical pinch rolls located near the end of the loop pull the skelp out of the storage loop and feed it into the furnace. The speed of the pinch roll is varied by an automatic loop control located on the back loop approximately 70 feet from the furnace. The skelp, which has been traveling on edge, again assumes a horizontal position and is fed up an inclined roller ramp to the furnace. The furnace threading machine (Figure 41-10) has driven pinch rolls, one convex and one concave, to give the skelp a dished shape to provide sufficient stiffness to permit it to be pushed through the

FIG. 41-12. Diagram depicting schematically the operations performed in a continuous forming and welding mill.

furnace during the furnace-threading operation. As soon as the skelp is entirely through the furnace and is being pulled by the forming and welding unit, the threading rolls are opened up and become inoperative until the mill must again be threaded.

The Butt-Welding Furnaces—The furnaces used on the continuous weld mills are long and narrow and usually have several firing zones, individually controlled. The furnaces may be gas- or oil-fired by burners set in the side walls and firing directly at the edges of the skelp passing through the furnace as shown in Figure 41—11. The skelp is supported on water-cooled skid bars. To secure a high production rate and good fuel economy, the furnaces usually are equipped with metallic recuperators which heat the combustion air to about 1000° F. The furnace must have sufficient length to heat the skelp passing through it to a temperature of approximately 2450° F. A blower usually is provided to furnish a blast of air on the edges of the skelp as it leaves the furnace. This raises the temperature of the edges to approximately 2600° F for welding.

Forming, Welding and Reducing Mills—Upon leaving the furnace, the skelp passes through the forming rolls which are designed to bend the skelp into an open-sided oval with the opening downward (Figure 41—12). An air- or water-cooled welding horn, which is located directly below the bent skelp and ahead of the welding stand, guides the skelp edges. A nozzle applies a jet of air, or of air-oxygen mixture, onto the skelp edges at this point to maintain welding temperature. The air blast also helps in freeing the edges from scale.

The hot skelp then passes through the second or welding stand, where the edges of the skelp are squeezed together to form the weld. A reduction of 4 to 6 per cent produces a satisfactory weld. The pipe passes directly from the welding rolls to a series of reducing passes where the diameter of the pipe is further reduced. The forming, welding and reducing stands, with individual

motor drives for each stand, consist of alternate vertical and horizontal passes.

Stretch reducing also is employed in the continuous weld mills. This principle was discussed previously under the butt-weld process.

Hot Sawing and Preliminary Cooling—A rotary-type flying hot saw is used for cutting the sized pipe to length. The saw is of the continuous running type with the length of cuts determined by the length and r.p.m. of the crank. The saws will cut lengths from 18 to 54 feet at maximum mill delivery speeds. Individually motor-driven roller conveyors which operate at greater than the mill delivery speeds are provided after each saw to carry the pipe away from the saws to cooling beds. Screw-type kickouts are provided to discharge pipe from the saw delivery conveyor to the screw-type cooling beds where the temperature is lowered enough to permit descaling and further sizing.

Sizing, Cooling and Inspecting—In a typical mill (Figure 41—7), the pipe passes from the first cooling rack onto a conveyor that carries it to the sizing machine. The sizing machine, which consists of three roll stands, performs, as its name implies, the final sizing operation.

The pipe is then taken to a second and much larger cooling rack where its temperature is lowered so that the pipe may be inspected and straightened. If the pipe has been cut to multiple lengths at the flying saw, a parting saw, usually located at the second cooling bed, cuts the pipe to standard lengths. One or more crop saws also located at the cooling bed may be utilized if required. A water bosh sometimes is incorporated in the cooling bed to provide adequate cooling capacity without excessively long cooling beds.

After being inspected, the pipe is taken to the finishing department where it is faced, threaded, tested, coated, bundled, or stenciled, as required. Pipe to be galvanized is straightened and usually faced prior to being galvanized.

SECTION 3

ELECTRIC-RESISTANCE-WELDED TUBING

Small-diameter tubing of light wall thickness, primarily for mechanical and structural purposes, is sometimes fabricated from strip which is formed into shape and welded electrically. Rimmed or killed steel may be used and such tubing is furnished either cold rolled or hot rolled, pickled and oiled according to the desired product.

Steps in the Manufacture of Electric-Resistance-Welded Tubing—The sequence of operations required in the fabrication of electric-resistance-welded tubing are slitting the strip, forming, welding, sizing, cutting and finishing.

Slitting—Strip is received at the pipe mills in coils 36 inches wide weighing up to 14,000 lbs. This wide strip must be slit into the correct width required to form the finished tube size.

The wide coils are loaded onto a ramp from which they are permitted to roll, as required, onto a charging buggy which moves the coils to the pay-off reel of the slitting machine. The buggy is provided with an elevator by which it is possible to center the coil on the mandrel of the reel which is then expanded and the retaining bands on the coil removed. The reel, which is motor driven, is rotated to slowly unwind the strip which is threaded into a set of three breaker rolls which flatten it sufficiently to facilitate threading through pinch rolls into the slitter knives. These knives, which are tool-

steel discs, are mounted on arbors above and below the strip and are spaced with rings to slit to the desired width. From the slitter the strips pass to the recoiler where they are wound between thin, steel disc spacers. The narrow strips of scrap from the edges of the wide strip pass over the recoiler onto the scrap winder.

After the strip has been threaded completely through the line, the recoiler and slitter motors are adjusted to pull it through the slitter knives with any desired tension. The slitter, recoiler, scrap winder, breaker rolls and pay-off reel are each driven by separate motors. However, the pay-off reel and breaker rolls are not synchronized with the others as they are used only when threading the strip.

When the entire coil has been slit and wound on the recoiler mandrel, steel bands are placed around each of the narrow coils. An unloading buggy is elevated under the coils which, after the mandrel is collapsed, are pushed off hydraulically onto the buggy. The coils are then banded, weighed and are ready for the tube-welding machine.

Forming—Although the range of sizes handled by each mill is limited, the process of forming and welding the tubing in the several mills is identical except for the number of rolls and the power required.

Coils from the slitting line are fed either directly into forming rolls or into a "looper" to permit continuous

FIG. 41—13. Schematic representation of the sequence of operations performed by a typical machine for making electric-resistance-welded tubes from steel strip.

forming of strip welded end-to-end in the smaller sizes. The strip first passes through an edge conditioner where the edges are shaved by cutting tools to present a smooth, clean surface for welding. The strip then passes through a series of from six to nine pairs of horizontal and three or four pairs of vertical forming rolls (Figure 41—13). The first five pairs of horizontal rolls are driven from a line shaft. The other rolls are not driven. The lower rolls are on fixed centers and the upper rolls, driven through link gearing, are adjustable so that the strip, first shaped into a shallow "U," is progressively made deeper. Finally, the sides are bent in and the strip formed into a circular shape as it leaves the last stand

of rolls. In forming wider strip, which is not looped, additional stands of rolls are used and a pair of pinch rolls provided to assist in feeding the first end of the strip into the mill.

Welding the Tube—The open tube passes directly from the forming rolls to the welding electrodes (Figure 41—14) where the seam is welded by the electric-resistance method. These electrodes are copper discs mounted on a revolving transformer so that one disc, or electrode, is on each side of the opening to be welded. The tube is guided under the electrode and pressure maintained at the weld by vertical rolls.

The welded tubes then pass under a cutting tool which

FIG. 41—14. Tube passing under welding electrodes.

removes the outside flash which resulted from the pressure during welding. After removing the flash, the tube is cooled by passing through a spray of soluble oil.

Sizing the Welded Tube—The sizing mill consists of four pairs of driven horizontal rolls and four pairs of idle vertical rolls all of which are mounted in the same manner as the forming rolls and are made of tool steel. Sizing is performed cold.

Finishing—The outside flash from the welding operation is removed by a cutting blade as was described under welding the tube. To remove the inside flash or burr on sizes over $1\frac{1}{4}$ inches, a roller-type mandrel can be placed in the tube a short distance from the welding electrode. To perform this operation an additional roll stand is required to support the outside of the tube. When the burr must be removed from tubes $1\frac{1}{4}$ inches

in diameter or smaller, the operation is performed by an air hammer located in the middle of the sizing mill. Hammering is done on the seam with a solid mandrel on the inside of the tube which is also supported underneath by a grooved die.

After the tube leaves the sizing mill it is cut to determined lengths by a rotary-head cut-off machine which travels with the tube during the cut. Either disc cutters or parting tools may be used.

The cut tubes are then transferred to the finishing floor where they are straightened in rotary straighteners. The tube is then cropped or cut to length by rotary-head cut-off machines and processed through a battery of profilers which face the ends and chamfer the O.D. and I.D. after which they are inspected and packed for shipment.

SECTION 4

ELECTRIC-WELDED LARGE-DIAMETER PIPE

Applications of the Process—Large-diameter pipe in sizes beyond the practical limits of the seamless process is fabricated by electric welding. This type of pipe, which is employed for water lines, gas mains, oil lines, tanks, pressure vessels, etc., may be made from rolled-steel plate of any weldable quality. The size of the pipe which can be made by this process is practically unlimited, since, when the circumference of the desired pipe exceeds the plate width capacity of the rolling mill, two or more plates may be welded together longitudinally to provide the necessary width or, if only a short length is desired, the plate may be bent lengthwise, permitting it to be formed with only one longitudinal weld. Where long-length, large-diameter pipe is required, the desired length may be made by welding together two or more pieces circumferentially.

Steps in the Manufacture of Electric-Welded Pipe—The sequence of operations required to make plates into pipe by the electric-weld process as practiced by National Tube Division are shearing, planing, crimping, bending, welding, expanding and finishing.

Shearing and Planing—Plates employed in the manufacture of electric-welded pipe are rolled on either a plate or strip mill as described elsewhere in this book. The plate is transferred to the edge-planing machine where it is aligned so that the two edges will be parallel and square with the ends after planing. A clamping bar, hydraulically operated, holds the plate during the edging operation. Along the full length of both sides of the table, lead screws drive carriages carrying a series of cutting tools which trim the edges of the plate.

The series of cutting tools are arranged so that no single tool will be required to remove more than a reasonable amount of stock from the rough edges of the rolled or sheared plate.

Crimping—Forming plate into the circular shape required for pipe is usually performed in three operations. The first operation, called crimping, consists of bending the edges of the plate so as to avoid a flat surface near the longitudinal seam of the pipe.

Crimping may be performed in a large crimping press which deforms the edges of the plate for a distance of approximately 6 inches in a hydraulically operated press. Crimping may also be performed by crimping rolls which roll the edges to the desired radius as the plate is drawn through the roll pass.

Bending—The crimped plate is then conveyed to what is called the "U"-ing machine. In this operation, the plate is centered over a series of parallel rocker-type

dies which lie along the axis of the plate. A large "U"-shaped die, which is as long as the longest length of plate fabricated and which is operated by a 2000-ton press, is moved down on the plate, forcing it between the dies which automatically conform themselves to the operation and assist in forming the plate into the "U" shape. The plate is then transferred to what is called the "O"-ing machine. This machine consists of two semi-circular dies which are as long as the plate to be formed. Rollers mounted on vertical spindles prevent the "U"-shaped plate from falling and keep it in correct alignment as it enters the "O"-ing machine. The "U"-shaped plate rests in the bottom die, and the top die, operated by an 18,000-ton hydraulic press, is forced down, deforming the plate until it is the shape of an almost closed circle which is then ready for welding.

Welding—Welding may be performed by any one of the numerous methods. However, the most common is the submerged-arc method. In this method, coalescence is produced by heating with an electric arc or arcs between bare-metal electrode or electrodes and the work. The welding is shielded by a blanket of granular, fusible material or flux on the work. Pressure is not used and filler metal is obtained from the electrode and sometimes from a supplementary welding rod.

It is extremely important that the gap in the formed pipe be properly positioned for welding. Two steel archways supporting a longitudinal guide are located over the conveyor approaching the welding machine. As the pipe moves over the conveyor, the guide enters and continues along the gap, guiding it into the welding machine.

The welding operation is started by striking an arc beneath the flux on the work. The heat produced melts the surrounding flux so that it forms a sub-surface conductive pool which is kept fluid by the continuous flow of current. The end of the electrode and the work piece directly under it become molten and molten filler metal is deposited from the metal electrode onto the work. The molten filler metal displaces the flux and forms the weld.

The specially designed welding heads used for this process perform the triple function of progressively depositing the flux along the joint, feeding the electrode, and transmitting welding current to the electrodes. The flux is supplied from a hopper connected to the head by tubing. The bare electrode is fed into the welding head from a coil mounted on a reel.

After the pipe is welded on the outside, the weld is inspected and conditioned on the ends when required. At this time, square pieces of metal are welded to the

FIG. 41-15. The "U"-ing machine forming the crimped plate into a "U" shape.

FIG. 41-16. 30-inch O.D. pipe emerging from the outside-welding machine.

FIG. 41—17. Expanding a 40-ft. length of 30-inch O.D. pipe in the hydraulic expanding machine.

pipe at the ends of the weld to enable the inside-welding machine to start at the end of the pipe.

The automatic machine which does the internal welding is similar in design to the outside welder, and is mounted on the end of a long cantilever arm and the pipe is drawn over this arm by a carriage.

After welding, the scaly deposit left from the flux must be cleaned out. This is accomplished by running the pipe over a series of rollers and, at the same time allowing the entry of a cantilevered tube which is attached to a vacuum system. The weld is then carefully inspected and any defects corrected with manual welding equipment.

Sizing or Expanding—The final pipe diameter is obtained by hydraulically expanding the welded shell against a retaining jacket. The pipe is placed in an ex-

panding machine and mandrels forced into each end expanding the pipe to the required diameter at the ends only. Retainer jackets then encircle the body of the pipe which is filled with water and expanded with hydraulic pressure to the limits of the jackets. The pressure is then reduced and serves as a hydrostatic test. In addition to obtaining close diameter control, this method cold works the metal, obtaining higher mechanical properties, and is a good test of the weld.

Finishing—Following the rounding-up or expansion operation, the pipe is placed in special machines which face the ends. This operation insures that the ends will be smooth and accurately within a plane at right angles to the longitudinal axis of the pipe. If the pipe is being prepared for welded joints, the ends are beveled in this operation.

SECTION 5

SEAMLESS STEEL TUBULAR PRODUCTS

Historical—Although the modern developments for manufacturing seamless or weldless steel tubes did not begin until about 1890, they are, nevertheless, the result of nearly a century of experimentation. As mentioned in the introduction to this chapter, the first attempts to make seamless tubes of steel that were commercially successful involved the two basic processes known as cupping and piercing. In the cupping process, which was first used about 1845, a circular sheet or plate was forced by successive operations through several pairs of conical dies, each pair being deeper and more nearly cylindrical than the previous one, until the plate took the form of a tube, or cylinder with one end closed. This method is still in use for certain sizes. In the piercing process, a round hole was first made along the central axis of a round billet which was then rolled and drawn over mandrels to form a tube. The mill for lengthening such hollow billets was first patented in England by Church and Harlon about 1841. The rolling mill and the draw

bench afforded simple and comparatively cheap methods of elongating the hollow billet, but the development of a method for piercing it proved a difficult matter. The oldest and simplest method was to heat the billet to a high forging temperature and hydraulically force a punch through its center while in this hot state. As it was essential that the hole be exactly concentric with the billet throughout its entire length, a feat that is hard to accomplish with a billet more than a foot or so in length, recourse was had to drilling a small hole in the cold billet, then heating the billet and enlarging the hole by piercing in a press. About 1888 a patent was granted for a process whereby a small ingot was cast about a core of refractory material, which hollow ingot was to be treated as described for hollow billets.

In the decade preceding the twentieth century, the bicycle became a very popular vehicle, and the growth of the bicycle industry created a demand for high-class seamless tubes in very large quantities. The early

methods of seamless tube manufacture were slow and tedious, and orders aggregating millions of feet of tubing for bicycle construction could not be filled. In 1895 the first American seamless tube plant, using rotary piercing, was constructed in Ellwood City, Pennsylvania, and operated successfully for many years in the manufacture of bicycle tubing. The equipment at this plant consisted of a **Stiefel disc piercer**, a **Pilger rolling mill**, and cold-drawing benches on which the tubes were finished.

After 1900 the automotive industry began to grow and had a remarkable influence on the seamless tube industry. In the first place, the popularity of the automobile soon caused a great decrease in the manufacture of bicycles, with a consequent loss of seamless tube business. On the other hand, the great increase in the use of automobiles created an immense demand for motor fuels and lubricants, which greatly stimulated expansion in the oil industry and thus developed a new and enormous market for seamless tubes. In the transition period, the seamless tube manufacturer turned to the boiler industry, and the next step in the development of the seamless process related to the production of all forms of stationary and locomotive boiler tubes. The seamless tube soon displaced the wrought-iron and lap-welded steel tubes which had previously been standard in boilers.

After World War I the discovery of enormous oil pools with flush production created a demand for pipe to be used in the wells and in the transmission lines. The later discovery, after 1920, of huge natural-gas reservoirs in remote districts, from which the gas could be transported to consuming markets only in steel pipe lines, sometimes over 1,000 miles long, resulted in another large market for seamless pipe. Some idea of the size of the oil and gas industry in the United States may be gained from the fact that there are over 500,000 producing oil wells and over 550,000 miles of pipe lines in existence.

The seamless tube mills prior to 1920 were scarcely able to make pipe over 6 inches in diameter and longer than 25 feet. In 1925 National Tube Division developed the so-called **double-piercing process**, which consisted of piercing a heavy-walled shell and then expanding this in a second piercing operation to a larger diameter tube with a lighter wall. This development made possible the production of tubes up to 16 inches in diameter. The Pilger process had also reached a production stage at this time, but a thorough study of this method caused its rejection for American manufacturing conditions because of the low production per man-hour. Further study of the **double piercing and expanding process** later led to the rotary-rolling process, by which it is now possible to produce seamless tubes up to 26 inches in diameter and in lengths exceeding 40 feet.

Scope and Requirements of Seamless Tube Products—The expansion of the seamless tube industry described above was also greatly influenced by the adaptation of the piercing process to the many different types of steels which were developed during this period. Steels melted by many processes can now be successfully converted into seamless tubes. In general, killed open-hearth and electric-furnace steels are used. However, improvements in the technique of Bessemer-steel manufacture have resulted in the production of large quantities of deoxidized acid-Bessemer steel which is converted into seamless tubes with excellent results.

Because of the severity of the forging operation involved in piercing, the steels used for seamless tubes must have good characteristics with respect to both surface and internal soundness. A study of the character of the steel as revealed by deep-etching the cross-section tends to show that a sound, dense cross-section, free

from center porosity or ingot pattern, is the most satisfactory for seamless tubes. For this reason steels of the thoroughly killed types are to be preferred to strongly rimming steels or semi-killed steels. Although rimming steels and semi-killed steels have been successfully converted into seamless tubes, the results are not always uniform, either because of a poor inside surface, due to internal porosity, or because of high losses from external seams, caused by surface defects. Metallurgical developments since 1920 have contributed greatly to the improvement of steels for seamless tubes and are discussed in detail in another section.

As a result, the seamless process has been extended to include practically all of the regular and alloy grades of steel. At the present time all of the ordinary carbon steels, even those containing as much as 1½ per cent of carbon, are processed in commercial quantities. Many of the high-sulphur steels developed for machining are also manufactured into seamless tubing.

All of the intermediate alloy steels, such as those listed in the specifications of the American Iron and Steel Institute and the Society of Automotive Engineers, are available in tubing. As a consequence the application of seamless tubing to automotive parts has been extended until there is now between 150 and 200 lbs. of tubing in each car manufactured. The alloy steels used by the ball and roller-bearing industry are now available in seamless tubing. This tubing is made from steel of special cleanliness.

In the last twenty years, numerous steels of special composition for heat and corrosion resistance have been developed. Seamless tubes are now satisfactorily made from material of most of these steels. These include the chromium steels containing from 1 to 30 per cent chromium and numerous other alloyed steels containing chromium with additions of such elements as molybdenum, nickel, manganese, columbium (niobium), silicon, and titanium. In general, it can be stated that all of the alloys which are ferritic or pearlitic in structure are satisfactory for piercing. The alloy steels which are generally of the austenitic type can be successfully pierced if the austenite remains stable at forging temperatures. A few of the austenitic steels which have a considerable proportion of ferrite at forging temperatures have not, as yet, been satisfactorily pierced. For example, an alloy such as the 25 per cent chromium—10 per cent nickel, which is partially ferritic, will not pierce, whereas an alloy with 25 per cent chromium and 20 per cent nickel can be pierced satisfactorily.

Seamless pipe of numerous special properties has been developed to meet the needs of the oil industry. In this field the pipe employed for rotary drilling must possess great torsional strength and high resistance to fatigue stresses. An idea of the stresses to which the pipe is exposed in drilling service may be gained from the realization that the power for the rotation of the drill bit on the lower end of the pipe is applied at the upper extremity, which, in some cases, is more than three miles distant. The string of drill pipe itself may weigh up to 370,000 lb., and when rotating at 200 r.p.m. or more, only material of the highest strength and toughness will perform satisfactorily. Drill pipe is usually made with heavy upset ends, and the full lengths of pipe are normalized on the completion of the forging operations.

The casing for such deep oil wells requires seamless pipe having a high resistance to collapse to withstand the high external pressures which exist. Casing has been set to depths of nearly 20,000 ft. under very high hydrostatic heads. Other classes of seamless pipe and specialty tubing made for the oil industry include oil-well tubing, pump tubing, and line pipe.

The expansion of the oil-refining, chemical, and high-pressure steam industries has also demanded special seamless pipe. Satisfactory alloy-steel tubing and pipe are made to withstand temperatures up to 1200° F coincident with pressures as high as 3000 lbs. These industries also use high-pressure pipe lines at temperatures as low as -150° F, and steel pipe which is tough and strong at these low temperatures is now produced in considerable quantities.

Steelmaking Practices—As indicated previously, the steel for seamless tubes must be made with special forging properties. The major portion of the tonnage used consists of straight carbon steels, ranging from 0.05 per cent to 0.50 per cent carbon and 0.35 per cent to 1.50 per cent manganese. These grades are made in standard, stationary open-hearth furnaces and special tilting open-hearth furnaces employing the duplex melting process. Many of the special alloy steels are necessarily melted in basic electric furnaces to obtain the particular metallurgical requirements which are often specified. The open-hearth furnaces tap between 150 and 180 net tons and are of the mixed-fuel type, burning tar or oil and coke-oven or natural gas.

The stationary open-hearth furnaces making these steels at National Tube Division operate on approximately a 40-per cent cold-scrap, 60-per cent hot-metal (basic iron) charge, while the tilting furnaces are charged with a mixture of blown metal from the Bessemer converter and the requisite amount of molten pig iron with varying additions of cold steel scrap, depending upon the conditions at the plant. Regardless of the initial charge in either the stationary open-hearth or the duplex melting furnace, the slags employed and the final working and refining periods in the two types of furnace are identical.

As stated previously, seamless tubes are also produced from deoxidized Bessemer steel. This is an acid-Bessemer steel which has been treated in the vessel to remove a considerable portion of the dissolved oxygen as a gas and further treated in the ladle to develop a silicon content of 0.10 to 0.30 per cent. Deoxidized Bessemer may also be produced by treatment in the ladle with sufficient aluminum or its equivalent to insure practically no evolution of gases during solidification. Deoxidized acid-Bessemer steel is a killed steel with a homogeneous ingot structure as compared to the conventional rimmed or capped Bessemer steels. The importance of having good forging properties can best be realized by the fact that previous to the development of deoxidized Bessemer steel, it was commercially impractical to produce seamless pipe, by the piercing process, from Bessemer steels.

Deoxidized acid-Bessemer steel has a high ratio of yield strength to tensile strength. Its machining and welding properties are similar to open-hearth steels of equivalent mechanical properties. The combination of high yield strength and good ductility makes it peculiarly suited for seamless tubular products. Over a period of years, a considerable amount of experience has been gained by the National Tube Division in applying deoxidized acid-Bessemer steel to many types of seamless tubular products.

Since the surface quality of the steel for seamless tubing is of the utmost importance, molds are thoroughly cleaned, hot dipped, and coated on the inside surface with pitch or other carbonaceous material before the steel is teemed. The ingots used are of corrugated contour and range in weight from 10,000 to 22,500 lb. Various forms of hot tops are used for special requirements.

Rolling Mills—The rolling mills consist of blooming mills and bar mills. The practice employed at the rolling

mills in preparing the semifinished round used in producing seamless pipe has a definite influence on the quality of the finished product. The time elapsing between pouring of the ingots and charging in the soaking pits, the time in the soaking pits, and the heating of the ingots at carefully regulated temperatures for the various grades of steel are some of the factors which receive close attention and are made a matter of supervision by the metallurgical departments. The use of rolls without ragging and the practice of rotating the ingot through 90 degrees after two drafts in collared passes have proved advantageous in eliminating mechanical surface defects.

The uniformly heated ingots, varying in size from 23½-inch by 26½-inch to 32-inch by 32-inch depending on the bloom size and billet requirement, are rolled in 40-inch two-high reversing mills according to definite schedules of light drafts in the initial passes and uniform reductions in succeeding passes. When the ingot has been reduced to the required bloom section, it is sheared for the top and bottom discard, the extent of the discard being regulated by the type of steel, the character of the heat, and the appearance of the blooms produced.

The major portion of the blooming-mill product is delivered direct after shearing and without reheating to two-high reversing bar mills which are located in tandem with the blooming mill. The bar mills are provided with a number of extra housing sets, which permits a roll change to be made in less than 10 minutes. Rounds 4¾ inches to 13¾ inches in diameter are thus rolled direct from ingots. Smaller-sized rounds are produced by the reheating of small blooms and rolling on additional bar mills.

The bar-mill rounds are hot-sawed to length and centered for the seamless mills. Seamless-tube rounds must be rolled to an accurate diameter and cut to accurate lengths, as each round produces a given length of pipe and accurate round weights are necessary. All rounds are hot-stamped for identification and racked in cradles for the various tube orders.

The solid rounds used for making seamless tubes must undergo a thorough surface-conditioning operation. It is now general practice to peel all rounds 4¾ inches and larger, and then by chipping or by scarfing with an oxy-acetylene torch to remove any remaining seams or other defects evident to the inspectors. Rounds smaller than 4¾ inches in diameter are converted from small blooms from which the surface defects have been removed by chipping or scarfing. The most careful attention to the thorough removal of surface defects is necessary to eliminate seams and other pipe-mill losses.

Sequence of Operations—The sequence of operations in seamless-pipe mills varies slightly from mill to mill. At the Lorain Works of National Tube Division it follows three general patterns determined by the size of the pipe to be produced. The round billets are first uniformly heated to piercing temperature in special gas- or liquid-fuel-fired furnaces. They are then processed through the various operations in the following order, depending upon the diameter of tube to be produced:

Pipe Size—2-inch to 4½-inch diameter
Piercing Mill
Plug Rolling Mill
Reeling Machine
Reheating Furnace
Sizing Machine

Pipe Size—3½-inch to 16-inch diameter
First Piercing Mill
Second Piercing Mill

(Continued on Next Page)

Plug Rolling Mill
Reheating Furnace
Rotary Rolling Mill
Reeling Machine
Reheating Furnace
Sizing Mill

The operation of each of the above units will be described in detail in the remainder of this section. In the overlapping sizes of the range 3½-inch to 4½-inch diameter, the heavier-wall pipe is processed through only one piercing operation whereas the two piercing mills are employed in producing the light walls. Also, in the overlapping sizes of the range 14-inch to 16-inch diameter, the lighter-wall pipe is rotary rolled, the heavier-wall pipe by-passing the second reheating operation and the rotary-rolling mill.

The Mannesmann Machine for piercing round billets for making seamless tubes was patented in 1885. In this machine, the principle of helical rolling is employed. The two steel rolls, which bring into play the forces used to produce the cavity in the work piece, are positioned side by side and have their axes inclined at opposite angles 6 degrees to 12 degrees with the horizontal center-

line of the mill. These rolls measure from 20 inches to 30 inches in length and from 32 inches to 48 inches in diameter. The roll surfaces are contoured so that, in the horizontal plane through the centerline of the pass, the space between the rolls converges toward the delivery side for a length of from 5 inches to 15 inches to a minimum, called the gorge, and then diverges to form the pass outlet. The converging and diverging angles formed by the roll surfaces vary from 2 degrees to 12 degrees. The shafts of these rolls are mounted in bearings which can be adjusted laterally in the housing to permit the space between the rolls to be properly set for the size of work piece being rolled. The inlet end of each roll shaft is fitted with a universal coupling which, through long spindles, connects with a common reduction gear powered by an electric motor. The size of this motor and reduction unit depends on the size range to be produced on the mill, varying between 700 and 3,500 h.p. These motors are designed for a pullout torque of 300 per cent. The rolls are cooled by water sprays. The elevation of the centerline of the pass is determined by two guides, one of which is mounted above and the other below the center of the mill in the space between the rolls.

Between these guides in the pass outlet a projectile-shaped piercing mandrel is held in position on the end of a water-cooled mandrel-support bar, located on the delivery side of the mill. The opposite end of this bar is mounted in a thrust bearing which is carried in a reciprocating carriage that is latched stationary during the piercing operation. The pointed end of the piercing mandrel extends just beyond the gorge toward the entering side of the rolls.

The Operation of Piercing—A solid round bar or billet of the proper length and diameter to make the size and

FIG. 41-18. Mannesmann piercer in operation.

FIG. 41-19. Sketch illustrating action of different parts of Mannesmann piercer in the piercing of a solid billet.

weight of tube desired, is heated uniformly to the usual temperature for rolling light sections. With the rolls revolving at constant speed (800 to 1000 surface feet per min.), the heated billet is transferred to a horizontal trough, which positions the axis of the billet on the inlet side of the mill coincident with the centerline of the pass.

The heated billet is pushed forward into the space between the rolls, which has been adjusted so that the gorge is approximately $\frac{3}{4}$ inch less than the diameter of the billet. As soon as the leading end of the billet has

contacted the rolls, the force of the pusher is removed. Because of the obliquity of the roll axes, the motion imparted to the billet between the rolls is one of rotation and axial advance. When the leading end of the billet has advanced to the gorge, it encounters the nose or pointed end of the piercing mandrel. The grip of the rolls is sufficient to continue the advance of the work piece against the retarding effect imposed by the piercing mandrel. When the rearward end of the billet is rolled clear of the piercer mandrel, the thrust-bearing carriage

FIG. 41-20. Sketches illustrating action of rotary-piercing mill on the round billet.

is unlatched and the mandrel withdrawn from the billet, now a hollow shell, which is then conveyed to a reheating furnace in preparation for further fabrication into a finished tube. These shells are produced in lengths up to 26 feet in less than a minute.

The Action of the Rolls—It is evident that the forward motion of the billet is caused by the inclination of the axes of the rolls. How these two rolls, by exerting pressure only on a surface of the billet, are able to force the metal over the mandrel to form a tube from a solid billet is not so readily grasped. It is to be especially noted that the mandrel is not forced through the metal, but that the rolls cause the metal to flow over and about the mandrel. To bring about this result, the rolls must first draw metal away from the center of the billet, which action tends to form a central hole, or cavity, for the entrance of the piercer point. The truth of this statement is evident from the fact that a small, but somewhat irregular, hole may be formed in a billet without the use of the piercer point. In practice, the end of the piercer mandrel is placed sufficiently forward to prevent the formation of a cavity ahead of the point. Advantage is taken only of the tendency of the rolls to form this cavity.

The Principle Involved in Forming the Cavity—Indeed, such a hole can be opened up in the center of any solid cylindrically shaped plastic body by rolling it between, even, two flat surfaces. Steel workers, particularly hammermen, are familiar with the fact that, if a piece of steel in the form of a round be pressed or hammered into an oval form several times in succession, a rupture will occur in the center that will extend longitudinally through the middle of the bar. The reason for the formation of this rupture is plainly due to that fact that when pressure is applied to the round bar at diametrically opposite points sufficient to deform it, making one diameter shorter and that at right angles to it longer, the spreading of the metal, which takes place along the long diameter and in opposite directions, sets up a lateral tension that may cause its particles to be drawn away from the center (Figure 41—20).

Flow of the Metal in Piercing—As the billet, which is in a plastic state, enters the mill, the rolls grasp it at diametrically opposite points on its circumference. As they draw the billet forward in the converging portion of the pass, they continue to compress it at these opposite

points and, since the billet is being revolved rapidly, these points are continually changing. As the compressive rolling or cross-rolling proceeds from the point of initial contact of the piercer rolls to the gorge, the diameter of the billet is reduced and the section is changed from a circle to an oval with the long diameter in a vertical position. Since the billet is rotating, the central portion is acted on by all of the forces which are applied around its circumference during successive contacts between the billet and rolls. If a sufficient reduction is effected in this manner, a cavity will be formed in the center of the billet even without the presence of a piercer mandrel. In practice, this cavity is not permitted to form in advance of the nose of the mandrel, since the rough surface of the self-formed cavity might not permit the inner surface of the shell to be subsequently rolled smooth by the action of the mandrel. It is for this reason that the end of the piercer mandrel is positioned in advance of the gorge so that it will actually effect the opening in the center of the billet, being assisted in its function by the cross-rolling action. To avoid the difficulty of accurately centering the mandrel, the forward end of the billet is centered to insure that the point of the mandrel will penetrate the billet at or very near its axis. Centering is not absolutely necessary; however, it assists in starting the end of the mandrel in the center of the billet and reduces wear on the mandrel. If the end of the piercer mandrel is positioned too far in advance of the gorge, the cross-roll action on the center of the billet will not be great enough to reduce the resistance sufficiently to permit the grip of the rolls to advance the billet over the mandrel.

Once the end of the mandrel has penetrated the axial center of the billet, the piercer mandrel serves as a third roll so that, with the properly designed pass, the metal of the work piece is helically rolled over the piercing mandrel (rather than extruded) to produce the hollow shell. The grip of the rolls on the hollow in the diverging portion of the pass, due to the obliquity of the roll axes, tends to draw the billet forward as the reduction in wall thickness is being made, and, as a consequence, tends to increase the length of the pierced hollow shell at the expense of diameter.

Double Piercing—It is to be especially noted that the amount of metal displaced increases considerably as the O.D. size (outside diameter) is increased. In 1925, the National Tube Division developed the process known as double piercing. In this process the solid billet is

FIG. 41—21. Rotary-rolling mill.

FIG. 41—22. Rotary-rolling mill in operation.

first pierced to a comparatively heavy-walled shell, after which, without reheating, it is put through a second piercing mill. The second mill further reduces the wall thickness and increases the diameter and length of the piece. This practice has extended the permissible diameter range of the automatic-mill method of producing seamless tubes by dividing the requisite work of piercing in the two stages. The double-piercing process has the further advantage that it definitely improves the concentricity of the tube, since any eccentricity produced in the first operation results in a temperature differential between the thick and thin sections which favorably influences the displacement made in the second piercing mill.

Rotary Rolling—The large demand for pipe between 16 inches and 36 inches in outside diameter for the transportation of natural gas for long distances raised a serious question as to the best manner of manufacturing such pipe. The existing lap-weld processes for making such pipe sizes were both costly and slow and also unsuited for the manufacture of lengths over 40 feet. It is also not feasible to roll pipe over 16 inches in diameter on the automatic rolling mill, and this feature made it questionable whether seamless pipe in these sizes could be economically made. The National Tube Division developed the rotary-rolling mill, which has made possible the production of pipe as large as 26 inches in outside diameter in lengths up to 45 feet and with wall thicknesses as light as 0.312 inch. Other large sizes are produced with wall thicknesses as light as 0.250 inch.

The rotary-rolling mill is a modification and enlargement of the cone-type piercing mill. The shafts of this mill, which drive the 74-inch (diameter) conical rolls, are in separated horizontal planes and are at an angle of 60 degrees with the axis of the pipe being rolled. A diagram of this mill is shown in Figure 41—21. Each shaft is powered with a 1500-h.p., 200-500-r.p.m., D.C. motor, which provides peripheral roll speeds of 800 to 2400 feet per minute. In operation, the conical rolls grip and spin the pipe, feeding it forward over a large tapered mandrel, thereby effecting a decrease in the wall thickness of the pipe and an increase in the diameter. The length of the tube is substantially unchanged by the operation. The rolling action is similar to that which takes place in a tire- or ring-rolling machine, except that in the rotary-rolling mill a forward helical advance is imparted to the tube, which is supported on the inside by the tapered mandrel.

The Plug Rolling Mill is a motor-driven, non-reversing, single two-high stand, which resembles a reversing bar mill. There are, however, several differences between the two. Instead of roll tables, the mill is equipped on the entering side with a movable trough and pusher and on the delivery side with a stationary guide table and mandrel-bar support. The guides on the latter table, two or more in number, are of the double-bell type and are mounted on cross beams and lined up one behind the other directly in back of the grooves in the rolls. The water-cooled mandrel bar, which is anchored in the support at the rear of the table, projects

FIG. 41—23. Plug rolling mill.

through a series of these guides with its opposite end terminating about $\frac{1}{4}$ inch short of the vertical centerline of the rolls. The free end of the mandrel bar provides support for the mandrel or plug during the working cycle. The work rolls, which are from 22 inches to 38 inches in diameter, depending upon the size of the mill, have several semi-circular grooves machined in their surface. With the rolls in position one above the other, the opening formed by the groove is not a true circle but is slightly oval with the long axis in a horizontal plane. This flare of the groove at the roll surface is provided to prevent the edge of the groove from shearing the work piece. In general, only one mandrel bar and one groove are used in the rolling of a given size tube. The tube is passed through this roll stand twice, being rotated through 90 degrees between the passes so that the entire surface receives an equal and similar treatment in the slightly ovalled groove. To permit the tube to be stripped rapidly from the mandrel bar, the top roll is supported by counterweights and arranged to be elevated mechanically for a rapid opening of the pass. Stripper rolls, located just to the rear of the main rolls, are grooved to correspond with the main rolls. The lower stripper roll is also arranged for mechanical movement for rapid closing of the pass. These stripper rolls rotate in a direction opposite to that of the main rolls and function only when the top main roll is in its elevated or open pass position.

The Operation of Plug Rolling—The pierced shell, except for the smaller pipe sizes, is reheated after the

piercing operations. With the pierced shell lying in the feed or delivery trough, an alloy-steel mandrel or plug is attached to the end of the bar, the bar holding the plug at the correct position in the roll groove. The plug is somewhat larger in diameter than the support bar in order to provide clearance between the inside of the tube and the support bar. In order to start the shell over the plug and permit the rolls to secure a good bite upon it, the shell is shoved into the pass with considerable force by a compressed-air-operated ram or pusher. Once started, the force of friction due to the pressure exerted by the revolving rolls is sufficient to draw the shell rapidly over the plug, slightly reducing its diameter and wall thickness and increasing its length. As soon as the shell has passed through the groove, the mandrel is removed from the bar. The top work roll is elevated approximately $1\frac{1}{2}$ inches. The lower stripper roll is then elevated to raise the tube clear of the bottom work roll and to grip it in the grooves of the stripper rolls, which return it to the entering side of the mill. Another mandrel is then placed on the bar, and the tube is rotated through an angle of 90 degrees. The top work roll and the lower stripper roll are returned to their original position, and the pusher again enters the tube in the pass. As soon as the tube has passed through the groove for the second working pass, it is returned again to the entering side of the mill, from which it is discharged for further fabrication. In this way the wall of the tube, supported by the mandrel on the inside and subjected to the action of the rolls on the outside, is reduced in thickness to the

FIG. 41-24. Schematic plan view (above) and elevation (below) of a plug rolling mill.

gage desired. The pierced billet is proportionately lengthened and slightly reduced in outside diameter. The wall reduction normally made in the plug mill is approximately $\frac{1}{8}$ inch to $\frac{1}{4}$ inch. After plug rolling, the tube has a uniform wall of the desired thickness throughout but is slightly out of round or oval shaped, not perfectly straight, and still at a bright-red heat.

The Reeling Machine is similar in construction and operation to the Mannesmann piercer except that the rolls, which are about 30 inches long and 34 inches in

diameter, are almost cylindrical in form. The rolls are adjusted laterally in the same manner as that described for the Mannesmann piercer and are separated by a space a little less than the diameter of the tube to be reeled. The rolls are motor-driven and are geared together to revolve in the same direction at a surface speed of approximately 900 feet per minute. In operation, a cylindrical mandrel, which is placed between the rolls, is supported on the delivery end by a water-cooled mandrel-support bar. Like the piercing mill, the opposite

FIG. 41-25. Reeling machine.

FIG. 41—26. Reducing and sizing machine.

end of this bar is connected to a thrust bearing carried in a reciprocating carriage, locked stationary during the reeling operation. On the inlet side of the mill a conveyor carries the tube through stationary guides to contact with the rolls. Since the rolls are revolving in the same direction and with axes oppositely inclined, they cause the tube to revolve and helically advance over the mandrel. The elevation of the mandrel and tube during reeling is maintained in the proper horizontal position by stationary guides mounted between the reeler rolls above and below the pass. Owing to the fact that the total space between the reeler rolls and the mandrel is a few thousandths of an inch less than twice the wall thickness of the entering tube, a slight reduction in the thickness of the wall is effected during the reeling operation. This slight reduction made in the reeling operation has the effect of burnishing the inside and outside surfaces of the tube and slightly increasing its diameter. The function of the reeler is, therefore, to round up and to burnish the inside and outside surfaces of the tube delivered from previous fabricating operations.

Sizing the Tube—The manner of sizing the reeled tube depends on the diameter of pipe that is being produced. For sizes 3 inches and over the sizing process consists merely of passing the tube, reheated if necessary, through two or more stands of sizing rolls, the grooves in which are slightly smaller than the diameter of the tube delivered from the reeler. The diameter reduction effected in the sizing mill is made to insure uniform size and roundness throughout the length of the tube.

Since it is not economical to pierce, roll and reel tubes

of small diameter, the production of hot-finished tubes less than 3 inches in diameter requires a reducing and sizing process for which a special machine is employed. This machine is similar to a continuous rolling mill. It consists of 8 to 16 stands of two-high grooved rolls about 12 inches in diameter, arranged on the continuous plan and set about 2 feet apart, center to center. Instead of standing vertically, the housings for these rolls are inclined 45 degrees, so that adjacent stands lie at right angles to each other and the loci of the centers of the pass openings formed by the grooves, which gradually decrease in size from the first to last, are in the same straight line. The grooves in the initial stands are slightly oval in shape. However, the grooves in the last two stands on the delivery end of the mill are preferably round. As the tube from the reeling machine is too cold to be reduced in diameter, it is passed endwise into a long reheating furnace located at the entering end of the reducing mill where it is heated to a uniform temperature just below the scale-forming point. It is then pushed by a mechanical pusher directly into the first stand of the reducing rolls, being drawn continuously through the successive stands in which it is elongated and reduced to the outside diameter desired. The smallest size to which tubes are generally reduced by this process is $1\frac{1}{4}$ inches. By properly regulating the surface speed of the successive roll stands, the elongation is made to compensate almost exactly for the decrease in diameter, while the wall thickness remains substantially unchanged.

Warm Working—It has been known for some time that

the cold working of steel pipe by various drawing, rolling, or compressing methods will raise the yield strength and in some cases increase the collapse resistance. Such material worked at room temperature loses a considerable amount of ductility. If steel which has a yield point of 60,000 lb. per sq. in. is cold worked to raise the yield point to 90,000 lb. per sq. in., a considerable amount of force must be exerted. A steel having a yield point of 60,000 lb. per sq. in. at room temperature will have a yield point of approximately 30,000 lb. per sq. in. at some higher temperature. The amount of force or work required to deform the steel at this higher temperature is much less, although the increase in the yield point of the steel is quite similar to that obtained when the work is done at room temperature.

National Tube Division practice in warm working consists of making seamless pipe in the conventional manner, but slightly oversize. After hot sizing, the pipe temperature is equalized over its entire length to the desired temperature, which ranges from 650 to 1,000° F, and is quickly passed through a five- or seven-stand set of sizing rolls following which it is air cooled on regular cooling tables. The reduction in diameter in this pass is approximately 5 per cent.

The furnace used to equalize the pipe temperature is divided into two zones: a cooling, or heating zone if cold pipe is charged, and an equalizing zone. Air is heated, passed through the ducts into the furnace and recirculated. Thermocouples placed in the air ducts control the temperature within narrow limits.

As previously stated the mechanical properties are increased by warm working. Test results show that a carbon steel which, in the as-rolled condition, will average 65,000 lb. per sq. in. yield strength and 108,000 lb. per sq. in. ultimate strength with an elongation of 27 per cent

in 2 inches will, after warm working, average 95,000 lb. per sq. in. yield strength, 115,000 lb. per sq. in. ultimate strength with an elongation of 24 per cent in 2 inches. Resistance to collapse, one of the most important considerations in oil-well-casing design, is markedly increased by warm working. For example, 7-inch O.D. casing with a wall thickness of 0.317 inches will have its collapse value increased from an average of 4,370 lb. per sq. in. in hot-rolled pipe to 6,320 lb. per sq. in. after warm working, an increase of 45 per cent.

Spray-Quenched Deep Well Casing—When higher strength casing than that produced by the warm-working process is desired for deep oil wells, carbon-manganese steel pipe is heat treated by a special process developed by National Tube Division. In this process, the hot-rolled pipe is heat treated in a continuous unit by water quenching from 1650° F and tempering at 600 to 1000° F. A series of barrel-type gas-fired furnaces are used for heating the pipe. During heating and quenching, the pipe is rotated. The total length of the eight-barrel continuous furnace (Figure 41—27) is 47 feet, and the rate of heating, depending on pipe size, is 5 to 20 feet per minute. The capacity of this unit may be increased by the addition of more barrel furnaces. After heating to 1650° F, the pipe is quenched as it passes through a specially designed water-spray ring containing nozzles which spray water on the complete periphery of the pipe.

After quenching, the steel pipe is placed in a tempering furnace (Figure 41—28) and heated in a 50-minute cycle to 600 to 1000° F, depending upon the final properties desired. The pipe is rotated during heating in the tempering furnace to maintain straightness and uniformity of heating. The continuous tempering furnace is fired with gas and the pipe temperature is checked with a radiation-type pyrometer as it leaves the furnace.

FIG. 41—27. Heating and spray-quenching equipment.

FIG. 41-28. General view of the entry side of a tempering furnace for quenched steel pipe.

FIG. 41-29. General view of a set of five stands of sizing rolls.

FIG. 41-30. Cut-off machine for the preparation of pipe for the cold-expanding operation.

FIG. 41-31. Expander head and guide with pipe in position to be expanded (24-in. outside diameter by 0.500-inch wall pipe).

When the pipe leaves the tempering furnace, it immediately passes through a set of five stands of sizing rolls, shown in Figure 41—29. Due to the formation of martensite during quenching, an expansion of the steel occurs which increases the outside diameter of the pipe, and introduces a limited amount of ovality and out-of-straightness. The sizing operation insures uniform size in the quenched and tempered product; however, the severity of the sizing pass must be limited.

Test results show that a carbon-manganese steel with average hot-rolled mechanical properties of 64,000 pounds per square inch yield strength, 100,000 pounds per square inch ultimate strength and 30 per cent elongation will, after spray quenching and tempering, exhibit average mechanical properties of 123,000 pounds per square inch yield strength, 136,000 pounds per square inch ultimate strength and 23 per cent elongation. A marked increase in collapse resistance also results from this heat-treating process. For example, 7-inch O.D. casing with a wall thickness of 0.408 inch will have its collapse resistance increased from 6,400 pounds per square inch in hot-rolled pipe to 12,290 pounds per square inch after heat treating—an increase of 92 per cent.

Cold-Expanded Seamless Pipe—One of the new developments in the line-pipe industry is the production of seamless cold-expanded pipe in sizes 16 to 26 inches O.D. This pipe presently is being manufactured at the Lorain Works of National Tube Division.

The hot-rolled seamless pipe produced in a Mannesmann-type mill from solid billets up to 12¼ inches in diameter is expanded in a rotary-rolling mill. After the pipe leaves the rotary rolling mill, it enters a pair of cut-off machines (Figure 41—30) which trim both ends. In these machines (the first of their kind in America) the pipe is held stationary as a six-tool cutting head revolves around the end, cutting through from the outside of the pipe. The new machines are controlled automatically by electronic devices.

The pipe is next conveyed to the cold expander shown in Figure 41—31, where it drops into the expander trough and one end is held firmly against a backstop. A 60-foot ram made of 14-inch O.D. seamless pipe is positioned at the opposite end of the pipe and an expander plug is fitted on the bar cap at the end of the ram. The expander plug is then forced through the pipe by a pressure of 300,000 pounds (1500 horsepower).

At the end of the stroke, the backstop opens to permit passage of the plug, which drops from the bar cap onto an elevator. The elevator lowers the plug to a conveyor which carries it back to the entry end. Here another elevator raises it to an automatic aligner which again positions it for fitting onto the bar cap and expanding another pipe. Five plugs of the same diameter are used in sequence to permit uninterrupted operations and cooling of the plugs between use. The expander plugs, made at the Lorain Work's foundry, are built-up discs fitted with nickel-chromium-iron alloy rings. The plugs to produce expanded seamless pipe of 24-inch nominal outside diameter are under 24 inches in diameter and 8½ inches thick. They expand the pipe to its nominal outside diameter. Power is supplied to the ram through an electrically driven gear-reduction unit. Two heavy chains, one on each side, are attached to a cross head to drive the ram. The plug is lubricated through a flexible pipe which feeds from a reel and leads through the ram to the bar cap. Clamps which hold the pipe in the expander are operated by an oil hydraulic system at 2000 pounds per square inch pressure.

After cold expansion, the pipe enters a rotary straightener and then is conveyed to an inspection table where

it is rotated during visual inspection. Two rings are cut from each lot of pipe. One is flattened and prepared for a standard strip tensile test to determine ultimate strength and elongation and the other ring is hydraulically tested for transverse yield strength.

After the pipe ends are beveled, the finished pipe is again inspected for surface and end flaws, after which it is hydrostatically tested to a pressure that exerts a fiber stress equivalent to 85 per cent of the specified minimum yield strength.

Pipe manufactured by this process is cold worked in the transverse direction. The operations involved in cold expanding a seamless pipe about 40 feet long may be performed in 60 seconds, using a ram speed of 175 feet per minute. Depending upon the size, cold-expanded seamless pipe is produced at the rate of about 50 tons per hour. The diameter of the pipe is increased during cold working and, although a water-soluble oil is used as a lubricant, there is a temperature rise in the pipe during expansion. The pipe length is reduced about 1½ per cent, with less than 1 per cent change in wall thickness. Cold working seamless pipe in the transverse direction increases the yield strength to a greater degree than the ultimate strength. Excellent transverse ductility is obtained due to the nature of the seamless process.

The Continuous Seamless Process—The two most recently constructed National Tube Division seamless mills utilize equipment entirely different than that used in the conventional seamless process. The rolling mill and reeler of the conventional mill are replaced by a continuous rolling mill (Figures 41—32 and 41—33) with nine tandem individually powered stands of two-high grooved rolls. Figure 41—32 illustrates the method of reduction employed by this continuous rolling mill. The rolls in the consecutive stands have their axes at 90 degrees to each other and are driven by motors which provide a total of 8500 horsepower. The pipe mill requires an internal mandrel against which the work piece is rolled to reduce wall thickness. This cylindrical mandrel extends entirely through the pierced billet and passes through the mill with the work piece. In the first two roll stands, the diameter of the pierced billet is reduced so that the inner surface is in substantial contact with the mandrel bar. Each of the next two stands makes a reduction in wall over a portion of the circumference, the two jointly completing the first increment of reduction. The next two stands, the fifth and sixth in this mill, make a similar complete reduction but of somewhat less magnitude. The next two succeeding stands (7 and 8) are designed to effect a very slight reduction, the purpose of which is to planish the tube surface. The shape of the tube which has been oval in the preceding stands is changed to approximately circular section in the ninth stand. The rounding up operation effected by this stand frees the inner surface of the tube from the mandrel bar to facilitate withdrawal of the mandrel.

In the operation of the mill, after a billet has been pierced by a conventional Mannesmann piercing mill, a lubricated mandrel, considerably longer than the pierced shell, is inserted and both pass through the rolling mill. The tube and mandrel are then kicked out of the pass line to a stripper which mechanically removes the mandrel (Figure 41—34). The rolled tube is then further processed by one of two methods depending on the desired product.

After withdrawal of the mandrel, the rolled tubes are reheated (Figure 41—35) before being processed in either a sizing mill or a tension reducing or "stretch" mill. The stretch mill (Figure 41—36) which is similar in construction to the continuous rolling mill, consists of twelve two-high roll stands with the individual stands

FIG. 41-32. Pass design for a nine-stand continuous tube-rolling mill when rolling 5.250-inch O.D. by 0.240-inch wall pipe shell.

FIG. 41-33. Overall view of a nine-stand mandrel mill.

powered by 200-horsepower motors. Tension reducing, as described in connection with the butt-weld process, is unique in that without the use of a supporting mandrel the wall thickness is diminished while the diameter is reduced. This operation differs from the conventional reducing mill in which the wall thickness of the tube is increased as the diameter is reduced. In the tension reducing mill, the tension forces to which the tube is subjected between roll stands are not only effective in

reducing the wall thickness of the tube but, in addition, make possible in successive stands more than 20 per cent greater diameter reductions than can be made in the conventional mill. The faculty of permitting the entering tube wall to be maintained or reduced while large diameter reductions are being made in successive stands permits a single entering tube size to be employed for the production of all tube sizes in the size ranges up to 3½-inch O.D. This unit, therefore, permits production at

FIG. 41-34. Mandrel bar being removed by stripper conveyor from rolled tube held against stripper block.

FIG. 41—35. Interior view of a tube-reheating furnace.

FIG. 41—36. Overall view of part of the twelve-stand stretch-reducing mill, with tube-reheating furnace in background.

approximately constant tonnage regardless of the diameter being produced.

To produce 4½-inch O.D. tubing, the maximum size currently being produced on this seamless mill, the rolled tube is sent through a sizing mill instead of the stretch reducing mill.

Having both a sizing and stretch mill permits continuous production since it is possible to divert tubes to either unit depending on the desired size.

The pierced billet which is 5½ inches O.D. by 0.450-inch wall by 22 feet long and pierced from a solid round 5½ inches in diameter by 8 feet long, will emerge from the continuous reducing mill as a tube 5 inches O.D. by 0.200-inch wall which is 62 feet long. This tube, after passing through the stretch reducing mill, if rolled into 2¾-inch O.D. tubing with 0.190-inch wall, will be 140 feet long.

The long tubes are cut into two sections by a rotary

saw on the cooling table. The half sections are then cut into predetermined lengths by high-speed rotary-blade cutters before going to the finishing floors.

Rolling Heavy-Wall Tubing—When rolling heavy-wall tubing, the pierced shell after leaving the piercing mill by-passes the continuous rolling mill and goes directly to an Assel mill (Figure 41—37) which is specifically designed to roll this product. It consists of three equally spaced rolls set at an angle of 8 degrees, which cross roll the pierced shell over a freely revolving mandrel which is inserted before the shell enters the mill. The roll design is similar to the Mannesmann piercer in that there is a converging inlet which grips the billet and rolls it down on the mandrel. The wall thickness is then reduced to an amount determined by the hump in the rolls. The rolls are approximately 13 inches in diameter at the gorge and are driven by a variable-speed motor through one drive. Roll positions are changed by motor-driven screw-downs which are tied together to give equal movement to each roll.

The advantage of this mill is that the tube is rolled over a polished mandrel which provides an inside surface that is smooth and free from scratches. Sizes from 2½-inch to 4½-inch O.D. with wall thicknesses from 0.250-inch to 1¼ inches can be produced. Smaller diameters can be made by further processing the rolled product through a 12-stand reducing mill.

Seamless Fabricating Practices—In the discussion of the various phases of seamless tube manufacture in this section, the role of each unit was described. It was also indicated that the number of operations is dependent on the size of the tube to be produced. To further clarify these discussions, the following examples, which typify the variations employed in the manufacture of seamless tubes, are given to develop the operations step by step.

In producing a 2¾-inch O.D. by 0.154-inch wall single-length hot-rolled tube, a solid billet 3¼ inches in diameter and weighing approximately 82 lbs. is pierced to a shell 3⅞-inches O.D. with 0.215-inch wall, about 11 feet long. This pierced shell is passed, without reheating, to the plug rolling mill where it is plug-rolled in a 3¼-inch groove to produce a tube 3¼-inches O.D. with a 0.140-inch wall and 17 feet, 6 inches long. The plug-rolled shell is then reeled to approximately 3⅞-inches O.D., 0.140-inch wall, and about 16 feet, 6 inches in length. After reeling, the tube is passed through a reheating furnace and into the reducing-sizing mill from which it emerges 2¾-inch O.D. with 0.154-inch wall and approximately 22 feet, 3 inches long. From this tube, the crop-ends, and any test pieces that may be required, are cut in the finishing operations described in a later section.

In producing a double-length hot-rolled tube 8¾ inches O.D. with 0.277-inch wall, a solid billet 8¼ inches in diameter, 6 feet, 5 inches long, weighing 1166 lbs. is pierced in the first piercer to a shell 8 inches O.D., wall thickness of 1¼ inches and 12 feet, 10 inches long. Without reheating, this shell is further processed in the second piercer to a shell 8¾ inches O.D., with 0.470-inch wall, and approximately 28 feet long. The shell from the second piercer, after reheating, is plug-rolled in an 8⅞-inch groove to 8⅞ inches O.D., 0.277-inch wall and 46 feet, 9 inches long. The plug-rolled tube is transferred directly to the reeling machine which produces a tube 8¾ inches O.D., 0.277-inch wall, and 45 feet, 5 inches long. The tube then receives two or more passes in the two-high sizing mill from which it emerges 8¾-inch O.D. with a 0.277-inch wall and approximately 46 feet long. It is then ready for crop-ending and the other finishing operations.

To produce 26-inch O.D., 0.303-inch wall double-

FIG. 41—37. Roll design. Assel mill.

length hot-rolled tubes, a solid billet $12\frac{1}{4}$ inches in diameter, 10 feet long and weighing 4007 lbs., is pierced to a shell 14 inches in outside diameter, 1.640-inch wall, and 18 feet, 3 inches long in the first piercer. This shell, in the same heat, is entered in the second piercer where it is rolled to 17 inches O.D., 0.750-inch wall, and 30 feet, 2 inches long. After reheating, the shell is plug-rolled to form a tube $16\frac{3}{4}$ inches O.D., 0.500-inch wall, and 44 feet, 9 inches long. The plug-rolled shell is reheated a second

time, after which it is rotary rolled to $26\frac{1}{4}$ inches O.D., 0.303-inch wall, and 45 feet, 8 inches long. Without reheating, it is then reeled to $26\frac{1}{2}$ inches O.D., 0.303-inch wall, 45 feet, 3 inches long. The tube, after reeling, is again reheated in the tunnel-type reheating furnace, after which it passes through two stands of two-high sizing-mill rolls, forming a hot-rolled tube 26 inches O.D., 0.303-inch wall, and 46 feet long, ready for the finishing operations.

SECTION 6

COLD-DRAWN, OR COLD-FINISHED, TUBES

While the ordinary requirements for pipe and tubing can be met by the hot-rolling processes just described, there are many requirements that demand greater accuracy, higher physical properties, better surfaces, thinner walls and smaller diameters than can be produced by hot-working methods. This demand is met by cold drawing the hot-rolled tubes as a finishing operation. This phase of tube production is analogous to the drawing of wire and the cold rolling of sheets described in preceding chapters.

In the early history of seamless tube production, cold drawing was employed in almost every instance as a finishing operation, but, as the art of hot rolling developed, the necessary finish and dimensional requirements have been met to a greater and greater degree in the hot-rolling operation. However, a substantial proportion of tubing is still cold drawn for the following reasons:

1. To produce tubes with thinner walls than can be hot rolled.
2. To produce tubes with smaller diameters.
3. To produce tubes longer than can be hot rolled in certain sizes.
4. To secure better surface finishes.
5. To obtain closer dimensional tolerances.
6. To increase certain mechanical properties, such as tensile strength.
7. To produce shapes other than round.
8. To produce tubes with varying diameters and wall thicknesses from end to end.
9. To make small lots of tubing of odd sizes and gages that do not justify a hot mill run.

One and five-sixteenth inches is about the minimum diameter it is practicable to produce by hot rolling, and 0.083 inch is the thinnest wall of commercial hot-rolled tube, which is available in the smaller diameters only. The diameter and wall thickness range of cold-drawn tubing produced by the National Tube Division is from $\frac{1}{2}$ -inch O.D. by 0.035-inch wall to $10\frac{3}{4}$ -inch O.D. by 2-inch wall.

The fact that hypodermic needles are seamless steel tubes that are cold drawn from hot-rolled tubing in small specialty plants conveys the idea of how far seamless tubing can be reduced by cold drawing.

Principle of Cold Drawing—Tube drawing is essentially the same as wire drawing, as explained in preceding chapters with two important exceptions: viz., the inside diameter of the tube must be supported while it is passing through the die to effect wall reduction and control the size of the hole, and comparatively short lengths are involved as in bar drawing. The process consists of pulling the tube through a die, the hole of which is smaller than the outside diameter of the tube being drawn, and at the same time supporting its inside surface by a mandrel anchored on the end of a rod so that it remains in the plane of the die during the drawing operation. Figure 41—38 shows the operation. The mandrel may be omitted if it is not necessary to make a reduction in the wall thickness, or if the dimensions and surface of the inside are not important. A modification of this method consists of drawing on a bar rather than over the mandrel, in which method the bar travels through the die with the tube and must be removed later. The resistance of the metal to passage through the restricted space between the die and the mandrel exceeds the yield strength of the metal at this section, thereby resulting in plastic flow. As a result of the reduced metal section leaving the die, the velocity is increased, the amount of increase being dependent upon the cross-sectional reduction. It is evident that the reduction or draft may be increased only up to a certain limit, depending on the ultimate strength of the section leaving the die, because, if the resistance and balancing pull exceeded this stress, the section leaving the die would break. In drawing tubes over a stationary mandrel, the maximum practical sectional area reduction does not exceed 40 per cent per pass, while, in drawing tubes on a bar which is free to move with the tube, the area reduction can be 50 per cent. As in wire drawing, every inch of metal passing through the die is subjected to stress almost up to its breaking strength and is thus given a test of its physical

FIG. 41—38. Cold drawing a seamless steel tube.

FIG. 41—39. Draw bench with tube going through die.

fitness to withstand high stresses in its ultimate service. Any flaw or defect of consequence is brought to light under this severe treatment.

The Draw Bench—A cold-draw bench for tubes consists of a heavy steel frame or bench, in the middle of which is located a die head for holding the die. At one end of the bench is located an adjustable holder to anchor the mandrel rod. At its other end a shaft is mounted carrying a sprocket wheel over which passes a heavy, endless, square-linked chain. This chain lies in a trough on top of the bench, which extends from the sprocket wheel to the die head, where the chain passes around an idler and returns underneath the bench to the sprocket wheel. The sprocket wheel is driven by a variable speed motor through suitable reduction gearing. A carriage called a **plyer** runs on tracks on the top of the bench and over the chain that lies in the trough between the tracks. This plyer is equipped on one end with jaws to grip the tube and on the other end with a hook to engage a link of the draw chain. The plyer is connected by cable to a motor-actuated drum by which means it is returned to the die head after drawing a tube. The jaws grip the reduced or pointed end of the tube which projects

through the die about 6 inches. The closing of the jaws is effected by the motion of the hook in dropping into engagement with the chain. The whole action of gripping the tube and engaging the chain is automatic, once the operator pushes a button to return the plyer to gripping position. The mandrel-rod anchor is equipped with an air cylinder to push the mandrel into operating position inside the die after the pointed end of the tube is inserted in the die. Draw benches for small tubes are equipped with two mandrels with their supporting rods, so that a tube is being loaded on one mandrel while another tube is being drawn off the other. A motor-driven indexing mechanism places the anchor in the pass line so that the mandrel rod is in perfect alignment with the die and plyer jaws prior to the beginning of the draw. A friction-roller mechanism automatically loads the tubes on the mandrel rods. All controls for the draw benches are grouped at the operator's position near the die head so he does not have to move away from that position when operating the bench.

The total length of a bench is about 80 to 100 feet. The capacity of draw benches may be from 50,000 to 300,000 pounds pulling power. Chain speed may vary from 20

FIG. 41—40. Rotary tube pointer and feeder mechanism.

to 150 feet per minute and is automatically controlled so that the tube is started through the die at a slow speed, and, as soon as it is fairly started, the speed increases to the predetermined drawing rate. Dies are made with a conical outer surface which fits in a holder mounted in the die head. Dies up to a 3-inch hole size are made with tungsten-carbide inserts or nibs. Larger dies are made from hardened tool steel, chrome-plated on the wearing surface. Mandrels are chrome-plated, hardened tool steel and are either made in the form of a bar from 6 inches to 12 inches long with one end upset to form the working surface and the other end tapped for connection to the mandrel rod (see Figure 41—38) or, in the case of larger mandrels (2 inches and over), they are made in disc form with a central hole for engagement with the mandrel rod. In the drawing-on-the-bar method, hardened and ground bars of a diameter to correspond with the inside diameter of the drawn tube and somewhat longer than the drawn tube are used. As the bar-removal operation requires some time, three or more bars constitute a set, which permits the drawing of a tube during the interval required for inserting a bar in the next tube and extracting the bar from the tube previously drawn.

Preliminaries to Cold Drawing—The hot-rolled tubes after cooling are pointed on one end. This pointing consists of reducing the outside diameter, for a distance of about 6 inches, sufficiently to permit the reduced portion

to enter the hole in the draw die freely, so that the jaws of the pincer can grip this end of the tube. If more than one cold-draw pass is to be given the tube, the point is made slightly under the final die size, if possible. Where large diameter reductions are made on small tubes, a point that would enter the final die may be too small and weak to stand the earlier reduction, in which case the original point may be further reduced after a few passes or, in the case of very small tubes, the pointed end may have to be cut off and a new point made on the reduced diameter and wall section. This procedure may have to be repeated several times in drawing very small tubing. Tubes with diameters $2\frac{1}{2}$ inches to 3 inches and over are usually open pointed with a reduced section, 2 inches or 3 inches long, which has a rather sharp shoulder or offset joining the two diameters. A pulling pin with a cylindrical head is inserted in the tube so that the head engages the shoulder of the point and the stem of the pin projects through the die far enough to enter the pincer jaws. Pointing is done on rotary swagers or steam or air hammers after the end of the tube has been heated to a forging heat (see Figure 41—40). Tubes of certain grades of steel receive an annealing heat treatment, prior to cold drawing. This treatment, which is usually confined to high-carbon and alloy steels of the air-hardening type, is necessary to obtain additional ductility. All tubes are pickled in dilute sulphuric acid to remove scale and oxides from the outside and inside

FIG. 41—41. Pickling tubes.

surfaces. The pickling practice is quite similar to that employed in preparing wire for drawing or sheets for cold rolling. The pickle tubs are 40 to 50 feet long, about 4 feet wide, and 5½ feet deep. They are usually built of reinforced concrete and lined with vitrified brick laid in a sulphur compound mortar (Figure 41—41). Steam for heating and agitating the bath is led into the bottom of the tubs and discharged through jets or perforated acid-resisting pipes. A wash tub of similar construction is located near the pickle tubs, and after the tubes are pickled free of scale they are dipped in the wash tub to remove the acid and any sludge or loose scale. A similar tub is provided for lubricant for cold drawing, in which great care is exercised in dipping to assure that lubricant reaches the entire interior surface of each tube. This lubricant, which is an emulsion containing flour, tallow, and water in proper proportions, is used for process-drawing all tubes and for finish-drawing large-diameter tubing which requires a heavy reduction. Where tubes with bright finish are required, a special oil-base emulsion is used. After being thoroughly coated with lubricant, the tubes are placed on a conveyor chain on which they are carried through a continuous gas-fired drying oven (about 200° F) where the excess lubricant is drained and the moisture is evaporated from the lubricant. Throughout these operations the tubes are handled in bundles up to 10 tons in weight. From the drying oven the tubes are then sent to the

cold-draw benches or to stock piles near the benches.

The Cold-Drawing Operations—One cold-draw pass produces a cold-drawn tube of close dimensions, good surface, and of any mechanical property within the usual limits of cold-worked steel. Additional passes may be necessary to secure: (1) thinner walls, (2) better surface finishes, (3) smaller diameters, or (4) longer lengths. The bundle of pointed, pickled, inspected and lubricated tubes is laid on a table at the chain end of the bench, with open ends toward the mandrel-anchor end of the bench. The mandrel on its supporting rod is held so that the powered pinch rolls, into which a tube has been entered, drive the tube over the mandrel and rod until the mandrel is just back of the pointed portion. The operator then swings the tube into the pass line and operates the control for the push-up which advances the tube and mandrel to drawing position. The cable-driven pleyer-return mechanism moves the pleyer carriage toward the die head, in a direction opposite to that in which the draw chain is moving, until the carriage contacts a limit which releases the cable mechanism and permits the hook, which has been elevated, to drop into engagement with the draw chain. The engagement of the hook with the chain permits the grip jaws to close on the projecting point, and the motion of the carriage draws the tube through the die. When the open end of the tube clears the die, the pleyer hook automatically disengages from the chain. Another tube

is loaded on the mandrel and the cycle is repeated as before. When, after a series of draw passes, the inside diameter of the tube becomes too small to accommodate a substantial mandrel, the tube may be further reduced in both its outside and inside diameters by sinking it through a die without a mandrel or bar on the inside. Such a reduction results in a thickening of the tube wall which is uniform and predictable; however, the inside diameter cannot be held to the close tolerances produced with the use of a mandrel or bar support.

The Tube Reducing or Rockrite Process is used for the same purposes as conventional cold drawing; i.e., to produce tubing with smaller diameters and lighter walls, closer tolerances, better surface finish, higher mechanical properties, better machinability, etc., than may be obtained by hot rolling. Longer lengths than obtainable by either hot rolling or cold drawing—up to 100 feet or more—are possible, but such long lengths, especially in the smaller diameter range associated with Rockrite material, may not be conveniently handled through finishing operations, hence little use is made of this feature. Production is generally confined to the smaller-diameter tubes although the upper limit is established only by capacity of existing machines. The Rockrite process has a slower production rate in feet per hour than conventional drawing, but accomplishes much greater reduction per pass so that the net effect is more or less equivalent production rates, particularly where a Rockrite machine performs the work of three or more cold-draw passes, as is usually the case. Advantages of the Rockrite process over conventional drawing include improvement in the concentricity of the product, and elimination of certain intermediate operations (such as cutting, pointing, annealing, pickling, doping, etc.) required by the successive cold-draw passes used to accomplish the same total reduction; less material waste is also experienced because there is no point-crop to discard. Disadvantages include slower production rates than conventional drawing where small reductions are involved, and the time required for a size change is

much greater. Additionally, the relative die costs of the two processes greatly favor conventional drawing when small production lots of odd sizes are to be made.

Principle of Rockrite Process—The Rockrite process accomplishes simultaneous reduction of tube diameter and wall thickness by a cold-swaging action which utilizes compressive forces rather than the tensile forces employed in conventional drawing. This fact removes the reduction limitation present in the cold-draw process which is governed by the ultimate tensile strength of the reduced section. In the Rockrite process, very large reductions in one pass are found feasible—as much as 85 per cent or more; this may be compared with the 40 per cent reduction per pass which is the practical upper limit in the drawing process. This comparison is even more striking when it is understood that four successive passes of 37.8 per cent reduction each are required to effect a total reduction of 85 per cent.

Of fundamental importance in the Rockrite process are two semi-circular dies which have matching, tapering, semi-circular grooves machined into their curved faces. In operation, one die is placed on top of the other so that the matching semi-circular grooves make a circular pass. The dies are geared to each other in such a fashion that they rotate in opposite directions when they are moved laterally (in the plane of the grooves), and a converging (or diverging, depending on the direction of lateral movement) circular pass is traced by the die grooves. When a tube is held stationary on the center line of this pass, the converging path of the die grooves reduces its diameters. If now a stationary mandrel of the proper taper is also positioned in the center line of the pass, the inside of the tube is supported and the tube wall is reduced and extruded or elongated by compression between the die and mandrel. In actual practice, the dies are in constant, lateral and rotary, reciprocal motion. Modifications in die contour permit repetition of the swaging action to reduce an entire tube of given diameter and wall thickness to one of smaller diameter and lighter wall thickness, with the length being in-

FIG. 41—42. Vertical section through tube reducer pass—showing dies at start and end of stroke.

creased in direct proportion to the amount of reduction in a cross-sectional area. Such modifications include contour-relief at both ends, and an ironing section of constant diameter at the smaller end. Contour-relief at the inlet or large end of the die grooves permits feeding the tube, in small increments, into the pass during the short interval when the dies are not in contact with the tube. Contour-relief at the outlet or small end of the die grooves permits rotation of the tube during the corresponding time interval at the end of the working stroke; this rotation serves to prevent the formation of fins and to round up the finished section. The constant-diameter ironing section is of sufficient length to permit several working strokes on each increment of reduced tube, and serves to size and round up the reduced tube. The inside diameter of the finished tube is governed by the diameter of the mandrel at the point located directly beneath the beginning of the ironing section of the dies; this point is called the "size-point." It is obvious that minor changes in I.D. size may be made by axial movement of the mandrel. O.D. size may not be altered so simply, requiring regrinding and refinishing operations in existing dies.

The Rockrite Machine—Rockrite machines are classed as continuous or intermittent, but the production mechanism is essentially the same in the two types. The machine proper consists of a heavy steel frame, some 30 to 40 feet long and 8 to 10 feet wide. The forward end of the frame contains the mechanism which actually swages the tubes. This mechanism, called the "saddle," is a housing containing the rolls into which the dies are keyed, and which slides back and forth on ways in short reciprocating strokes, being driven by connecting rods attached to cranks geared to the 40 to 100-horsepower main-drive motor. A stationary rack attached to the frame engages one of the intermeshed gears on the roll ends, and thus produces reciprocating rotation of the dies as the "saddle" moves back and forth. The tapered mandrel is located in the desired position in the pass by a long mandrel rod running back, inside the tube being processed, to a thrust block located at the rear of the machine frame.

The tube being processed is gripped at its back end in a vise carried in the "cross-head"—this last being the tube feeding and turning mechanism. A long screw—running from beyond the back end of the machine, through a suitable drive-nut in a stationary housing, up to the "cross-head"—advances the latter a predetermined amount during the time interval at the end of each back stroke of the "saddle" when the tube is not

contacted by the dies. Similarly, a splined shaft—running from the back to the front end of the machine frame, and passing through the "cross-head"—rotates the "cross-head" vise, together with the tube it grips, approximately 60 degrees during the corresponding period each time the "saddle" reaches the forward end of its stroke. This splined shaft also drives an outlet friction vise which serves to rotate the tube being processed when its back end is no longer gripped in the "cross-head" vise.

The chief difference between the continuous and intermittent machine types is the method of charging a new tube. In the so-called continuous machine, two mandrel-rod locks, or thrust blocks, located some 20 feet apart, are employed. In use, assuming both locks closed and the machine in operation, the rear lock is opened and a new tube is charged over the end of the mandrel rod up to the forward lock; the rear lock is then closed and the forward lock opened, allowing the tube to be moved forward until it touches the end of the tube being reduced—in which position it remains to be gripped by the "cross-head" on its return to initial position. Suitable automatic controls open the "cross-head" vise at the forward end of its travel, actuate a high-speed return motor, and then close the vise again when the "cross-head" has returned to its initial position at which time the regular feed stroke is resumed. The "saddle" remains in motion during this entire cycle and the production time lost is negligible. In the intermittent machine, when the "cross-head" reaches the forward end of its travel, the "saddle" is stopped, the "cross-head" vise opened, the mandrel-rod thrust block unlatched, and high-speed return motors actuated to return the "cross-head," and back out the mandrel rod and mandrel. A new tube is then placed in position, the mandrel rod and mandrel returned to position and the mandrel-rod thrust block locked, then the "cross-head" vise is closed to grip the tube, and finally the "saddle" is restarted in motion. Since reduced tubes are too long to handle conveniently through finishing operations, a flying saw has been devised to cut shorter lengths as the reduced tube emerges from the machine.

Preliminaries to Rockriting—Hot-rolled tubes, or those which have been previously cold-drawn or Rockrited, may be cold-reduced by the Rockrite process. Tube preparation generally first involves an annealing operation to insure the ductility required by the swaging action; some plain low-carbon steels are ductile enough as received from the hot mill, but hot-rolled alloy steels and all previously cold-drawn or Rockrited tubes must

FIG. 41—43. Continuous annealing furnace.

Fig. 41—44. Car-bottom annealing furnace.

be annealed. Tubes are next pickled and straightened, then both ends cropped square with the tube body, and finally they are coated with an oil base or flour-tallow-water lubricant by immersing horizontally in the desired solution—this last operation is more commonly referred to simply as “doping.” The pickling operation is employed to remove mill scale or annealing scale, and utilizes an inhibited sulphuric-acid solution, the same as employed in preparing tubes for cold drawing. The straightening operation is performed in a rotary straightener, and may be preceded by a so-called “break-down” pass through a press straightener when excessive camber necessitates this operation. Tube ends must be cut square because the trailing tube is used to feed the one preceding it when the forward tube is no longer gripped by the “cross-head” vise.

Rockrite Machine Operation—No more than one operator is required for each Rockrite machine, and in some instances one operator may handle two or more machines. The principal duty of the operator is charging new tubes and disposing of reduced material. In the case of intermittent machines, he must also start and stop the “saddle,” and manually open and close the “cross-head” vise. A coolant solution is constantly poured onto the dies during the motion of the “saddle,” and the operator must control its flow and be sure that it is adequate and continuous.

The number of strokes per minute made by the “saddle” is variable within limits (say 70 to 140 per min.), but this is generally fixed by supervision—depending on

the steel grade being processed, amount of reduction, and rate of in-feed. The in-feed is also variable—from 0 to $\frac{1}{16}$ inch or more per stroke—but this is similarly controlled by supervision—depending on the steel grade being processed, the amount of reduction, and the class of product being manufactured. The amount of reduction is governed by the die and mandrel contour, and, except for minor mandrel adjustment (which alters the size of the finished product) is beyond the control of the operator. The stroke of the “saddle” is constant for any given machine size, and increases from about 15 inches to 2 feet and longer as the rated capacity of the machine increases.

Annealing and Redrawing—While a large proportion of tubes receive only one cold-draw pass, many require a number of passes for reasons previously noted. Because cold drawing hardens and reduces the ductility of tubes, it is necessary to anneal them after each cold-drawing operation. Before further cold-drawing, the annealed tubes must be pickled and lubricated as previously described. All tubes, except bright-finished mechanical tubes, receive a final anneal or heat treatment after the last cold-draw pass. Many tubes receive a special normalizing treatment before the last pass in order to obtain the proper grain structure in the finished tube. This annealing is performed in either continuous tunnel or car-bottom batch furnaces fired with gas. The continuous furnaces are provided with heat-resisting driven rolls spaced about 3 feet apart, on which the tubes are carried through the furnace at a predetermined rate depending on the tube section, annealing

temperature, time at temperature, etc. (see Figure 41—43). The car-bottom batch furnaces are arranged in a battery and are served by a special charging crane. Less than two minutes is required to discharge a 5-ton batch of annealed tubes and recharge the furnace with a new batch. The furnaces will accommodate tubes up to 50 feet long (see Figure 41—44). Both types of furnaces are fully equipped with recording pyrometers. Each furnace is divided into four zones, and the temperature is automatically controlled in each zone. When extreme softness or freedom from scale or both are requested, the tubes are enclosed in a heat-resisting sheet-metal box and annealed in a car-bottom batch furnace. The final anneal or heat treatment is varied to produce tubing with the desired mechanical properties. Table 41—III illustrates the effect of this heat treatment on AISI-C-1015 steel. The mechanical properties shown are representative expected values for all but the soft-annealed condition, where they reflect the approximate softest condition expected.

Finishing Operations on Cold-Drawn Annealed Tubes

After the final heat treatment, the cold-drawn tubes are finished in preparation for shipment. The principal finishing operations consist of straightening, cutting, inspecting and testing. Straightening is performed on various types of straighteners, viz., press, rotary, continuous and post. The rotary type consists of rolls set with axes oblique with the pass line (see Figure 41—45). These rolls are somewhat smaller in the center than at the ends to afford a line contact with the tube, which passes

between the two driven rolls on one side and the three idle rolls on the other. The tube is helically advanced by the rolls which are adjusted to bend the tube progressively as it moves through the machine. Initial bends in the tube are removed and a straight tube is produced. Care must be exercised to have the roll setting adjusted accurately, especially on light-walled tubing, to prevent crushing the tube. Some very thin-walled tubes can be straightened successfully only on a post set in the floor carrying grooved blocks which support the tube while it is sprung into straightness by hand. Where exact straightness is required, as in some mechanical tubes, gag press straighteners are used. Operators of these presses develop great skill in giving the tubes the proper deflections between the supporting dies so that the desired amount of permanent set remains. A proving table, on which the tube rotates, is equipped with dial gages, which provide a quick and accurate means of determining straightness. Each tube is spark tested as a final check to identify it as made of steel having the composition specified. The hardness is established by Rockwell or Brinell tests, and tension tests of samples indicate the mechanical properties. Microscopic examination of the grain structure is an essential phase of the inspection program. Each tube is given a visual inspection for surface defects, both inside and outside. Pressure tubing is hydrostatically tested to internal pressures in excess of service pressures that may be encountered. The usual range of test pressure is from 1000 to 5000 pounds per square inch. On pressure

FIG. 41—46. Rectangular shaped sections of seamless tubing. Scale 1" = 2 $\frac{3}{4}$ ".

tubing, manipulation tests on coupons consist of flattening, expanding, flanging and crushing. All tubes are carefully measured for outside diameter, size and wall thickness. A protective coating of oil, or rust preventive, is usually applied before shipment. Light-gage tubes are boxed and small-diameter tubes are bundled to prevent injury during shipment.

Mechanical Tubing—Tubing for mechanical purposes is made in a wide range of sizes ($\frac{3}{8}$ -inch O.D. to 10 $\frac{3}{4}$ inches O.D.) and in many wall thicknesses in round and special sections. Some of these special sections are square, rectangular, oval, streamline, octagon, hexagon, etc. (see Figures 41—46 and 41—47). Square and rectangular sections are produced on a bench equipped with a Turk's head in place of the regular die. This Turk's head consists of a frame in which are mounted four rolls with their axes in one plane and so arranged around the pass line that the faces of the rolls form a square or rectangular hole through which the round tube of proper size is pulled, thus producing the desired section. Other special shapes are made in dies in which

the bore corresponds to the outside contour of the finished tube, or in which shaped mandrels support and control the inside dimensions. Mechanical tubing has wide application and can be found in airplanes, automobiles, agricultural machinery, electrical equipment, household equipment, etc. Specific uses include ball-and roller-bearing races, gravity conveyor rolls, bushings, separators, hydraulic cylinders and hoists, oil-well pumps, bicycle frames, metal furniture, etc.

Pressure Tubing—Tubing used to withstand internal or external gas, steam or fluid pressure in refining, chemical, or evaporator apparatus is designated as pressure tubing and is usually furnished in the full-annealed state to assure ductility under service conditions. The most common applications of pressure tubing are in boilers, condensers, heat exchangers, evaporators, cracking stills, refrigerators, and air-conditioning apparatus. Many of these applications can be met by hot-rolled tubing, but the smaller-size, light-walled tubes can be produced only by the cold-drawing process or by the Rockrite process.

FIG. 41-47. Special shaped sections of seamless tubing. Scale 1" = 2 1/4".

Dimensional Tolerances of Cold-Drawn Mechanical Tubing—While dies for cold drawing mechanical tubing are held to the same exact sizes as wire- and bar-drawing dies, the fact that thin-walled sections will spring out of round while a solid section cannot, accounts for the somewhat greater tolerances required in tubing than with solid sections.

Surface Finishes—The various surface finishes in both hot-rolled and cold-drawn tubing are as follows:

1. Hot Finished
Hollow-forged billets and hot-rolled tubing.
2. Normalized
Hot-rolled or cold-drawn tubing.
3. Soft Annealed
Hot-rolled or cold-drawn tubing.
4. Medium Annealed
Cold-drawn tubing only.
5. Finish Annealed
Cold-drawn tubing only.
6. Hard Drawn (Unannealed)
Cold-drawn tubing only.
7. Ellwood B. F. (Bright Finish)
Cold-drawn tubing only.
8. Bright Annealed
Cold-drawn tubing only.
9. Specially Smooth (Cylinder Finish)
Cold-drawn tubing only.
10. Pickled
Hot-rolled or cold-drawn tubing.
11. Sandblasted or Shotblasted
Hot-rolled or cold-drawn tubing.
12. Polished
Cold-drawn tubing only.

1. **Hot Finished**—Hollow-forged billets have a surface appearance much smoother than hammered or pressed forgings, but may show a slight marking that will clean up with very little stock removal. Hot-rolled tubing has a surface finish comparable to plates or sheets of equal thickness. The thin-walled tubing, because of the high reduction in the rolling operation and the low finishing temperatures, will have a better surface than tubing with heavy walls. A light, tightly-adhering mill scale,

blue-black in color, is found on both the outside and inside surfaces of hot-rolled tubing.

2. Normalized—Whether hot-rolled or cold-drawn, all normalized tubing will be coated with scale, the thickness of which depends upon the thickness of section and grade of steel. Thin-walled tubing can be brought to temperature and cooled rapidly, thus avoiding long exposure to oxidizing atmospheres at high temperatures, while heavy sections require a longer exposure. Scale formation is directly proportional to time and temperature. Some alloy steels, notably those containing chromium or nickel in small percentages (1 to 5), usually are more heavily scaled when normalized, due to the time-temperature effect.

3. Soft Annealed—Soft annealing, as commonly applied to pressure tubing, or mechanical tubing that is to be manipulated cold, leaves a light scale from reddish brown to blue-black in color that is comparable in thickness to the scale on hot-finished tubes, but is usually less tightly adhering and of a more porous nature. This surface may at times resemble that caused by rusting in storage or in transit. Oil used for protective coating may be absorbed by the oxide film, and the tubing may have the appearance of not being properly oiled, when fully protected against normal atmospheric corrosion.

4. Medium Annealed—Due to the lower temperature employed, medium annealed tubing is very slightly scaled and the loose scale can usually be rubbed off easily, leaving a black oxidized surface.

5. Finish Annealed—As the temperature at which tubing is finish annealed produces an oxide film of blue color, the tubing has a blue-black appearance and the smooth surface produced in the cold-drawing operation is not disturbed. The oxide film offers a slight protection against local rusting or discoloration.

6. Hard Drawn (Unannealed)—As the tubing has no heat treatment after the cold-drawing operation, the surface is more or less bright, depending on the number of passes through the die and on the nature of the lubricant used in cold drawing. Normally, thin-gage tubing will have a smoother and more uniform surface than heavy-walled tubing.

7. Ellwood B. F. (Bright Finish)—Ellwood Bright Finish is applied to hard-drawn tubing in the lighter gages and smaller diameters and is secured by special treatment in the cold-drawing processes. The appearance of this tubing is like that of cold-drawn bar stock.

8. Bright Annealed—Annealed cold-drawn tubing may be furnished with a scale-free surface, when so specified, by annealing the material in a controlled atmosphere or bright annealing furnace.

9. Specially Smooth (Cylinder Finish)—Cylinder finish is often required in oil-well-pump tubing, hydraulic jacks and hoists, air cylinders and similar applications where a smooth, dense inside surface is desired. Due to the surface hardness and the fact that there are no circumferential scratches, as in machined or ground bores, this finish is particularly valuable in cylinders using soft plunger packing. This finish can also be supplied on the outside surface when desired.

10. Pickled Finish—Where mill scale or scale from heat treatment is objectionable, tubing can be furnished with pickled surfaces, both inside and outside. This is often desirable when the tubing is to be machined, especially in automatic machines using formed cutters, as the tool life is materially increased. Pickling also permits close surface inspection.

11. Sandblasted Finish—The method of removing scale by blasting is usually confined to heavy-wall pressure tubes, but facilities are available for treating mechanical tubing on both inside and outside surfaces. Sandblasting

gives a dull silvery finish, which is very susceptible to discoloration in handling and storage. A bright, smooth finish is obtained on heavy-walled, hot-rolled tubing, when sandblasted or pickled, and then burnished in a special finishing operation.

12. Polished Finishes—Polishing machines polish both the outside and inside surfaces of tubing. The polished finishes are classified as follows:

Grade "A" secured by use of No. 80 grit abrasive.

Grade "B" secured by use of No. 120 grit abrasive.

Grade "C" secured by use of No. 180 grit abrasive.

Grade "D" secured by use of No. 320 grit abrasive.

In the polishing operation, stock is naturally removed from standard-sized tubing, and, unless otherwise specified on the order, it will be assumed that O.D. tolerances may be under and I.D. tolerances may be over nominal dimensions.

Annealing of Plain Low-Carbon Steel Tubing—The temperature employed for annealing plain low-carbon steel tubing is dependent upon service requirements involving ductility, stiffness, manipulating properties, machinability, etc. In general, the higher the annealing temperature, the greater will be the ductility and softness of the material.

Hot-Finished Tubing—Tubing in the as-rolled condition is generally finished at temperatures just around the upper critical range of the steel which results in a structure similar to that obtained by normalizing. Hot-finished tubing, therefore, has good strength and ductility and can be used in those cases requiring good manipulating properties for bending and cold-drawing operations.

Finish Anneal—Unless otherwise specified, plain low-carbon steel tubes are given a finish anneal at 932° F, which restores moderate ductility to the metal. This anneal is used where stiffness and ease of machinability are important and ductility not so essential.

Soft Annealing—Where ductility is of paramount importance, plain low-carbon steel is soft annealed at 1300° F. This anneal will effect a high degree of recrystallization. This treatment is specified in all cases where severe bending and cold-drawing operations are necessary, also on all pressure tubing. In employing this anneal, free-machining qualities and stiffness are sacrificed to obtain good ductility and manipulating characteristics.

Cold-Drawn Tubing—Tubing in the cold-drawn condition will have maximum strength with slight ductility. Cold-drawn unannealed tubing will have good machinability and is specified where service requirements involve maximum hardness and high surface finish for plating, etc.

Medium Anneal—The temperature employed for medium annealing plain low-carbon steel is 1112° F. This anneal will correct the cold-worked structure to the extent of recrystallizing the ferrite but the carbide particles will still remain elongated in the direction of cold work. This anneal is applied to tubing required to withstand a moderate amount of cold forming and slight bending operations.

Normalizing—In order to obtain complete grain refinement, it is necessary to heat the steel to a temperature just above the critical range and cool in still air. This treatment causes complete recrystallization and refinement of the ferrite grains and the formation of lamellar pearlite. The mechanical properties obtained with this treatment on low-carbon steel are very similar to those obtained by soft annealing. Normalizing as a final treatment is generally not applied to low-carbon steel tubing except in special cases and on modified grades where such properties as impact resistance are specified.

SECTION 7

THE CUPPING PROCESS

Applications of the Process—A considerable quantity of tubular goods is made by the process of cupping a flat circular disc, and drawing out this cup to the desired diameter and length, on equipment such as that illustrated in Figure 41—48. Such is the practice at the Christy Park Plant of National Tube Division, where it is designated as the **cupping process**. Although seamless pipe was originally made by this method, the process is now employed only in the manufacture of special tubes and cylinders. Practically all of the gas cylinders used for the transportation of ammonia, carbon dioxide, oxygen, hydrogen, compressed air and other commercial gases, such as refinery products, are made by this method. In addition, special hydraulic cylinders for water and air receivers, airplane pumps, shells, and other specialties can be manufactured by the cupping practice. When first patented in 1851 by Remond, in England, it was intended for making all sizes of tubes. It is practicable now for all sizes larger than about three inches, but since tubes can be made so readily by the rotary-piercing processes, already described, it is seldom used except for the manufacture of cylinders. The greatest drawback to the method is the difficulty of making tubing in long pieces. The maximum lengths vary from ten to twenty feet, according to tube size and wall.

Chief Details of the Cupping Process—Although the cupping process requires considerable skill and experi-

ence, the principles of the process are simple and easily understood. The steel is delivered to the tube works in the form of square plates the sizes of which are calculated to contain the necessary volume of metal for the finished tube, plus a sufficient amount to compensate for normal losses in manufacture. These sizes may vary from two to seven feet square, and from $\frac{3}{8}$ inch to 4 inches in thickness. The smaller sizes of these plates are heated to a forging temperature in a suitable furnace, and placed in a press having a cutting die (Figure 41—49) where they are sheared to a circular plate, or disc form. Since this operation does not cool the plates to a great extent, they are immediately passed to a second press, placed in a position concentric with the circular opening of a die, and forced through it by a round-nosed plunger operating from above (Figure 41—50). The hollow cup thus formed is then placed in a third press where a mandrel forces the cup through a smaller die which deepens the cup, and, at the same time, reduces its diameter and leaves it practically cylindrical.

Plates for the largest sizes are cut into the disc form before heating, usually by an oxy-acetylene-torch cutting machine. These discs are then heated and cupped in the same process used for the smaller sizes.

Hot Drawing the Cupped Piece—After the final cupping process, the cup is again reheated preparatory to hot drawing on the horizontal bench. This bench (Figure

FIG. 41—48. Hot-draw bench in operation.

FIG. 41—49. View of press punching disc from square plate preparatory to first cupping operation.

FIG. 41—50. View of press starting first cupping operation.

FIG. 41—52. Hammer swag-tubes being heated at open end for subsequent swaging.

41—48) consists of a heavy, cast steel, trough-like frame, provided in each side with suitable recesses for the insertion of dies and at one end with a powerful hydraulic plunger long enough to force a punch through the full length of the bench. The punch, of a size corresponding to the inside diameter of the tube desired, is placed on the end of the plunger, and a series of dies of successively decreasing diameters are dropped into the recesses of the bench-frame, which supports them in line. The reheated cup is now dropped into the bench trough, between the dies and the plunger, with its closed end facing the first and largest of the dies. The plunger advances, enters the cup, and pushes it slowly through the whole series of dies, elongating it and reducing its wall thickness and diameter at the same time. At the end of the forward stroke of the plunger, stripper tongs

are used to hold the forging while the punch is slowly retracted. As the drawing pressure is limited to a force less than that required to punch through the closed end of the cup, the operations of heating and drawing may have to be repeated to draw the tube down to the dimensions required. After the final operation, the plate which has taken the form of a tube with one end closed, may be cut off, or the closed end may be left intact to form the bottom of a cylinder. The bottom of the cylinder is frequently formed into a concave section by inserting a convex die at the end of the bench and forcing the drawn forging against this die at the end of the forward stroke. Tubes that require it are straightened in a gag press designed for the purpose. After inspection and testing, the process, so far as the tube-making is concerned, has been completed. The hot-drawn tubes under

FIG. 41—51. Hot-drawn ing one end of a tube to form the open end of a cylinder.

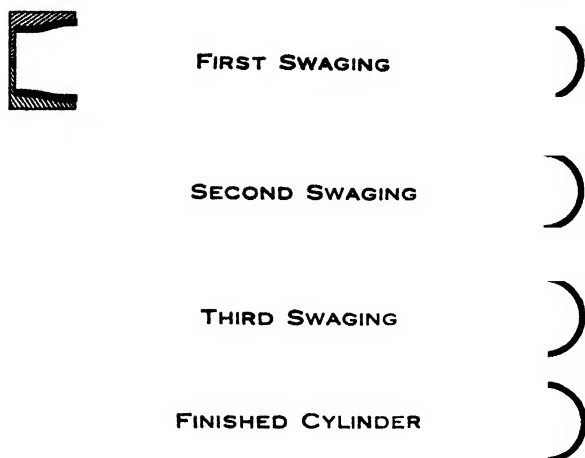

FIG. 41—53. Diagram of the swaging operations.

12 inches in diameter may be cold drawn, or cold drawn and annealed. These operations are carried out as already described.

Forming Cylinders—To form the necks of large cylinders (over 10 inches in diameter), the open end of the tube, after careful inspection, is trimmed evenly, heated to a forging temperature, and swaged under a hammer as shown in Figures 41—52 and 41—53.

Spinning—Another method for contracting, or closing, the ends of seamless tubes is known as spinning. This method is generally applied in the manufacture of small cylinders in which the end of a tube may be closed and perfectly welded in the same operation. Spinning is accomplished by a machine, which in principle is a lathe with a hollow spindle provided with a grip for holding

the tube in correct position for spinning. In carrying out the process, the end of the tube to be spun is heated to a dull-red color, the tube is placed in the machine, and the spindle is rotated at a high speed (600 to 1500 r.p.m.). The tool holder is mounted on a carriage which permits longitudinal and cross feeding of the center of sweep rotation, as well as adjustment of the sweep radius. A blunt tool of high-speed steel is brought to bear against the heated part of the tube and slowly swung around the end of it. The friction of this tool against the rotating tube generates heat at a high rate, and by repeatedly manipulating the tool the temperature may be raised to the point of incipient fusion for the steel of the tube. Figure 41—54 shows the different steps in the operations of closing the end of a tube. This illustration shows that, with each sweep of the tool around the end of the tube, the metal is gathered closer and closer towards the center, until the heat at the center has become so intense as to melt the metal, thus closing the end with a weld. After closure is effected, it is further possible to thicken the head thus formed by continued manipulation of the tool with simultaneous feed against the tube end.

The necks of cylinders can also be formed in this machine by alternately moving the tool carriage incrementally in the axial direction and manipulating the tool so that it does not cross the center of rotation. In this manner, closure is not effected, but a prolongation or neck is formed which may be tapped to receive a valve or connection. In the forming operation, external heat is supplied by oxy-acetylene torches. It can readily be seen that this principle is adapted to the forming of a great variety of ends.

The machine is of special value in the manufacture of small tanks or cylinders by simply cutting pipe into short lengths and spinning the ends to the closure or to the contour desired.

FIG. 41—54. Ends of a tube at different stages of the spinning process, showing the progress of the operation from the tube on the left to the closed cylinder on the right.

SECTION 8

HOT EXTRUSION

Historical—The hot extrusion process has been successfully used to shape non-ferrous metals for many years and has also been used to a limited extent for some years in Europe for the production of carbon-steel tubes and bars. The presses, usually mechanically driven, permitted little flexibility in speed control, and the grease and graphite lubricant used left much to be desired. Tool life was short and only rather low extrusion ratios could be used. This made the operating cost of the process too high for economical use in this country where labor costs are much higher than in Europe.

During the late 1940's, the French inventor Jacques Sejournet developed the use of glass as a lubricant at the Persan plant of Comptoir Industriel D'Etirage et Profilage de Metaux to the point where stainless steel and other ferrous alloys of high strength and high melting point could be extruded much more satisfactorily and economically than was previously possible.

The extrusion process is well suited for the production of tubes or solid shapes of stainless steels and other high-strength alloys for which orders are usually for small quantities. With this process, it is possible to produce shapes which are difficult or impossible to form by other processes, to shape some steels which are difficult to roll or forge and some which previously could only be cast. Included in materials difficult to form are tubes of alloys known as non-pierceable because they cannot be produced on conventional seamless-pipe mills.

Advantages of Hot Extrusion—One of the advantages of the process is the ability to produce orders of small tonnage which cannot be rolled economically. The cost of dies for a special shape is insignificant in comparison with the cost of rolls and a size change can be made on the extrusion press in a few minutes except when it is necessary to change for a different size of billet to produce the required section. It is, therefore, a simple matter

FLOOR PLAN - EXTRUSION DEPARTMENT

Fig. 41-55. General plan of extrusion plant.

to make changes in the design of a section to be extruded, while the cost of such a change to a rolled section might be prohibitive. This ability to make changes is of particular advantage for new developments. Special formed sections can be extruded experimentally in small quantities until the best procedure for extruding and machining can be developed.

The extrusion process, which takes place at a substantially uniform temperature, with the steel under heavy compression in all directions, gives an end product with a fine and uniform structure well suited for further processing by cold drawing or machining. Some producers, particularly the French at Persan, specialize in precision sections which are cold drawn from extruded shapes.

All extrusions tend to be slightly greater in cross-sectional dimensions at the back end than at the front end. Several factors probably contribute to cause this effect. The glass coating is heavier on the front end of the piece, the die wears and its temperature increases as the extrusion is made. To obtain the accuracy of size usually required, it is necessary to cold reduce, cold

draw, or finish machine the extrusion. In the production of alloy tubes, it is possible to extrude small tubes with lighter walls than it is practical to pierce and roll on conventional seamless mills and to produce them with a much better surface. This means that the amount of tube-reducing or cold-drawing work on small tubes can be greatly decreased.

The Extrusion Press—For satisfactory operation, the extrusion press must be ruggedly constructed to withstand the heavy forces involved and remain in accurate alignment. When extruding tubes, it is essential that the mandrel be accurately centered in the die or eccentric tubes will result. The dies, which are thin, must be well backed up to minimize deflection. The die holder must be accurately centered with the bore of the container.

The furnace must be able to heat the billets uniformly to a closely controlled temperature and supply them to the press substantially free of scale.

Before heating, the billets must be properly conditioned. For some non-ferrous metals, the condition of the surface is not of particular importance. For example,

Fig. 41-56. Stud welder which flash welds studs to billet ends to provide support for billets carried on hangers through furnace.

FIG. 41—57. Billets supported on conveyor are shown here entering the gas-fired furnace for preheating to 1600° F.

brass is extruded with a dummy block smaller than the container so that the billet is scalped and the surface layer is not extruded. With stainless steel however, the billets must be machined to a smooth surface.

The extrusion press at Gary Works of National Tube Division embodies a number of new design features which were found to be desirable when the experimental work was being performed in France. It has a main ram of 2000 tons capacity and a separate piercing ram of 500 tons capacity which can be used separately or together. The stroke of the main ram is 100 inches. The container is movable so that the discard can be easily removed as will appear later.

The Extrusion Operations—The general plan of the extrusion plant is shown in Figure 41—55. Turned rounds in lengths up to 20 feet are received and stored in the yard until needed. They are transported into the building by straddle truck and distributed by overhead crane to the four saws for cutting into the desired billet lengths. As mentioned before, these bars already have been turned. The finish must be rather smooth as any undue roughness will affect the finished product. The saws are of the milling-cutter type in order to produce a straight cut with a smooth surface, perpendicular to the axis of the bar. The billets are piled on pallets, which can be handled by a fork truck or by overhead crane. If intended for the production of tubes, they are next delivered to the drill presses where holes about $\frac{1}{4}$ inch larger than the inside diameter of the extruded tube are drilled from end to end on the axis of the billet. It is important that the drilled holes be straight and on center, as otherwise the extruded tube will be eccentric. Three drilling machines using high-speed twist drills about 4 feet long have been provided for this work. Oil holes

through the drills carry an ample supply of coolant to the cutting edges. Two of the machines are of the horizontal type which rotate the work while the drill is fed into it and the other machine is vertical and feeds the rotating work down over a stationary drill. The largest hole which can be drilled by any of these machines is 3 inches in diameter. Most of the stainless steel that is

FIG. 41-61. Tool assembly for the extrusion press shown schematically in Fig. 41-60.

drilled and cut tends to work harden, and all sawing and drilling is performed at a slow speed and with a heavy feed.

The billets are then transferred to a lathe where one end is chamfered. This chamfer is provided on the lead end of the billet, which contacts the die, and has been found necessary to eliminate a surface flaw known as "corner defect."

The billets are next taken to the stud welder shown in Figure 41-56. Here, each billet is upended and a $\frac{3}{4}$ -inch carbon-steel stud with a round head is flash-welded to its end. Hangers on the overhead conveyor then pick up the billets and carry them through the gas-fired furnace where they are heated to about 1600° F. The furnace, which is shown in Figures 41-57 and 41-58, has a water-cooled slot in the top to permit the hangers to pass through. The slot is covered by overlapping alloy seal-plates which travel with the hangers and ride on water-cooled rails. The furnace is fired with coke-oven gas and is equipped with 54 radiant burners in the side walls with three zones of control. It has a rated heating capacity of 8 tons per hour at

2300° F. It is operated at only 1600° F, however, in order to minimize scaling of the steel.

The billets leaving the gas-fired furnace are rapidly conveyed to one of the salt pots. These are electrically heated baths of barium chloride which are operated at 2300° F. Each bath is 14 inches wide by 10 feet long inside, and has four pairs of electrodes connected to two transformers of 200-kva capacity each. It is important that the billets be uniformly heated throughout and that they be free of scale as it will cause rapid die wear at the extrusion press. The salt-bath furnace has, to date, proved to be the most satisfactory equipment for achieving the desired results.

After moving through the salt bath, the billets are lifted by conveyor and quickly carried to a point near the extrusion press, where the supporting stud is removed by an air chisel. The layer of salt which adheres to the billet helps to prevent formation of scale. The billet falls into a trough on the charging carriage, as shown in Figure 41-59. As the carriage moves toward the press, the trough drops to a horizontal position and discharges the billet, which rolls across the table to a

FIG. 41-62. Cycle of operations in the production of an extruded tubular section.

FIG. 41—63. View at the inlet side of the extrusion press.

trough on the opposite end. As it rolls, it wraps itself in a fibre-glass veil which acts as a lubricant in the container of the press. Figure 41—60 shows a longitudinal section through the press. The tooling is shown in Figure 41—61.

Before the glass-wrapped billet is introduced, the stem is fully retracted, the mandrel is extended from the stem the proper distance to permit it to reach through the die when the extrusion is started, a dummy block is placed over the mandrel and against the stem, and the mandrel is covered with a woven-glass sock. The container is placed in its forward or closed position, a die and holder are placed in the die carriage, and the carriage is moved up against the container and locked in position. A glass cartridge of approximately the same diameter as the container is placed in the container and pushed back against the die (Figure 41—62a). This cartridge may be a pad of fibre glass or a cake of powdered glass, or both. This glass, or a substantial portion of it, melts in contact with the hot steel and flows to the die, thus lubricating the bearing surface. The portion of the glass which does not melt serves to insulate the die and die holder from the hot metal. This glass is the important factor in reducing friction, thereby increasing die life and permitting longer pieces to be extruded and greater extrusion ratios to be used.

The stem with the dummy block and the mandrel now move forward rapidly under pre-fill pressure. The man-

drel enters the drilled hole in the billet and the dummy block presses against the back of the billet and compresses it until it fills the container (Figure 41—62b). The stem continues to move under high pressure and forces the hot steel through the die at a high speed (Figure 41—62c). The extrusion is usually performed in 2 or 3 seconds. It is desirable to perform this operation rapidly to avoid loss of heat from the piece and to minimize the temperature rise of the die and mandrel.

The traveling crosshead comes to rest against a splitting stop on the container housing before the dummy block reaches the die face. This leaves a short length of billet unextruded. The dummy block has slots in its outer surface and its face is chamfered so that the hot steel tends to flow over and attach itself to the dummy block. The stem is then pulled back a few inches and the container also moves back a short distance. The unextruded piece of billet, or discard, and the dummy block stick to the container and the extruded piece pulls back through the die, thus leaving a gap between the container and the die. The hot saw then descends through this gap and severs the discard (Figure 41—62d). Another forward movement of the container then pushes the end of the extrusion through the die (Figure 41—62e) and it is removed by the outlet conveyor. The die and its carriage are retracted, the container again moves forward, the crosshead stop moves away, and the stem is moved in to push the discard and dummy block from

FIG. 41-64. View at the outlet side of the extrusion press.

the container (Figure 41-62f). They fall to a conveyor which carries them to the side of the press, where a small hydraulic press squeezes the discard from the dummy block. The dummy block falls to a chute from which it is picked up by a device which raises it into position where the mandrel will pick it up. There are always several dummy blocks in the system to permit cooling before reuse.

After the discard is pushed from the container, the stem is retracted and the mandrel retracts inside the stem where it is water-cooled. A rotating brush moves in and cleans the container of glass residue. The die and its holder are removed from the die carriage and another die and holder previously prepared are inserted. The die which has been used is cleaned and prepared for another extrusion. Normally, from three to six dies are used in rotation. Figures 41-63 and 41-64 show the inlet and outlet sides of the extrusion press.

Piercing Billets—Tubes with inside diameters of $2\frac{1}{2}$ inches or larger and walls of not less than $\frac{5}{16}$ inch can be made by piercing the billets on the extrusion press instead of drilling them as described previously. A piercing head is placed on the end of the mandrel and pushed completely through the billet and through the die. The piercing head and a short slug of metal sheared from the inside of the billet drop off and the stem with the dummy block then advances and extrudes the piece.

Other Billet-Piercing Methods—In other plants it is common to provide a separate vertical press for the piercing operation. A section of the tooling for one such press is shown in Figure 41-65. Here the billet is first

FIG. 41-65. Tooling used in some plants for the piercing of hot billets for extrusion. Piercing is performed on a separate vertical press by the method shown schematically in this sketch. Pierced billets must then be reheated before transfer to the extrusion press.

compressed by the ram which then guides the piercing mandrel to the center of the billet. The piercing mandrel advances to a point near the bottom, while the ram retracts and allows the billet to extrude backward. The back-up mandrel is then withdrawn and the piercing mandrel forces a small slug out as it completes its operation. Some use two presses and first pierce to a point near the bottom with a closed die pot on the first press, then complete the piercing on the second machine. In any case, it is necessary to reheat the billet before extruding.

There are other extrusion presses on which a closing plate is inserted between the container and the die while the mandrel pierces the billet to a point near the end, forming a closed cup. The closing plate is then removed and the mandrel completes the piercing operation, forcing a small slug through the die, after which the stem moves ahead to make the extrusion.

When solid shapes are extruded there is, of course, no mandrel, and the stem and dummy block are solid. Otherwise, the operation is exactly the same as for extruding tubes.

Operation of the Press—The press is operated by four men. One man on the inlet side of the press controls the conveyor delivering billets from the salt bath and cuts the stud from the billet. The second man operates all press controls except the dummy-block conveyor and die carriage. The third man removes the dummy block, disposes of the discard, and places the glass pads in the container. The fourth man operates the die carriage and takes care of the dies.

Tooling—All the extrusion tools are highly stressed in operation and must be made of alloy steels which will withstand heat. The containers are 36-inch outside diameter forgings with a $14\frac{1}{2}$ -inch bore at the entry end. The bore has a slight taper to accommodate a liner of the

TUBING DIE

FIG. 41—66. Sketch of die used for the hot extrusion of tubular sections.

desired inside diameter, which is pressed into the container. Liners are not removed until worn out; therefore, a container is provided for each liner. Stems, both solid and hollow, are provided to fit each liner with about $\frac{3}{16}$ -inch clearance on the diameter. These stems are subjected to compressive stresses up to 160,000 lb. per sq. in.

Dies range from $\frac{3}{4}$ to $1\frac{1}{2}$ inches thick and are of the general contour shown in Figure 41—66. They have a short bell-mouth, a straight bearing section which is usually about $\frac{3}{16}$ inch long, and a flared section on the

outlet side. Dies of 10 per cent tungsten steel and 5 per cent chromium hot-work steel have given good service. At best, dies wear rather rapidly, due partly to the fact that their temperature is raised considerably during each extrusion. Long extrusions cause much more rapid die wear than short ones. Dies of harder materials, and steel dies with hard facings such as stellite, have been tried experimentally but have not as yet proved successful.

Dies for solid shapes present more problems than dies for tubes. Unsymmetrical shapes have a tendency to bow or twist when extruded because the metal flows more easily and therefore faster through the wider portions of the aperture and through the portion at the center of the billet. Also, it is difficult to lubricate the re-entrant corners. To minimize these difficulties, the aperture in the die should be located so that the sections more difficult to extrude are as near the center as possible. Bearings sections can be made longer on the sections where the flow is fastest, and the bell-mouth part of the die can be increased to encourage glass flow to certain sections.

Mandrels are made from 5 per cent chromium steel, hardened and ground to size. These mandrels must withstand the heavy compressive stresses transmitted by the billet under pressure and also the tension caused by friction of the extruded piece. Failure is usually due to necking-down near the back end where the stresses are greatest. Due to the heavy stresses, there is a minimum limit for the size of mandrel of any definite material and for any certain extrusion. In general, it has been found best to keep the mandrel diameter over 1 inch, although smaller ones have been used.

Dummy blocks are of the same steel or a similar steel as that used for mandrels, with the addition of about $1\frac{1}{2}$ per cent tungsten.

Dies, mandrels, and dummy blocks are preheated to about 300° F in a small furnace before placing them in use. The container is kept warm with an electric heater when the press is not in use. If these things are not done, the tools may break due to thermal shock.

Power Supply—Power for the press is supplied by two 300-gallon per minute pumps. They supply water at

FIG. 41—67. Stretch straightener with rotatable head for the straightening and removal of twist from extruded sections.

3600 lb. per sq. in. pressure through two air-hydraulic accumulators. An air compressor is available to charge the accumulators, when necessary. One pump and one accumulator supply water for the main ram only. The other pump and accumulator supply the piercer ram and auxiliary equipment, including the die carriage, the die locks, the discard separator, and the container shift. An oil-hydraulic system operating at 500 lb. per sq. in. supplies the power to operate the main control valves through servo-mechanisms, the saws, and the hydraulic motor for the charging-carriage travel.

Finishing Operations—The extruded piece is carried on the outlet conveyor past a hot saw which can be used to divide the length if desired. The extrusion is then submerged in a quench tank if it is of austenitic stainless

steel. Steels which cannot be quenched are discharged onto skids to cool.

All extruded pieces are covered with a thin coating of glass which, due to its abrasive nature, must be removed before any cold work is performed. Quenching removes a portion of this glass, but the remainder must be removed by pickling. Before this de-glassing operation, special shapes are straightened on a stretch straightener, shown in Figure 41—67. This machine has a capacity of 100 tons, and one of the heads is rotatable so that any twist in the piece can be removed.

After straightening and de-glassing, solid shapes are cut to length. Tube hollows (a mill term for semifinished tubes produced by hot extrusion), after de-glassing, are further processed by cold drawing or tube reducing.

SECTION 9

FINISHING OPERATIONS

The hot-rolling processes described in the previous sections of this chapter on tubular products do not produce pipe in its final form. Though less spectacular, the finishing operations are a very necessary part of the production process. After leaving the straightening rolls, all pipe passes through a sequence of operations which depend on the size and class being produced. Pipe, rolled to a common specification on the hot mill, may be finished into various classes of pipe in the finishing operations. Inasmuch as these operations differ only slightly and usually only in the design of the equipment, the operations on seamless pipe have been selected as being typical of all classes.

Straightening—From the hot mills the hot-rolled pipe is delivered to the straightening machine which consists of two driven rolls from 2 to 3 feet long and 19 to 28 inches in diameter and three idler rolls 1 to 2 feet long and 12 to 18 inches in diameter, the former and two of the latter being set obliquely and opposite to each other, in position and angle, so that when a length of pipe is inserted between them it is held firmly by two sets of rolls. The third idler roll being between these confining points can be adjusted to bring pressure to the pipe and thereby perform the straightening. As in the reeling operation, the pipe is kept between the rolls by guides properly set between them and at some distance below the center line, depending on the size of pipe. The pipe, which is inserted between the first driven and idler rolls, is grasped, rapidly revolved, and drawn forward. During this action, the axis of the pipe is deflected by the middle idler roll which effects the straightening. The grip of the second driver and third idler roll finally throws the pipe clear of the machine.

Inspection and Cutting—When seamless pipe leaves the straightening rolls, it is delivered to a table where it is thoroughly inspected for straightness, size and external and internal surface defects, such as seams, pits, etc. The pipe is then delivered to the cutting-off machine where the crop ends are removed and the ends are cut smooth and perpendicular to the pipe axis, beveled for welding, or, if the pipe is to be threaded, it is chamfered to aid in starting the threading dies. The end is then reamed to remove any burrs and the wall thickness of the cut end measured to insure proper uniformity. Depending upon the class of pipe, a number of cut-off portions may be subjected to a flattening test to determine the ductility of the steel in the individual pipe.

Pipe Joints—A pipe joint is a means of connecting two or more lengths of pipe, so as to permit transportation of liquids or gases under leak-proof conditions, or

to permit the use of long lengths of pipe for mechanical or structural purposes. Generally speaking, joints may be divided into three classes:

1. Joints with threaded ends for couplings or flanges
2. Special connectors or couplings for use with plain-end or flanged-end pipe; as for example, Dresser, Victaulic, Vanstone, and similar joints.
3. Welded joints, including plain-end pipe beveled for welding, slip-joint casing and line pipe and double-belled-end line pipe with inserted chill ring for welding.

Joints with Threads and Couplings—The threaded and coupled joint is, by far, the most widely used and is the adopted standard of the American Petroleum Institute for casing, tubing, drill pipe, and line pipe. American Petroleum Institute (A.P.I.) casing in sizes 13 $\frac{3}{8}$ inches O.D. and smaller, tubing and drill pipe are manufactured with round threads; A.P.I. line pipe and 16-inch and 20-inch outside-diameter casing with the modified A.P.I. (Briggs') thread. "National" standard pipe to be fitted with couplings or flanges is manufactured to the applicable parts of the American Standards Association Threading Specifications. The great increase in the loads and internal pressures to which many types of threaded joints have become subject in the past few years has resulted in additional efforts to improve physical properties and threading practice. Thread form, thread depth, lead, and taper are maintained within the limits of the rigid tolerances given in the specification of the American Petroleum Institute and other organizations, so that coupling threads will mate properly with the pipe threads when made up to the power-tight position.

Threading Pipe—To secure good threaded joints it is necessary to have clean, smoothly cut threads of the proper taper and pitch, and to secure such threads it is necessary to have threading dies made with full consideration for the following: lip, chip space, clearance, lead, lubricants or cutting oils, and, for power machines, number of chasers.

Lip—Figure 41—68 illustrates clearly what is meant by lip on a chaser. The lip forms a slanted cutting edge which promotes curling of the chips and gives an easy cutting action, similar to that of a properly ground lathe tool, instead of the pushing-off effect caused by chasers which have no lip; it also permits a higher cutting speed. The angle to which the lip should be ground depends upon the kind of material to be threaded and the style and condition of the chasers and chaser holder. For Bessemer-steel pipe, this angle should be from 15 to 20

FIG. 41-68. Threading die showing lip, lip angle, chip space, clearance and cutting edge.

degrees; for open-hearth steel, the lip angle should be from 15 to 25 degrees.

Chip Space—Chip space is the space required in the die holder in front of the chasers to prevent the accumulation or packing up of chips. If sufficient chip space is not allowed, the chips will rapidly pack in front of the chaser, causing rough, torn threads, and creating a tendency on the part of the chaser to pick up stickers. The best design for this chip space provides an even curve for the chips to follow, with the back of each chaser well supported.

Clearance—Clearance is the space between the threads of the chasers and the threads on the pipe at a given distance from the cutting edge ("heel clearance" in Figure 41-68). This clearance is secured by die manufacturers in various ways. A simple method for getting clearance in the type of die known as "cutting-edge-on-center" or "center cut," consists of setting the chasers for machining with their cutting edge tangent with a larger circle than they are set for cutting threads. Clearance may be obtained on the "stock-on-center" type of chaser by machining in the same manner as a "cutting-edge-on-center" chaser, with the exception that their cutting edge is tangent to a smaller circle than when they are set for cutting threads. Stock-on-center chasers can also obtain their clearance by setting the chasers ahead of the center-line when they are being machined.

Lead or Throat—Lead is the angle which is machined or ground on the first three threads, more or less, of each

chaser to enable the die to start on the pipe, and also to distribute the work of making the first cut over a number of threads. The lead may be machined or, as is more common, it may be ground after the chasers are tempered. The proper amount of lead is about three threads. As the

FIG. 41-69. Sketch showing correct angle for re-grinding lead of chasers.

heaviest cutting is done by the lead, this section of the chaser should have a slightly greater clearance angle than the rest of the threads, but care must be used to see that this angle is not excessive. Excess lead clearance will cause the die to feed too fast, and the half threads cut by the lead are consequently damaged by the full teeth of the chasers (see Figure 41—69).

Number of Chasers—To get good results in threading at one cut, the die head should have a suitable number of chasers. The number is determined by the size of the pipe. In some cases as many as eighteen chasers are required. The number necessarily depends upon the design, size, and operative principle of the die; hence, no exact rule can be laid down for universal acceptance. When an insufficient number of chasers is used, the die will chatter and cut a rough thread.

Dies—Dies usually are designed with the chasers evenly spaced and arranged either with the stock on center or with the cutting edge on center, as shown in Figure 41—68, in which case the face of the chaser is in the same plane as the central axis. A more recent development places the chasers at an angle of 24 degrees with a radial or center line and spaces them at varying angles around the pipe. An odd number of chasers is used. This has several advantages among which is the steadying effect the unequally spaced chasers have on the die thereby reducing chatter. Sharpening is simplified since the rake or lip angle is set at 24 degrees by the angle of the chaser with the center line and sharpening consists of merely grinding parallel to the face of the chaser.

Chaser teeth are usually designed to have the even-numbered chasers cut one flank of the thread and the odd-numbered chasers cut the other flank. This is done so that the threads of any individual chaser will not cut both flanks and results in a smoother thread.

Lubricant—Care should be taken to provide the proper quality of threading oil, as the best die made will not produce good results with poor or insufficient oil. With hand tools or where the flow is intermittent, No. 1 lard oil can be used with success. Cottonseed oils have a tendency to gum if not used in a constant flow. Poor lubricants are destructive to dies, and more power is required to cut a thread when they are used. A good quality of sulphurized mineral oil should be used with a constant flow on power machines.

Gaging Pipe Threads—To keep pipe-threading practice at a high degree of accuracy, the mills maintain complete sets of standard gages with which the pipe-thread dimensions may be measured. For each size of pipe threaded, a master plug gage is kept at the mills, and these gages are returned periodically to the National Bureau of Standards for examination of accuracy. Except for the pipe-thread vanish angle, the threaded master plug gage represents a theoretically correct pipe thread as to pitch diameter, lead, taper, and thread form. The ring gage is the transfer medium, also certified for accuracy by the Bureau of Standards, and represents a theoretically correct coupling thread with reference to lead, taper, and thread form. The ring gage is threaded and sized so that it will screw onto the master plug gage a predetermined distance, known as the hand-tight position. On American Petroleum Institute gages, the hand-tight position is expressed as *standoff*, which is the distance from a scribed mark or notch in the master plug gage to the face of the ring gage. The *standoff* represents the advance from the hand-tight to power-tight position which has been determined as necessary to obtain a leak-proof and otherwise efficient joint. The working plug and ring gages used to verify the accuracy of the couplings and threaded pipe, respectively, are in turn

compared with the master plug and ring gages, so that the makeup from hand-tight to power-tight position in the joint will be uniform and within the specification tolerance limits. In addition to plug and ring gages, the mills are provided with various other types of high-precision gaging instruments, each one serving its particular function in indicating the accuracy of thread depth, thread form or angle, taper of threads in a specified length, pitch diameter, and lead or pitch. A more complete description of thread inspection and gaging instruments may be had by reference to American Petroleum Institute Standards 5-B.

Coupling Forgings—All threaded couplings are made of seamless steel forgings of a grade of steel at least equal to that of the threaded pipe with which they are used. Seamless coupling forgings, also called *blanks*, are cut from lengths of seamless pipe, pierced and rolled to the required coupling diameter and wall thickness.

Finishing Steel Couplings—The blanks are stamped with the necessary identifying marks. They are then placed in machines which true up the ends, taper the bore to conform accurately with the taper of the thread and, if required, recess or chamfer the ends internally. This is all performed in the same operation to assure alignment of the two ends of the finished coupling. The preparation of the coupling blanks is of great importance and care is taken to see that all operations associated with their preparation are properly carried out. The prepared blanks are tapped on automatic tapping machines. These machines tap both ends of the coupling in one chucking operation to assure accurate alignment of the finished coupling. After tapping, all couplings are inspected for pitch, taper and thread depth with precision instruments specially designed for this type of work. Size or pitch diameter is checked on hardened and ground, threaded gages.

To prevent galling of the threads, the couplings are electrogalvanized. As a first step in this process, the couplings are first washed with a soda solution to remove the oil adhering from the threading operation. Thoroughly cleaned on the inside, they are placed, several at a time, in a specially constructed plating tank filled with a zinc solution. In this tank the couplings are supported so that they collectively form the cathode, while zinc poles project into the couplings to form the anode. Upon the passage of direct current through the apparatus, the zinc is deposited upon the inside of the coupling as a firmly adhering coat, the thickness of which depends upon current density and time. Since the coat will not adhere firmly if the current density is too great, this factor is limited and maintained to give a tight coat, and thickness is controlled by time. As an additional safeguard against galling, to facilitate the tightening up of the couplings on pipe and also to prevent rusting of the threads in service, a special thread dope composed of zinc dust and non-drying lubricating greases has been prepared for use with couplings.

Testing the Pipe—From the threading machines, or from the cutting-off machines if the pipe is plain end or beveled for welding, the pipe is moved over a final inspection table, where each length is carefully inspected for surface defects, end finish, size, etc., to the hydrostatic-testing machine. If the pipe is threaded, the threads are lubricated, after which the couplings are screwed up to the established hand-tight position, examined for *standoff*, and then brought up to power-tight position by a power screwing-on machine. The pipe is then filled with water and an internal hydrostatic pressure is applied. This pressure may be from 400 to as high as 12,000 pounds per square inch, depending upon the kind of pipe, the size, and the service for which it is to

Fig. 41—70. Hydrostatic-testing machine.

be used. Some pipe, such as butt-weld pipe for ammonia purposes is also given an air test while submerged in water. For the hydrostatic test a specially designed machine is provided, which consists of a bench mounted on one end with a water-tight head connected with a hydraulic line and with a similar head made adjustable to suit different lengths of pipe, mounted on the other. A number of clamps for supporting the pipe and an air hammer for tapping the pipe during the test are mounted between these heads. When being tested, welded pipe is placed between the heads, the supporting clamps are applied, and the adjustable head is moved forward to seal the ends of the pipe tightly with packing rings or gaskets. Water is admitted until the pipe is full and no air pockets remain. The pressure line valve is then opened until the gage indicates the specified test pressure, which is maintained for five seconds, during which time the pipe is jarred automatically with the air hammer. The face of the air hammer is brought to bear upon and vibrate against the pipe, which is thereby subjected to impact and vibration while under maximum internal stress. The pipe is then unclamped from the testing machine, and one end is elevated while the water flows out, carrying with it flakes of detached scale.

Because of the enormous head pressures encountered in testing pipe, the higher test pressures are usually applied by what is known as the "field testing" method, so called because it was originally used with portable equipment. The extremely high pressures are employed to test casing and tubing to be used in deep wells where very high working pressures are encountered. A cap is screwed onto the field end pipe threads and a plug, through which the water enters the pipe, is screwed into the coupling on the other end of the pipe. Since there are no restraining forces on the ends of the pipe, the internal pressure acting on the cap and plug hydrostatically test the pipe joint in tension. Because of the very high pressures involved in this test, safety precautions are an important factor when installing and operating this equipment.

A very important factor in setting oil-well casing is the amount of external pressure exerted on the casing. This pressure is usually directly proportional to the depth of

the well and together with the bursting pressure and joint strength determines the grade of steel and wall thickness of casing required in deep wells. The resistance to collapse is proportional to the ratio between the outside diameter and the wall thickness of the casing which is usually expressed as D/t . It also varies with mechanical properties, especially the yield strength, below the range of elastic failure.

In order to assure a satisfactory level of collapse resistance, representative specimens of casing are subjected to external hydraulic pressure under laboratory controlled conditions. The length of the specimen for closed end testing used by National Tube Division, is eight times the diameter. After outside diameter and wall measurements are recorded, the ends are sealed either with portable leakproof heads or by welded plugs and the specimen is inserted in a heavy-wall forged jacket which is sealed and closed with heavy bayonet-type heads. After filling the jacket and bleeding out all entrapped air, hydraulic pressure is applied to the outside of the pipe by a high-pressure electrically driven reciprocating pump until failure of the specimen occurs through collapse of the section. The hydraulic pressure applied during the test is indicated on a calibrated mercury pressure gauge. Open-end tests are made by sealing the specimen using suitable packing rings through openings in the heads of the collapse jacket. In this method, the length of the test specimen is fixed by the length of the collapse jacket and consequently the ratio of the length of specimen to its diameter varies with each size. The method of applying and registering the pressure during the test is the same as with the closed-end test.

The test results are recorded and used as a process control, and as part of the experimental work which is constantly being done to improve casing quality and manufacturing method.

Oiling—Each length of pipe as it leaves the testing pump is measured, and this information together with the necessary identification marks is stenciled on the pipe, which is then given a coating of protective oil as it passes through a spray machine. This oil is a hardening transparent oil that leaves a lacquer finish. Sizes $1\frac{1}{2}$

inches and smaller are identified by stamping the necessary information on metal tags rather than stenciling, and these sizes, after oiling, are bundled to facilitate handling and shipment.

Types and Uses of Joints—The joints shown in Figures 41—71 to 41—80 represent those best known and most commonly used.

Upsetting—For severe service, it is often necessary to provide additional strength in the joint, and for this reason the ends of the pipe are upset before cutting the threads. To accomplish this upsetting, the end of the pipe is heated to forging temperature, then inserted endwise between two semi-circular dies of the upsetting machine. These dies clamp the pipe from the outside, while a mandrel, carrying a collar of the exact size of the outside diameter of the upset end, is inserted into the pipe. As the mandrel advances, the collar comes in contact with the end of the pipe and pushes the hot metal back to fill the ring-like space between the mandrel and the die. By changing the design of the dies, the upsetting may be controlled to displace the extra thickness either to the inside or to the outside of the pipe. Figure 41—71 shows internal upset casing.

Internal Upset Casing with Long Couplings—This design of joint is manufactured with an internal upset to support the weight of a long string of casing when it is suspended freely in a well of great depth. The importance of proper mechanical properties in the steel, as well as highly accurate threading practice, can best be appreciated when it is realized that this joint (as for example in 7-inch outside-diameter casing) may be required to support a 16,000 foot multiple-weight string which is equivalent to a dead load of 540,000 lbs. or 270 tons. Casing joints may also be subject to rock pressures as high as 7,000 pounds per square inch.

Seamless Buttress-Thread Casing—Non-Upset—This joint (Figure 41—72) is a development of National Tube Division to satisfy the petroleum industry's need for a casing joint which will safely and economically support the weight of casing designed for deep wells. The high tensile strength of the buttress-thread joint is due largely to the combined effect of the coupling threads completely engaging the casing thread throughout their entire length, including the vanishing threads, and the three-degree flank angle of the thread which support the weight of the casing in the well. Used on the API casing grades and with full inside clearance, 5½-inch through 7½-inch O.D. casing combination strings of multiple weight can be designed for 20,000-foot depths and corresponding approximately 10,000 lb. per sq. in. bottom hole rock pressure.

A.P.I. Casing with Long Coupling—A.P.I. casing with long couplings is manufactured in sizes 4½ inches to 13¾ inches outside diameter. The general outline of the joint is as shown in Figure 41—73. Casing with long couplings is intended for use in wells of somewhat lesser depths than the internal upset type and may also be used in the

lower sections of casing strings where the internal upset shown in Figure 41—71 is not necessary to obtain the desired joint strength and safety factor against failure. When it is necessary to obtain added clearance inside a larger size of casing or in open holes, couplings of sub-standard outside diameter but otherwise having standard dimensions may be used.

A.P.I. Standard Casing—The A.P.I. Standard Casing Joint (Figure 41—74) was designed for oil-well depths of 5,000 to 7,000 feet with a safety factor of 2.0 against failure in tension based on minimum physical properties. However, this joint may be used in the bottom sections of longer strings of casing, thus resulting in some reduction to the cost of the string. This joint is available with a sub-standard coupling outside diameter, where additional clearance is desired because of the necessity of its being run inside another string of casing or in open hole. The A.P.I. Standard Casing Joint is furnished in sizes 4½ inches to 20 inches outside diameter.

A.P.I. Line Pipe—The A.P.I. line pipe joints are similar in general outline to the A.P.I. standard casing joints (Figure 41—74). A.P.I. line pipe is threaded to American Petroleum Institute Standards 5-L, and the same rigid control of threading tolerances maintained as for A.P.I. casing and all other classes of threaded joints. Until recently, the essential differences between line pipe and standard pipe joints were in the coupling diameters and length and also in the thread length, each of these dimensions being greater in A.P.I. line pipe than in standard pipe. The American Petroleum Institute has since adopted the American Standards Association thread lengths for line pipe, thus eliminating the longer line-pipe threads. Line-pipe and standard-pipe couplings may now be used on pipe threaded to either the A.P.I. or A.S.A. specifications. The threaded line-pipe joint, however, is subject to higher test pressures since, in actual service, line pipe is generally subject to far higher working pressures than is standard pipe; the latter being more suitable for low-pressure work, such as piping for plumbing and sprinkler systems.

A.P.I. External Upset Tubing—A.P.I. external upset tubing (Figure 41—75) is desirable for deeper wells and for wells of any depth that are pumped. Both ends of the tubing are externally upset in order that the metal area at the root of the first exposed thread, when the joint is properly made up, may be at least equal to the metal area in the body of the pipe and thus of equal strength in tension. This tubing can therefore better absorb the dynamic stresses induced by pumping as the possibility of a fatigue failure in the threaded section is reduced to a minimum.

A.P.I. Standard Tubing—A.P.I. standard (or non-upset) tubing is generally used in open-flow wells and in shallow wells where tubing is pulled from the well infrequently and is a medium for pumping or otherwise raising oil to the well surface and thence to storage tanks. The A.P.I. standard tubing joint is similar in gen-

eral outline to the A.P.I. casing (long coupling) joint (Figure 41-73).

A.P.I. Internal Upset Drill Pipe—The drill-pipe joint (Figure 41-76), which is manufactured with upset end, is subject to still greater and far more complex loading, since strings of drill pipe as long as 20,000 feet are supported by one joint which also transmits the torque from the rotary table to the body of the pipe and ultimately to the bit. The bit, in turn, revolving at high speed is subject to varying degrees of pressure, depending on the formation being drilled. Where cavings occur, the pressure on the bit, expressed in terms of column loading, is sometimes sufficient to induce very high stresses in the joints. Drill pipe is also subject to high internal mud pressure, which is required to wash cuttings to the surface and to act as a lubricant while drilling. While the joint as shown in Figure 41-76 is still the A.P.I. standard, most strings of drill pipe are now fitted throughout with tool joints; and the design of these tool joints is such that the greater part of the stresses incidental to drilling pass from the body of the pipe through the tool joint and into the next pipe section, thus reducing the possibility of V-notch failures through the threaded section of pipe. This is accomplished by flash-welding the tool joint to the upset, or by welding the tool joint to the body of the pipe back from the threaded end, or by shrink-fitting an extension in the tool joint to a special external upset and machined pipe end. Since it is not the purpose here to describe types and uses of tool joints, the reader is referred to A.P.I. Specifications 7-B and to the catalogs of various tool-joint manufacturers.

Standard Pipe—The standard pipe joint (Figure 41-77), while primarily intended for low-pressure steam, gas, and water lines, as found in buildings and industrial plants, is also used for structural purposes, as in hand railing, scaffolding, etc. This joint has been superseded for long transportation lines by the A.P.I. line-pipe joint and welded line-pipe joint.

Flanged Joints—While only two types of flanged joints are illustrated in Figures 41-78 and 41-79, there are a number of other types of flanged joints that may be more suitably adapted to specific problems, and the fact that they are not described or illustrated does not in any way detract from their recognized merits.

Threaded Flange Joint—Pipe to be fitted with standard screwed flanges is threaded to A.S.A. Standards (Briggs' threads). The flanges for use with steel pipe are generally manufactured from forged or alloy steel, depending on the temperature and pressure to which they are to be subjected. Joints of this type (Figure 41-78) are used for power plants, refineries, etc., where working pressures of 1,500 pounds per square inch and temperatures of 1000° F are quite common.

Flanged Joint—Vanstone Type is illustrated in Figure 41-79. Pipe for use with this and similar types of flanged joints is heated at the ends to forging temperature and upset or thickened by rolling back the metal. This is done to compensate for reduction in the metal thickness that would otherwise occur, when the pipe ends are flanged or rolled back to the position shown in Figure 41-79. Since the rolled-back pipe ends are not faced, leakage is possible, and to avoid this, gaskets of softer material are inserted between the pipe ends when making up the joint.

Expanded End for Welding and Double Expanded Ends for Welding—These types are illustrated by Figures 41-80 and 41-81. The female or expanded ends for both joints are formed by the same machine that prepares the ends for Vanstone type or any other formed-end joint. The joint shown in Figure 41-80 is frequently used for long transportation pipe lines employing light pipe walls

subject to low pressures. Figure 41-80 is also representative of slip-joint casing. The joint is made up in the field with the female or expanded end held uppermost on the casing slips. The male end is lowered into the expanded end, held in as near correct alignment as possible, and quickly tack welded, after which the welding is completed by acetylene torch. The joints shown in Figures 41-81 and 41-82 are also recognized as standards for welded pipe lines. Figure 41-81 shows expanded pipe ends fitted with a backing-up or chill ring which strengthens the joint and prevents the formation of metallic icicles when molten weld metal enters the space between the pipe ends and solidifies. The pipe ends are prepared for welding by thoroughly cleaning and removing any coating or dirt that would affect the quality of the weld, after which the ends are held by clamps in alignment with a specified gap between the ends; the pipe is then tack-welded, and, when in final position, welding is completed. Pipe may also be welded by placing a dolly having rollers mounted on it, under the pipe ends to be welded. The pipe may thus be rotated to facilitate welding. Plain-end pipe for welding is generally furnished to A.P.I. Specification 5-L which requires a bevel angle of 30 degrees and $\frac{1}{16}$ -inch flat at the end of the pipe. Plain-end pipe beveled for welding is used extensively for power-plant work where high temperatures and pressures are encountered. The welding is generally made either by the electric-shielded-arc or oxy-acetylene process, welding rods to suit the chemical and mechanical properties of the steel in the pipe being used.

Dresser-Type Joint—This joint (Figure 41-83) has been frequently used for transportation of high-pressure natural gas, also for low-pressure oil and water lines. It is easily and rapidly assembled and is made leakproof by tightening the bolts, thus exerting pressure on the gaskets and in turn on the pipe perimeter. The two gaskets are of rubber, or other suitable material, depending on the temperature to which the joint is to be subjected, and also upon the corrosive action of the fluid being carried in the pipe. The joint is designed to accommodate contraction or expansion due to temperature changes encountered in the line, and will also take care of a certain amount of misalignment. The ends of the pipe for Dresser-type couplings are gaged to specified diameter and roundness tolerances to insure proper assembly in the field.

Victaulic Joint—Like the Dresser-type joint, the Victaulic joint (Figure 41-84) is quickly assembled and designed to take up expansion or contraction due to normal temperature changes. This joint will also absorb a certain amount of angular misalignment. Figure 41-84 shows the grooved-end type of joint, the pipe ends being grooved or machined out to provide a seat for the coupling. Other formed pipe ends used with Victaulic couplings are:

1. The shouldered end.
2. The expanded end.
3. The folded-back end.

Of these, the expanded end is most generally used. The pipe ends are expanded in an upsetting machine and finished to the specified dimensions. The joint is assembled by first lubricating the pipe ends, and then slipping the ring gasket over one pipe end, after which the second pipe end is brought into position and the ring moved over to cover both ends of pipe. The metal housing or coupling, made in two sections, is mounted over the ring gasket so that it fits into the grooves or over the expanded or shouldered pipe ends, and is made leakproof by tightening the bolts, thus forcing the gasket

FIG. 41—85. Pipe discharging from a continuous galvanizing kettle.

against the pipe face. As will be seen in the illustration, the gasket is so formed that pressure inside the pipe tends to increase the resistance to leakage.

Galvanizing—The hot-dip process of galvanizing is widely used for applying zinc coating to steel pipe for protection from corrosion. The pipe is first thoroughly cleaned by washing in a water solution of caustic soda to remove all traces of oil, paint and grease. It is then pickled in a hot, dilute sulphuric-acid solution (containing an inhibiting agent) to remove all rust and mill scale, after which it is washed free of adhering acid by immersing in a bath of fresh, clean water. The fluxing operation then follows and is accomplished by immersing the pipe in a hot solution of zinc ammonium chloride until the temperature of the pipe approximates that of the solution. Upon removal from the fluxing tank, the pipe is thoroughly drained, then placed on the charging table of the galvanizing kettle where it is introduced into a bath of molten zinc maintained at a temperature of about 870° F. When the pipe has been immersed for a time sufficient to permit its temperature to reach that of the molten zinc, it is withdrawn slowly in an inclined position to permit the excess zinc to drain from both the inside and outside. It is then conveyed through the cooling tanks, at which time it is given a special chromate treatment which aids in preserving the bright, metallic appearance of the zinc coating.

Several methods are employed for processing pipe through the galvanizing kettle. An outstanding development is the continuous method of processing pipe in the size range $\frac{1}{2}$ -inch to 2 inches inclusive, whereby the pipe are handled on a series of spiral-groove rolls which rotate

the pipe with a screw-feed motion, imparting forward and lateral travel through the galvanizing kettle (Figure 41—85). This is accomplished by automatically charging the pipe on an inclined table equipped with spiral-groove rolls, the pipe moving on a downward slope of approximately 10 degrees and entering the kettle at the corner of one end. The pipe continues downward into the kettle until it is completely immersed, the direction of slope is changed from downward to upward by pivoting the pipe on the center roll. The pipe continues traveling forward and laterally, leaving the kettle at the diagonally opposite corner. A low-pressure air blast is directed on the pipe on the outgoing table, as it emerges from the kettle, to set the coating and maintain a smooth surface and bright luster. The pipe is then discharged into a tank containing a dilute solution of sodium dichromate.

The continuous method of galvanizing pipe has the advantage of a high production rate and uniform and closely controlled operation, $\frac{1}{2}$ -inch standard pipe, for example, being galvanized at a rate of 1250 pieces per hour. With bath temperature and immersion time closely controlled, a decided improvement is obtained in the uniformity of the inside and outside coating of the pipe. A full coating is also obtained, as the pipe is not wiped. This provides a surface coating of almost pure zinc which is believed to have corrosion resistance superior to pipe which has been wiped.

Galvanized pipe in sizes over 2 inches is processed by the batch method wherein the pipe is charged into the galvanizing kettle in batches, the amount of the batch depending on the size of the pipe being processed. In

this process, the pipe arc submerged by a sinking-arm arrangement and after a short interval are withdrawn from the kettle by a magnet, the pipe being pulled out of the kettle on an inclined plane to provide drainage of the excess zinc from the inside and outside surface. No wiping operation is normally employed on pipe processed by the batch method; however, in galvanizing pipe in sizes smaller than 1/2-inch or pipe requiring an exceptionally smooth surface and a minimum weight of coating, the pipe is withdrawn from the kettle on single-draw magnetic rollers, the excess zinc being air-wiped from the outside and blown from the inside surface during withdrawal.

Value of Zinc Coating for Pipe—Though zinc coating is readily soluble in dilute acids, strong alkalis and some mineral-salt solutions, galvanizing affords effective protection against ordinary atmospheric corrosion, because the zinc, when exposed to the air, immediately reacts with oxygen to form zinc oxide. This reaction progresses only to a limited extent, however, for the oxide remains as a thin film on the surface of the zinc coating, and protects the zinc from further oxidation. Since this oxide is insoluble in water and since the film adheres rather tenaciously to the zinc, it protects the underlying coating of zinc against all ordinary types of weathering, and as long as the zinc remains intact, the steel beneath is secure from corrosive action. If the zinc coating is broken, by bending or abrasion, and the underlying steel is exposed to corrosive influences, the zinc will still afford considerable protection. Being electro-positive to the steel, the zinc is dissolved instead of the steel as long as any zinc remains closely adjacent to the exposed steel. In underground piping, where the pipe is in direct contact with the earth, galvanizing is not generally suitable as protection against corrosion, because it may be quickly destroyed either by certain acids or by certain alkali substances in the soil.

ents which are being discussed. It is a homogeneous phase, consisting of a solid solution of carbon in the gamma form of iron. It is formed when steel is heated to a relatively high temperature, say above 1450° F, (788° C). The limiting temperatures for the formation of austenite vary with composition and will be discussed in connection with the iron-carbon diagram. The metallographic appearance of austenite is shown in Figure 42—7, which represents a sample of an alloy steel which has been very rapidly cooled from the temperature range at which the austenite is stable, the steel being high enough in alloy content to make possible the retention of austenite structure at room temperature.

The atomic structure of austenite is that of gamma iron—face-centered cubic—and the atomic spacing varies with the carbon content.

Pearlite—When a plain carbon steel of approximately 0.80 per cent carbon is cooled slowly from the temperature range at which austenite is stable, all of the ferrite

FIG. 42—4. The atomic structure of cementite. Positions of carbon atoms are indicated by solid circles; positions of iron atoms by open circles. (Hendricks, S. B.: *Zeitschrift für Kristallographie*, Vol. 74 (1930), 534-545.)

and cementite precipitate together in a characteristic lamellar structure known as pearlite. This structure is illustrated in Figure 42—8. It is generally similar in its characteristics to an eutectic structure but since it is formed from a solid solution rather than from a liquid phase, it is known as an **eutectoid structure**.

At carbon contents above and below 0.80 per cent, pearlite of about 0.80 per cent carbon is likewise formed on slow cooling, but the excess ferrite or cementite first precipitates usually as a grain boundary network, but occasionally also along cleavage planes of the austenite. This excess ferrite or cementite rejected by the cooling austenite is known as a **proeutectoid constituent**. The carbon content of a slowly-cooled steel can be estimated from the relative amounts of the pearlite and proeutectoid constituents in the microstructure.

FIG. 42—3. Crystalline structure of the allotropic forms of iron. Each white sphere represents the relative position of an atom in a "unit cube" of: (left) alpha and delta iron, which have the body-centered cubic form, and (right) gamma iron, which possesses the face-centered cubic form.

FIG. 42-5. The microstructure of slowly cooled, high-carbon steel showing pearlite with cementite in the grain boundaries. Magnification: 1000X.

The Iron-Carbon Equilibrium Diagram—The iron-carbon equilibrium diagram furnishes a "map" showing the ranges of compositions and temperatures within which the various phases are stable and the boundaries at which phase changes occur. Although heat treatment is largely concerned with a controlled departure from equilibrium, this diagram represents the limiting conditions and is basic to an understanding of heat-treating principles.

The iron-carbon equilibrium diagram is depicted in Figure 42-9. This diagram, covering, as it does, the temperature range from room temperature to the melting point of iron and carbon contents of from 0 to 5 per cent represents the equilibrium conditions for the entire range of steels and cast irons in both the liquid and solid states. Use of this diagram in ensuing discussions involves two constituents, **ledeburite** and **graphite**, which have not been mentioned up to this point. Although

FIG. 42-7. The microstructure of austenite. Magnification: 500X.

these are not ordinarily constituents of steels, their characteristics will be briefly discussed at this point.

Ledeburite—Ledeburite is the metallographic term for the iron-iron carbide eutectic, containing 4.3 per cent carbon. This eutectic is a constituent of iron-carbon alloys containing more than 2.0 per cent carbon and for this reason the dividing line between steels and cast iron is customarily set at 2.0 per cent carbon. The metallographic appearance of ledeburite in cast iron is shown in Figure 42-10.

Graphite—Cementite is unstable over certain ranges of composition and temperature and decomposes into iron and graphite. Thus, in most slowly-cooled cast irons, graphite is an equilibrium constituent at room temperature. The gray appearance of the fracture of such slowly-cooled cast irons reflects the presence of the graphite and the metallographic appearance of graphite in gray cast iron is shown in Figure 42-11.

FIG. 42-6. Micrograph showing spheroidized cementite in matrix of ferrite. Magnification: 1000X.

FIG. 42-8. The microstructure of pearlite. Magnification: 1000X.

FIG. 42-9. The iron-carbon equilibrium diagram, for carbon contents up to 5 per cent. From "Metals Handbook" (American Society for Metals), 1948 Edition; page 1182.

Graphite may, under certain conditions, be a constituent of steels and the metallographic appearance of graphite in a low-carbon steel which has been subjected to a prolonged heating at a temperature below that at which austenite is formed is illustrated in Figure 42-12.

The Iron-Iron Carbide Equilibrium Diagram for Steels—The portion of the iron-iron carbide diagram of concern in connection with the heat treatment of steel is that part extending from 0 to 2.0 per cent carbon. The general features of this diagram (Figure 42-9) will be discussed and its application to heat treatment will be

illustrated by considering the changes occurring on heating and cooling steels of selected carbon contents as depicted by the diagram.

Critical Temperatures—In Table 42-I, iron is listed as occurring in two allotropic forms, alpha or delta (the latter at very high temperature) and gamma. The temperatures at which these phase changes occur are known as critical temperatures and the boundaries in Figure 42-9 show how these temperatures are affected by composition. For pure iron, these temperatures are 1670° F (910° C) for the alpha-gamma phase change

FIG. 42—10. The microstructure of ledeburite. Magnification: 150X.

and 2552° F (1400° C) for the gamma-delta phase change. The critical temperatures on heating are designated as A_c (from the French "chauffage," meaning "heating") temperatures, while those on cooling are designated as A_r (from the French "refroidissement," meaning "cooling") temperatures. Although, in principle, the transformations A_c and A_r result from the same temperature of equilibrium, in practice, the A_r temperatures are lower than the corresponding A_c temperatures, falling as the cooling is more rapid; even with very slow heating or cooling these temperatures do not coincide and, therefore, the subscript "e" (for equilibrium) is used in the designation of the critical temperatures in the equilibrium diagram. The meaning and significance of the critical temperatures will be clarified in the following discussion of the changes occurring on heating and cooling iron-carbon alloys as depicted by the equilibrium diagram.

FIG. 42—11. The microstructure of gray cast iron showing graphite flakes. Magnification: 100X.

FIG. 42—12. Micrograph showing graphite particles in low-carbon steel. Magnification: 100X.

Changes Occurring on Heating and Cooling Pure Iron—The only changes occurring on heating or cooling pure iron are the reversible changes, (1) at about 1670° F from body-centered alpha iron to face-centered gamma iron and (2) from the face-centered gamma iron to body-centered delta iron at about 2552° F.

Changes Occurring on Heating and Cooling Hypoeutectoid Steels—Hypoeutectoid steels are those which contain less than the eutectoid percentage of carbon (0.80 per cent). The diagram shows the equilibrium constituents are ferrite and pearlite, the relative amounts of each depending upon the carbon content. The diagram also shows that at 1112° F the ferrite may hold in stable solution about 0.007 per cent carbon. At temperatures up to 1333° F, the solubility of carbon in the ferrite increases until at this temperature, the ferrite contains about 0.025 per cent carbon. The first phase change on heating (if the steel contains above 0.025 per cent carbon) occurs at 1333° F and this temperature is therefore designated as the A_1 critical temperature. On heating just above this temperature, the pearlite (ferrite and cementite) all changes to austenite. Some proeutectoid ferrite, however, remains unchanged. As we heat to temperatures farther above the A_1 temperature, the austenite dissolves more and more of the surrounding proeutectoid ferrite, becoming lower and lower in carbon, until at the A_3 temperature, the last of the proeutectoid ferrite has been absorbed into the austenite having the same average carbon content as the steel.

On slow cooling the reverse changes occur. The austenite first rejects ferrite (generally at grain boundaries) on cooling below A_3 and becomes progressively richer in carbon, until, just above the A_1 (eutectoid) temperature, it is substantially of eutectoid composition. On cooling below A_1 , this eutectoid austenite changes to pearlite so that the final product after cooling below A_1 is a mixture of ferrite and pearlite, the relative proportions of each constituent depending upon the carbon content.

Changes Occurring on Heating and Cooling Eutectoid Steels—Since no excess ferrite or cementite is present in eutectoid steel, the only change occurring on slow cooling or heating is the reversible change from pearlite to austenite at the eutectoid temperature. Thus, in the

case of eutectoid steels, the A_2 and A_1 temperatures coincide and this eutectoid composition and temperature is designated as the A_{s-1} point.

Changes Occurring on Heating and Cooling Hyper-eutectoid Steels—The behavior on heating and cooling hyper-eutectoid steels (steels containing more than 0.80 per cent carbon) is similar to that of hypoeutectoid steels except that the excess constituent is cementite rather than ferrite, so that on heating above A_1 , the austenite gradually dissolves the excess cementite until at the A_{cm} temperature all of the proeutectoid cementite has been dissolved and austenite of the same carbon content as the steel is formed. Similarly, on cooling below A_s , cementite precipitates and the carbon content of the austenite approaches the eutectoid composition. On cooling below A_1 , this eutectoid austenite changes to pearlite and the room temperature constitution is, therefore, pearlite and proeutectoid cementite.

The A_s Formerly Designated Critical Temperature—The diagram of Figure 42-9 shows a dotted line at 1414°F . This behavior differs from those at the A_1 and A_2 temperatures in that it does not involve a phase change. In the neighborhood of 1414°F and up to about 1454°F there is a gradual magnetic change, the ferrite being ferromagnetic below this temperature range, and paramagnetic above. The change is also accompanied by a heat effect. This A_s change is of little or no significance in regard to the heat treatment of steel.

The Effect of Alloys on the Equilibrium Diagram—The iron-carbon diagram may, of course, be profoundly altered by alloying elements, and, therefore, its application should be limited to plain carbon and low-alloy steels. The most important general effects of the alloying elements may be listed as follows:

1. The number of phases which may be in equilibrium is no longer limited to two as in the iron-carbon diagram.
2. The temperature and composition range, with respect to carbon, over which austenite is stable may be increased or reduced.
3. The eutectoid temperature and composition may be changed.

The alloying elements may be divided generally into two classes in respect to the second effect: those which enlarge the austenite field and those which reduce it. The elements which enlarge this field include manganese, nickel, cobalt, copper, carbon and nitrogen. Be-

FIG. 42-13. Section of the Fe-C-Mn equilibrium diagram at 13 per cent manganese content. From "Metals Handbook" (American Society for Metals), 1948 Edition; page 1252.

cause of this characteristic, elements of this type are descriptively known as **austenite formers**. Figure 42-13, which shows the 13 per cent manganese section of the iron-carbon-manganese equilibrium diagram, is illustrative of the effect of elements of this type. The large field in which austenite is stable, the lowering of the eutectoid temperature and carbon content, and the three-phase field in which alpha iron, austenite and carbides exist in equilibrium should be noted.

The commoner elements which decrease the "size" of the austenite field include chromium, silicon, molybdenum, tungsten, vanadium, tin, columbium, phosphorus, aluminum and titanium. Such elements are known as **ferrite formers**. Figure 42-14 showing the

FIG. 42-14. The effect of molybdenum on the composition and temperature range over which austenite is stable (After Bain.)

effect of molybdenum on the composition and temperature range over which austenite is stable will serve to illustrate the effect of alloys of this type. These steels will likewise have the three-phase zone in which austenite, ferrite and carbides will be in equilibrium at temperatures below the austenite field.

The effect of the elements on the eutectoid temperature and composition is summarized in Figure 42-15. It will be noted that manganese and nickel lower the eutectoid temperature while the other elements generally raise it. All of the elements seem to lower the eutectoid carbon content.

Grain Size—As described above, when a piece of steel is heated above the critical temperature, the ferrite and carbide react with one another to form austenite. The austenite is a crystalline phase differing distinctly from either the ferrite or carbide from which it is formed. Like any metal composed of a solid solution, it exists in the form of polyhedral grains. The reaction which forms austenite begins at a number of points in the interface of the carbide and ferrite. Each of the little islands of austenite grows until finally it reaches its similarly growing neighbors. As the temperature above the critical increases, further grain growth occurs, presumably by encroachment of a grain into adjacent grains. The final austenite grain size is, therefore, a function of the temperature above the critical to which it is heated. This grain growth may, however, be inhibited by carbides which dissolve slowly or remain undissolved in the austenite or by a suitable dispersion of non-metallic inclusions. Hot working refines the coarse grain size formed by heating to the relatively high temperatures used in

FIG. 42-15. Eutectoid composition and temperature as influenced by several alloying elements. (After Bain.)

forging or rolling and the grain size of hot-worked products is determined largely by the finishing temperature, that is, the temperature at which the final stage of the hot-working process is carried out.

Grain Size and Properties—The coarseness of the ferritic and pearlitic “grains” in the cooled steel reflects the grain size of the austenite prior to its transformation and the properties of the product are profoundly influenced by its grain size. The general effects of the austenite grain size are summarized in Table 42—II.

Determination of Grain Size—Grain size is customarily determined by viewing a polished plane section, prepared in such a way as to delineate the grain boundaries, under a microscope. The grain size is then determined by comparing the size of the outlined grains with a standard chart,* known as the A.S.T.M. standard grain-size chart. Two of the three most common methods of delineating the grain boundaries are to cool

the steel from its austenitizing temperature in such a way that the shape of the original austenite grains is outlined by (1) a grain-boundary network of ferrite in the case of hypoeutectoid steels, or (2) a grain-boundary network of cementite in the case of hyper-eutectoid steels. In the third method (3) the steel is

quenched to its full hardness and a polished section is etched with a special reagent which will disclose orientation differences in the martensite grains formed from the austenite on quenching. The index numbers of the standard grain-size chart represent by far the most common method of expressing grain size. These numbers are tabulated in Table 42—III together with the corresponding dimensions.

Fine- and Coarse-Grain Steels—As was mentioned previously, austenitic-grain growth may be inhibited by undissolved carbides or by a suitable distribution of non-metallic inclusions. Steels of this type are commonly referred to as inherently fine-grained or simply as fine-grained steels, while steels which are free from these grain growth inhibitors are known as coarse-grained steels.

The general pattern of grain coarsening in steels of the coarse- and fine-grained types on heating above the critical temperature is illustrated in Figures 42—16 and 42—17. It will be noted that the coarse-grained steel coarsens gradually and consistently as the temperature is increased, while the fine-grained steel coarsens only slightly, if at all, until a certain temperature is reached, above which an abrupt coarsening occurs. This temperature is known as the **coarsening temperature**. It should further be noted that either type of steel may be heat treated so as to be either fine or coarse grained, and as a matter of fact, at temperatures above its coarsening temperature, the fine-grained steel will usually

FIG. 42—16. Grain size as a function of austenitizing temperature for inherently coarse-grained steels. (After Bain.)

FIG. 42-17. Grain size as a function of austenitizing temperature for an inherently fine-grained steel (schematic). (After Bain.)

exhibit a coarser grain size than the coarse-grained steel at the same temperature.

The usual method of making steels which remain fine grained at 1700° F (A.S.T.M. E19-46) involves the judicious use of aluminum deoxidation. The inhibiting agent in such steels is generally conjectured to be a submicroscopic dispersion of aluminum nitride or, perhaps at times, aluminum oxide.

THE TRANSFORMATION OF AUSTENITE

Thus far, this chapter has largely been concerned with equilibrium conditions. Under equilibrium conditions, that is, with very slow cooling, it has been shown that austenite transforms to pearlite when it is cooled below the A_1 critical temperature, and at a temperature only a little below the A_{e1} temperature. When more rapidly cooled, however, this transformation is depressed and does not occur until a lower temperature is reached. The faster the cooling rate, the lower is the temperature at which transformation occurs. Furthermore, the nature of the ferrite-carbide aggregate formed when the austenite transforms varies markedly with the temperature of transformation and the properties are found to vary correspondingly. Thus, heat treatment is seen to involve

a controlled supercooling of austenite, and in order to take full advantage of the wide range of structures and properties which this permits, a knowledge of the transformation behavior of austenite and the properties of the resulting aggregates is essential.

Isothermal Transformation Diagrams—The transformation behavior of austenite can best be studied by a technique developed at the United States Steel Corporation Fundamental Research Laboratory in 1930. This involves studying the transformation behavior at a series of temperatures below A_1 , by quenching small samples to the desired temperature in a liquid bath, allowing them to transform isothermally and following the progress of the transformation metallographically or by dilatometric measurements. This procedure not only gives a picture of the rates of transformation at the various temperatures, but also furnishes information as to the metallographic structures characteristic of the various temperatures of transformation and permits a determination of the properties of these individual microstructures.

The general pattern of this transformation behavior at a single temperature is shown in Figure 42-18. It will be seen that there is first a period of time before any

FIG. 42-18. Transformation behavior at a single temperature in a series of manganese steels of about 0.55% carbon content. (After Bain.)

transformation starts. This period is sometimes spoken of as an incubation period. The incubation period presumably represents the period at the start of transformation when the volume of transformed phase around each nucleus is increasing very slowly. The transformation accelerates as it progresses so that the fastest transformation rate corresponds to about 50 per cent transformation. The rate then slows down again and the transformation goes to completion rather slowly. This general pattern is characteristic, but the rates themselves will vary with the temperature of transformation and, as will be shown later, with the composition and grain size of the austenite.

It has become customary to present data obtained in this manner as a plot, with the times required for the beginning and completion (and a few other stages) of the transformation as the abscissa and temperature as the ordinate. Such a diagram is known as an isothermal transformation diagram.

An isothermal transformation diagram for an eutectoid plain carbon steel, together with the hardness values and microstructures characteristic of transformation at the various temperature levels, is shown in Figure 42-19. It will be noted that the diagram has a nose or temperature of most rapid transformation at about 1000° F. The transformation rate at temperatures near the A_1 is very slow and it is likewise relatively slow at a lower temperature range.

Transformation to Pearlite—Transformation over the temperature range of about 1300° to 1000° F (in carbon and low-alloy steels) forms pearlitic microstructures and the characteristic lamellar appearance of these structures is apparent in the photomicrographs. It will also be noted that as the transformation temperature decreases, the lamellae become more closely spaced, so that as transformed at 1000° F they can hardly be resolved by the microscope. The hardness is also seen to increase as the lamellar spacing becomes smaller.

Transformation to Bainite—Transformation to bainite occurs over the temperature range of about 1000° to 450° F. The bainitic microstructures differ markedly from pearlitic in that they are acicular in nature. Here again, the hardness increases as the transformation tem-

perature decreases, though the bainite formed at the highest possible temperature is often softer than pearlite formed at a still higher temperature.

Transformation to Martensite—Transformation to martensite, which in this steel occurs at temperatures below 450° F, differs from transformation to pearlite or bainite in that it is not time dependent, but occurs almost instantly during cooling and the percentage of transformation is dependent only on the temperature to which it is cooled. Thus, in this steel, transformation to martensite will start on cooling to 450° F (designated as the M_s temperature), will be 50 per cent complete on cooling to about 300° F, and will be essentially completed at about 200° F (designated as the M_f temperature). The microstructure of martensite is likewise acicular but it is generally lighter etching than bainite. It is the hardest of the transformation products of austenite. It is possible to form a little martensite at, say, 425° F and then to cause bainite to form thereafter isothermally.

MICROSTRUCTURE AND MECHANICAL PROPERTIES

The dependence of the properties of steel upon its constitution has been emphasized in this chapter and, as would be expected, the properties of steel vary with the temperature at which the austenite transforms in accordance with the corresponding microstructural changes.

The microstructures discussed above fall into three general classes: pearlite, bainite, and martensite. In discussing the relationships between microstructure and properties, a fourth class of microstructure, tempered martensite, must also be considered. This is the structure formed when martensite is reheated to a subcritical temperature after quenching. Its microscopic appearance in a polished and etched specimen is illustrated in Figure 42-20. The general effect of tempering martensite is to precipitate and coagulate the carbide particles, so that tempered martensite microstructures consist of carbide particles dispersed in a ferrite matrix. The steel in this illustration has been tempered at a relatively high temperature and some tendency for the particles to as-

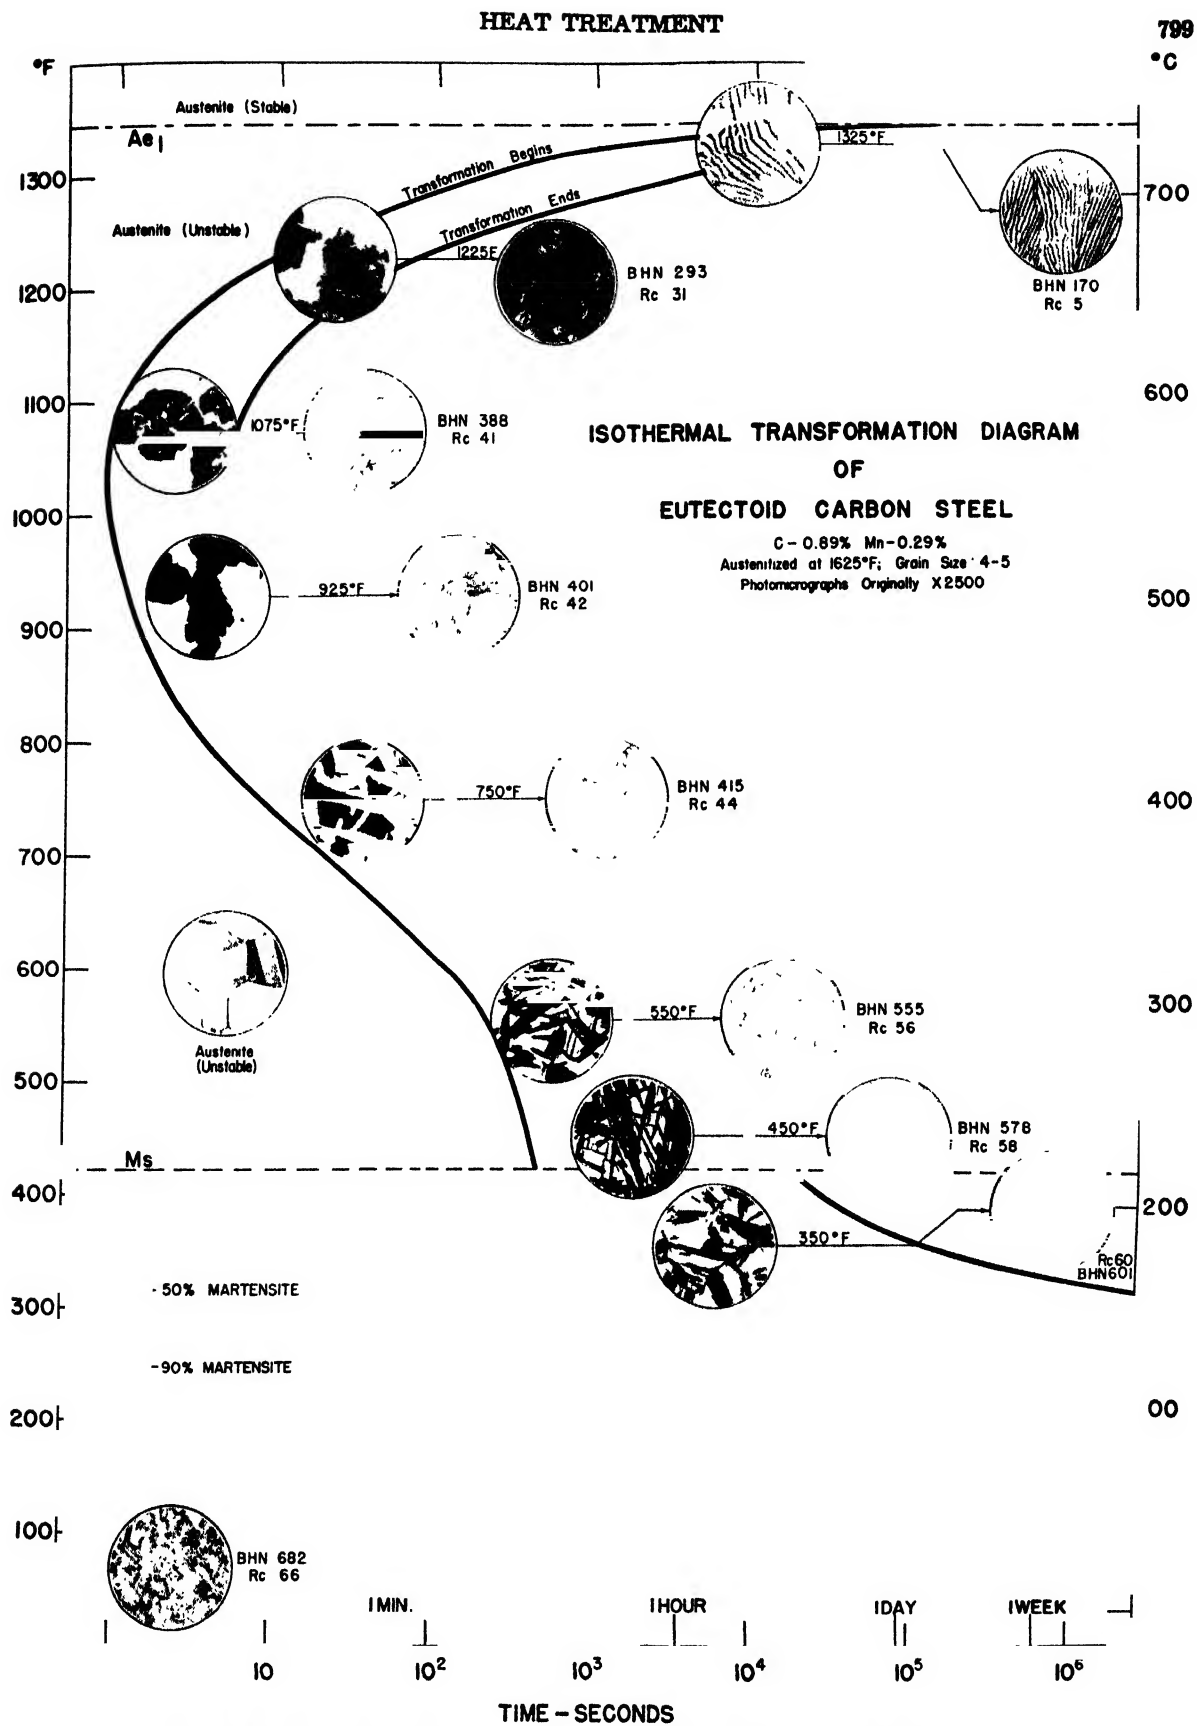

FIG. 42-19. Isothermal transformation diagram for a plain carbon eutectoid

FIG. 42—20. The microstructure of tempered martensite. Tempering temperature, 1022° F (550° C). Magnification: 2000X.

sume a spheroidal form can be noted. This microstructure, consisting of spheroidized or partially spheroidized carbides in a ferrite matrix is, as might be expected, a very favorable one in respect to ductility.

Each of these types of microstructures has characteristic properties typical of the class but the properties of pearlite and bainite also each vary quite widely with transformation temperature.

Properties of Pearlite—In any steel, the pearlites are, as a class, softer than the bainites or martensites. In general, even though softer, they are less ductile than the lower temperature bainites and for a given hardness they will be far less ductile than tempered martensite.

As the transformation temperature decreases within the pearlite range, the inter-lamellar spacing decreases, as was described above, and these "fine" pearlites, formed near the nose of the isothermal diagram, are both harder and more ductile than the "coarse" pearlites formed at higher temperatures. Thus, although, as a class, pearlite tends to be soft and not exceedingly ductile, its hardness and toughness both increase markedly with decreasing transformation temperatures.

Properties of Bainite—In a given steel, bainitic microstructures will generally be found both harder and tougher than pearlite, although the hardness will be lower than that of martensite. Within the class, as with pearlite, the properties generally improve as the transformation temperature decreases and "lower" bainite will compare favorably with, or exceed in toughness, tempered martensite at the same hardness. "Upper" bainite, on the other hand, may be somewhat deficient in toughness as compared with fine pearlite at the same hardness.

The properties of pearlite and bainite in an eutectoid steel are summarized in Figure 42—21.

Properties of Martensite—Martensite is the hardest and likewise the most brittle of the microstructures obtainable in a given steel. The hardness of martensite as a function of carbon content is shown in Figure 42—22. The hardness of martensite, at a given carbon content, varies somewhat with the cooling rate and this figure shows both the maximum hardness obtainable with very rapid cooling and the average hardness values which might be expected in practice.

Although, for some applications, particularly those involving wear resistance, the high hardness of martensite is desirable in spite of the accompanying brittleness, the principal importance of this microstructure is as the starting material for tempered martensite structures, which latter have definitely superior properties.

Properties of Tempered Martensite—Tempered martensitic structures are, as a class, characterized by relatively high toughness at any strength level. Their properties are illustrated in Figure 42—23. This chart designates, within plus or minus 10 per cent, the usual

FIG. 42—21. The properties of pearlite and bainite in a eutectoid steel.

FIG. 42-22. The hardness of martensite as a function of carbon content.

mechanical properties of any steel with this microstructure, regardless of composition. Because of its high ductility at a given hardness, this is the structure that is

aimed for in heat treating for toughness by quenching and tempering.

FACTORS AFFECTING TRANSFORMATION RATES

The major factors affecting the rates of transformation of austenite are its composition, grain size, and homogeneity. In general, increasing carbon and alloy content tend to decrease transformation rates. Increasing the grain size of the austenite likewise tends to decrease transformation rates.

Effect of Carbon Content—The effect on the transformation rates of decreasing the carbon content of a plain carbon steel is illustrated by comparison of Figure 42-24, which shows the isothermal transformation diagram for a 0.35 per cent carbon steel, with that for the eutectoid steel shown in Figure 42-19. It will be noted that the effect of lowering the carbon content has been to shift the lines of the diagram to the left, that is, toward more rapid transformation rates. This diagram differs from that for the eutectoid steel also in that the transformation to pearlite is preceded by a precipitation of ferrite and the diagram, therefore, shows a line designating the time for the initiation of this ferrite precipitation at the temperature levels wherein this separation precedes the formation of pearlite.

Effects of Alloys—Figure 42-25 shows an isothermal transformation diagram for a 0.35 per cent carbon, 1.85 per cent manganese steel. Comparing this with the lower manganese steel (Figure 42-24), it will be noted that the entire curve has been displaced to the right; that is, transformation at all temperature levels starts later and is slower to go to completion. This is characteristic of the effect of alloys in solution in the austenite; in general, increased alloy content delays the start of transformation and increases the time for its completion.

Although alloy additions tend in general to delay the start of transformation and to increase the time for its completion, they differ greatly, nevertheless, in both the magnitude and the nature of their effects. Figure 42-26 represents the isothermal transformation diagram for a 0.33 per cent carbon, 0.45 per cent manganese, 1.97 per cent chromium steel. By comparison with the plain car-

HEAT TREATMENT

803

FIG. 42-27. Isothermal transformation diagram for an SAE 4340 steel, containing 0.42% carbon, 0.78% manganese, 1.79% nickel, 0.80% chromium and 0.33% molybdenum.

FIG. 42-26. Isothermal transformation diagram for a 0.33% carbon, 0.45% manganese, 1.97% chromium steel.

FIG. 42-28. Comparison of the effect of grain size on the isothermal transformation of an SAE 4140 alloy steel, containing 0.37% carbon, 0.77% manganese, 0.98% chromium and 0.21% molybdenum.

bon steel (Figure 42-24), it will be noted that the effect of the chromium has been, not only to move the curve to the right, but also to change the shape of the curve. The time for beginning of transformation in the pearlite region has been greatly increased, while that for the beginning in the bainite region has been only moderately increased. Thus the diagram now has two "noses" (or time minima), one in the temperature region of transformation to pearlite and the other in the bainite region.

Figure 42-27 represents the isothermal transformation diagram for a more-complex alloy steel. This steel (SAE 4340) contains 0.42 per cent carbon, 0.78 per cent manganese, 1.79 per cent nickel, 0.80 per cent chromium and 0.33 per cent molybdenum. It will be noted that the effect of the addition of moderate amounts of these several alloying elements has been to displace the curve even farther to the right than that of the 2 per cent chromium steel (Figure 42-26). This is characteristic of the effect of alloys; relatively small amounts of several alloying elements are more effective in decreasing transformation rates than are larger amounts of a single alloy, i.e., more retarding than if they were merely additive.

Summarizing the effects of alloying elements on transformation behavior, it can be seen that the general effect of increasing the alloy content is to delay both the start and the completion of transformation and that the effect of alloy additions is cumulative. The effects of alloying elements, however, differ greatly both in magnitude and in specific effects on transformation in different temperature regions, so that a precise prediction of the effect of a given alloy combination is not yet quite possible.

Effect of Grain Size—The effect of increasing the grain size of the austenite is similar to that of alloys; it delays both the start and completion of the transformation. This is illustrated by Figure 42-28, which shows the isothermal transformation diagrams for the same alloy steel with both fine- and coarse-grained austenite.

Effect of Homogeneity of Austenite—The general effect of inhomogeneous austenite will be to speed up the start of transformation. This occurs because the initial

transformation will occur in the portions of the austenite which are "leaner" in alloy. In addition, undissolved carbides may act as nuclei for transformation, thereby hastening the start of transformation.

TRANSFORMATION ON CONTINUOUS COOLING

The preceding section has described the manner in which the microstructure and, therefore, the properties of steel vary with the temperature of transformation, and has shown how the isothermal transformation behavior governing these microstructural changes can be studied and depicted as isothermal transformation diagrams. The factors affecting transformation characteristics have been enumerated and the nature of their effects described. The composition of the steel, particularly in respect to the alloying elements, has been shown to be the major factor, and the effects of austenite grain size and homogeneity have also been described. Thus, the basic information about the transformation behavior of a steel is fully described by the isothermal transformation diagram.

This basic information tells what structure is formed at each reaction temperature, if the cooling is interrupted so that the reaction goes to completion at that temperature. The information is equally useful for interpreting behaviors when the cooling proceeds directly without interruption, as is the case in the industrial processes of annealing, normalizing and quenching. In these industrial processes, the time at a single temperature is generally insufficient for the reactions to go to completion at such a single temperature; instead, the end structure consists of an association of microstructures which individually were formed at successively lower temperatures as the piece cooled. But the tendency to form the several structures is still explained by the isothermal diagram.

The final microstructure after continuous cooling will obviously depend upon the times spent at the various transformation temperature ranges through which the piece is cooled. The transformation behavior on continuous cooling thus represents an integration of these times and this integration can be carried out by the

FIG. 42—29. Continuous-cooling transformation diagram for a 4340-type alloy steel, with superimposed cooling curves illustrating the manner in which transformation behavior during continuous cooling governs final microstructures.

method developed by Grange and Kiefer at the U. S. Steel Fundamental Research Laboratory. By this method, a continuous-cooling diagram generally similar to the isothermal transformation diagram, but depicting the transformation behavior on cooling at a series of constant cooling rates, can be constructed.

Such a diagram for an alloy steel is shown in Figure 42—29. This continuous-cooling diagram lies below and to the right of the corresponding isothermal diagram. That is, transformation on continuous cooling will start at a lower temperature and after a longer time than the intersection of the cooling curve and the isothermal diagram would predict, and this displacement is a function of the cooling rate, being larger as the cooling rate increases.

In order to illustrate the manner in which the transformation behavior on continuous cooling will govern the final microstructures, several cooling-rate curves have been superimposed on this diagram. A consideration of the changes occurring during these various cooling cycles will serve to illustrate the manner in which diagrams of this nature can be correlated with heat-

treating practice and used to predict the resulting microstructure.

Considering first the relatively slow cooling rate (less than 40° F per hour), the steel will be cooled through the regions in which transformation to ferrite and pearlite will occur and these constituents, ferrite and pearlite, will, therefore, make up the final microstructure. This cooling rate corresponds to a slow furnace cool, such as might be used in annealing.

At a somewhat faster cooling rate (40° to 150° F per hour), such as might be obtained on normalizing a large forging, the ferrite, pearlite, bainite, and martensite fields will all be traversed and final microstructure will contain all of these constituents.

At cooling rates of 150° to 2100° F per hour, the pearlite field will be missed entirely and the resulting microstructures will consist of ferrite, bainite, and martensite. This, therefore, is the microstructure to be expected on normalizing small or moderate sections of this steel.

Finally, on cooling at rates of from 2100° to 54,000° F per hour, the microstructure will be free of proeutectoid ferrite and will consist largely of bainite with a small

amount of martensite present. A cooling rate of at least 54,000° F per hour is necessary to obtain the fully martensitic structure desired as a starting point for tempered martensite on quenching and tempering.

Thus, the final microstructure, and therefore, the

properties of a steel, are dependent upon the transformation behavior of the austenite and on the cooling conditions, and can be predicted if these factors are known, or can be governed by controlling either or both of these factors.

SECTION 2

HARDENABILITY

The one attribute of a steel which is certainly of the greatest significance to the heat treater is its capacity for hardening, commonly referred to as its hardenability. This attribute has a two-fold significance; it is important, not only in relation to the attainment of a higher hardness or strength level by heat treatment, but also in relation to the attainment of a high degree of toughness through heat treatment to a desirable microstructure, usually tempered martensite or lower bainite. As a matter of fact, the attainment of toughness is the most important, since the attainment of a certain high strength level may often have little significance unless accompanied by a sufficient toughness to meet service requirements.

It should be clearly understood that hardenability refers to the depth of hardening or to the size of piece which can be hardened under given cooling conditions and not to the maximum hardness that can be obtained in a given steel. This maximum hardness, as previously described, is dependent almost entirely upon the carbon content (Figure 42—22), while the hardenability (depth of hardening) is, in general, far more dependent upon the alloy content and grain size of the austenite than upon the carbon content.

Relationship of Hardenability to Transformation Rates—In the preceding discussion, it was shown that, in general, the hardness of steel increases as the transformation temperature decreases. It was also shown that the lower-temperature transformation products, lower bainite and martensite, when tempered, exhibit superior properties in respect to ductility and toughness at a given strength level. It is apparent that, in order to realize the superior properties of these low-temperature transformation products, prior transformation at a higher temperature to softer products must, insofar as possible, be prevented. This means that the steel must be cooled through these high-temperature transformation ranges at a rapid enough rate that transformation does not occur, even at the nose of the transformation diagram. This rate, which will just permit transformation to martensite without any prior transformation at a higher temperature is known as the critical cooling rate for martensite, and furnishes one method for expressing hardenability. It can be readily ascertained from the continuous cooling diagram. For example, in the steel of Figure 42—29, the critical cooling rate for martensite is 54,000° F per hour or 15° F per second.

How Hardenability Is Expressed and Measured—Although the critical cooling rate can be used to express hardenability, it has the disadvantage that, in practice, cooling rates are ordinarily not constant, but vary during the cooling cycle. This is particularly true of liquid quenching, in which case, the cooling rate is always slower as the temperature of the cooling medium is approached, and is also greatly affected by the presence of a vapor phase in the earlier part of the quenching cycle. Furthermore, as already mentioned, hardenability refers to depth of hardening.

In order to facilitate the application of hardenability measurements to practice, it is, therefore, customary to express hardenability in terms of depth of hardening in

a standardized quench. The quenching condition used in this expression is a hypothetical one, in which the surface of the piece is assumed to come instantly to the temperature of the quenching medium. This is known as an ideal quench, and the diameter of a round which will just quench to the desired microstructure, or corresponding hardness value at the center, in an ideal quench is known as the ideal diameter (symbol D_i). Since the cooling rate relationships between the ideal quench and other quenching conditions are known, hardenability values in terms of ideal diameter can be used to predict the size of round which will harden in any quench, the characteristics of which are known, or similarly, if the diameter which will just harden to the center in a standardized quench is known, this can be converted into the ideal diameter value used to express hardenability.

The most direct method of measuring hardenability in terms of ideal diameter is by quenching a cylinder series. In this method, a series of bar sizes are quenched under identical conditions. These bars should have a length at least four times the diameter. They are then sectioned, etched, and cross-section hardness measurements made. The depth of hardening of each of the bars is determined by the point at which the etching characteristics change, which corresponds to a microstructure of 50 per cent martensite, or by the corresponding hardness value. This microstructure of 50 per cent martensite is a very commonly used criterion of hardenability because of the ease with which it may be located. The diameter of the bar in this series which just hardens to the center is noted and this is known as the critical diameter (D) for the series.

As mentioned above, this critical diameter value can be translated into the fundamental terms of ideal diameter (D_i) by the charts of Figures 42—30 and 42—31. In order to make this conversion, however, it is necessary to evaluate the factor expressing the severity of the quench (H factor). This factor can be evaluated quite accurately from the results of the cylinder series by a method to be described, but typical values of the H coefficient are tabulated in Table 42—IV.

Table 42—IV. Typical Values of the H Coefficient Designating Severity of Quench (H Value)

Agitation	Oil	Water	Brine
None	0.25-0.30	0.9-1.0	2
Mild	0.30-0.35	1.0-1.1	2.0-2.2
Moderate	0.35-0.40	1.2-1.3	
Good	0.40-0.50	1.4-1.5	
Strong	0.50-0.80	1.6-2.0	
Violent	0.80-1.1	4.0	5.0

The chart of Figure 42—32 enables the H value to be accurately evaluated from the results of a cylinder series. To use this chart, the values of $\frac{D_i}{D}$ (ratio of unhardened core diameter to diameter of the piece) for

FIG. 42-30. Relationships among ideal diameter, critical diameter and severity of quench. See also Figure 42-31.

the series are plotted against the diameter on a piece of transparent material, using the same coordinates as the chart. The resulting curve is then shifted until it matches one of the curves of the chart. The H value is then determined by dividing the H D value corresponding to any of the points by its diameter.

The following example is illustrative of the use of the charts of Figures 42-31 and 42-32.

Assume that the cylinder section being studied has indicated a critical diameter of 1.2 inches and that the H value of the quench has been found to be 0.4. The horizontal line of Figure 42-31 at 1.2 inches is then followed across until it intersects the curve corresponding to an H value of 0.4. The ideal diameter is then read for the

vertical line at this point and is found to be 2.6 inches. In a similar manner, the size of rounds which could be hardened under different quenching conditions for a steel of this hardenability can be determined from this chart. Thus a water quench with an H value of 1, would permit hardening in a 1.7-inch diameter bar, while air cooling with an H value of 0.02 would permit hardening in only a ¼-inch section.

The cylinder series method, just described, is the most direct method of measuring hardenability, but because of numerous advantages, the end-quench test, developed by Jominy and Boegehold, is the hardenability test which is now by far the most generally accepted and used. In this test, a cylindrical specimen one inch in di-

FIG. 42-32. Curves for estimating severity of quench (H) values from a cylinder series.

ameter and four inches long is heated to the desired hardening temperature and quenched in a fixture by a stream of water impinging upon only one end. The bar is then ground on two opposite sides to a depth of 0.015 inch below the surface and hardness measurements made at $\frac{1}{16}$ -inch intervals along the length of the specimen. The hardenability is expressed as a curve of hardness versus distance from the quenched end of the specimen. Figure 42-33 illustrates the type of quenching fixture used for this test and a typical end-quench hardenability curve is shown in Figure 42-34. Standard procedures for this test have been established by the American Society for Testing Materials and the Society of Automotive Engineers and the reader is referred to the publications of these societies for the details of the testing procedures.

This test furnishes a method of applying a continuous series of varying cooling rates to a single specimen, and,

since these rates are known, the results can be converted to hardenability values in terms of ideal diameter. The curve used for this conversion is shown in Figure 42-35. To use this curve, the distance along the end-quench bar to the desired microstructure, or corresponding hardness value, is noted and the ideal diameter corresponding to this distance is read from the curve. This ideal diameter value may then be converted into terms of bar size which can be hardened under any given quenching conditions, by the methods described above.

Hardenability and Heat Treatment—It has been emphasized in the preceding sections of this chapter that the most desirable microstructural constituents, from the standpoint of strength and toughness, are those involving transformation at the lower temperature levels, —lower bainite and tempered martensite. In order to obtain these desirable structures, the transformation rates must be slow enough, or in other words, the

FIG. 42-33. Quenching fixture for end-quench test.

FIG. 42-34. Typical end-quench hardenability curve.

hardenability must be high enough, to prevent prior transformation at a high temperature during the cooling cycle. The results of hardenability measurements serve to establish the limiting conditions in terms of cooling rates or quenching practices necessary to meet this requirement. Similarly, if the heat-treating practice and cooling conditions have been established and evaluated,

the hardenability necessary to obtain the desired microstructure may be determined by the methods described above.

Thus, it is seen that, in general, the suitability of a steel for a given heat treatment practice or the suitability of a heat treatment practice for a given steel is determined largely by its hardenability.

FIG. 42-35. Relationship between the distance from the quenched end of the end-quench test and ideal diameter.

SECTION 3

HEAT-TREATMENT PROCEDURES

Quenching and Tempering—The desirable properties of tempered martensitic microstructures have been emphasized in this chapter. Quenching and tempering is the heat treatment commonly used to obtain such microstructures and, therefore, represents the final heat treatment ordinarily used to obtain optimum properties in heat-treated materials.

This method is depicted diagrammatically in Figure 42—36. It involves a continuous cooling from the austen-

Fig. 42—36. Schematic transformation diagram for quenching and tempering.

itizing temperature through the martensite transformation temperature range at a rate rapid enough to prevent any transformation at temperatures above the M_s temperature, followed by tempering to the desired hardness or strength level.

Heating—The first step in this heat treatment, as in most of the heat treatments to be described, is the heating of the material to a temperature at which austenite is formed. The actual austenitizing temperature should, in general, be such that all carbides are in solution in order that full advantage may be taken of the hardenability effects of the alloying elements, although in some cases, particularly in tool steels, it may be desirable to leave some undissolved carbides. The temperature should not, however, be so high that pronounced grain growth occurs. The piece should be held at the austenitizing temperature long enough to dissolve carbides but, again, not long enough for excessive grain growth to occur.

Too rapid a heating rate may set up high stresses, particularly if irregular sections are involved, and is, therefore, generally undesirable. A heating time of one hour per inch of section is commonly employed, and this is a safe rule. In numerous cases, however, much more rapid heating rates may be employed. In such cases, the safety of the practice must generally be determined by experiment. The available heating rate will, of course, be determined by the mass of the material being heated and the rate at which it can absorb heat, the temperature to

which it is desired to heat, and the temperature and heat-transfer characteristics of the heating medium. In general, heating rates will be faster the higher the temperature, and the times will vary with the square of the thickness or diameter. Salt or liquid baths will have generally higher heat-transfer coefficients and, therefore, will heat more rapidly than furnaces in which the heating is in air. Since the heating rate is a function of the difference in temperature between the piece and the heating medium, rapid heating may be obtained by using a heating medium at a temperature well above the desired austenitizing temperature and removing the piece when this temperature is reached. Advantage is taken of this principle in continuous-furnace practice in which the temperature of the furnace is kept well above the desired temperature and the passage through the furnace regulated so that the piece being treated will reach the desired temperature at the outgoing end of the furnace. Temperature control is, however, uncertain in such treatment. Flame hardening, in which rapid heating is obtained by the actual impingement of a high-temperature flame on the surface of the piece being treated is also based on this principle. These rapid heating practices are the exception, however, and the usual and safe practice is a relatively slow and uniform heating to the austenitizing temperature, followed by a holding period at that temperature long enough to insure that the piece is at a uniform temperature throughout.

Unless special precautions are taken, heating will usually result in a certain amount of oxidation or scaling and may also result in decarburization. Both scaling and decarburization are usually undesirable. Scaling represents a loss of metal, mars the surface finish and may prevent rapid extraction of heat in quenching. Decarburization results in a soft surface and may seriously affect the fatigue life. The two processes do not, however, necessarily proceed together. For this reason, a slightly oxidizing atmosphere is often desirable when freedom from decarburization is important. Since the amount of scaling is largely determined by the time and temperature of the heating operation, austenitizing temperatures and times should be as low as is consistent with the principles described above in order to minimize scaling. Scaling is materially reduced by the presence of 4 per cent or more of carbon monoxide in the furnace atmosphere.

Special measures are necessary if complete freedom from scaling or decarburization is necessary. These measures include heating in a muffle containing reducing gases such as carbon monoxide or methane and hydrogen mixtures, packing in cast-iron chips or in a mixture of charcoal and sodium carbonate or heating in neutral salt or lead baths. All of these methods, however, have limitations and disadvantages and require special precautions to insure their success. The composition of the gases used in controlled-atmosphere heating varies with the temperature and must be carefully balanced so that neither carburization nor decarburization occurs. At the higher temperatures packing mixtures such as charcoal and sodium carbonate may also lead to carburization and their use is frequently very inconvenient. Salt or lead baths may become contaminated with oxides through contact with the atmosphere and these may accelerate decarburization. In general it is very difficult to insure absolute freedom from scaling or decarburization in heating for hardening.

Quenching—The primary purpose of quenching is, as described above, to cool the piece rapidly enough that no transformation occurs at temperatures above the martensite range. The first requisite of a quenching medium is, therefore, a sufficient cooling rate to accomplish this result. The necessary cooling rate is, in turn, determined by the size and hardenability of the piece being quenched, so that the choice of a quenching medium is primarily determined by these factors. The temperature gradient set up by the quenching operation results in relatively high thermal and transformation stresses which are usually, although not always, undesirable since they may lead to cracking or distortion. In order to minimize these stresses, the quenching rate should not be much in excess of that dictated by the size and hardenability of the piece.

The quenching media most commonly used are water, oils, or brine. The relative severity of quench of these media is indicated in Table 42—IV of this chapter. As indicated by this table, brine quenching is the most severe, although when thoroughly agitated, as by a submerged pressure-spray, water approaches it in severity. Oil is considerably less drastic, although its cooling rate may likewise be markedly increased by a proper and sufficient agitation.

Agitation of the quenching medium is important both because of acceleration of the cooling rate and because of the more uniform cooling obtained. Such agitation may be obtained from judiciously placed propellers, from pumps, or from pressure sprays.

The severity of water quenching varies with the temperature of the quenching bath, hot water being quite markedly slower than cold water. This is presumably because of the large amounts of steam which are formed in quenching into hot water and which cling to the work and surround it with "gas pockets." The cooling rate in hot water is, however, not only slower, but less uniform and this lack of uniformity may lead to distortion or even cracking. The increased cooling rate in brine is also presumably due to its increased boiling point which diminishes the chance of gas envelopes forming around the work. The cooling rate of oil quenches tends to increase somewhat with a moderate increase in temperature, presumably because of the decreased viscosity at the higher temperature.

Tempering—The martensite formed by quenching is very hard and very brittle and, as described above, its formation leaves high residual stresses. The purpose of tempering is to relieve these stresses and to improve the ductility, which it does at the expense of strength or hardness. The operation consists of heating at temperatures below the lower critical temperature (A_1). The stress relief and recovery of ductility are brought about through precipitation of carbide from the supersaturated unstable alpha-iron solid solution (martensite) and through diffusion and coalescence of the carbide as the tempering operation proceeds.

The effect of tempering on the residual stresses is illustrated by Figure 42—37. It will be noted that a considerable stress relief has occurred in tempering at 300° F and that tempering at 900° F has lowered the stresses to a quite low value.

A typical illustration of the effect of tempering on ductility as measured by the notch impact test is shown in Figure 42—38. It will be noted that the ductility first increases on tempering at temperatures up to 400° F, then decreases on tempering at temperatures between 400° and 600° F, and finally increases rapidly in tempering at temperatures of 800° F and above. This is a characteristic behavior and, in general, the temperature range 450° to 600° F should be avoided in tempering.

FIG. 42—37. The effect of tempering on residual stresses, in quenched cylinders. (Buhler, Buchholtz and Schulz: Archiv für das Eisenhüttenwesen, Vol. 5, 1932; pages 413-418.)

In order to minimize cracking, the tempering operation should immediately follow the quench. Allowing fully-quenched pieces to stand overnight before tempering is liable to result in a large proportion of cracked work.

The tempering of martensite results in a contraction and if the heating is not uniform, stresses will be set up by this unequal contraction which will cause distortion or even cracking. Similarly, too rapid a heating for tempering may be dangerous because of the sharp temperature gradient set up between the surface and interior of the piece. Recirculating-air furnaces are ideal

FIG. 42—38. The effect of tempering temperature on ductility (Charpy impact) properties of low-alloy steel.

for obtaining the uniform heating desired for tempering and are very commonly employed for this purpose. Oil or salt baths are very commonly used for low-temperature tempering and are generally safe, in spite of their rapid heating rate, since the temperature differential is low. Lead or salt baths may be used for higher tempering temperatures if the pieces to be tempered are not too large or irregular so that the heating stresses may be kept at a safe level.

Some steels exhibit a loss of toughness on slow cooling from temperatures of about 1000° F and above (the phenomenon known as "temper brittleness" which will be discussed further in another chapter) and therefore, a rapid cooling after tempering is generally desirable in these cases.

Martempering—As discussed above, the transformation to martensite, occurring during the rapid cooling through the martensite temperature range with the accompanying sharp temperature gradient, results in high stresses. A modified quenching procedure, known as martempering, which was developed by B. F. Shepherd, is helpful in lowering these stresses after quenching. This method is illustrated diagrammatically in Figure 42—39. In practice, it is ordinarily carried out by

FIG. 42—39. Schematic transformation diagram for martempering.

quenching the piece into a molten-salt bath at a temperature just above the M_s temperature, holding in this bath long enough to permit the piece to acquire the temperature throughout, and then air cooling to room temperature. Transformation to martensite then occurs during the relatively slow air cooling and, since the temperature gradient characteristic of the conventional quench is absent, the stresses set up by the transformation are much lower than in conventional quenching and tempering. Along with these lower stresses goes, of course, a much greater freedom from distortion and cracking. After martempering, the piece may be tempered to the desired strength level. Martempering has been applied to the heat treatment of tools, bearings, dies, etc. in which difficulty was encountered with quench cracking or distortion when heat treated by conventional quenching and tempering.

Austempering—As discussed above, the properties of lower bainite are generally similar in respect to strength

and somewhat superior in ductility to those of tempered martensite. Austempering, which is an isothermal heat treatment to lower bainite, therefore, offers an alternative method of heat treatment for obtaining optimum strength and ductility.

The austempering treatment is illustrated diagrammatically in Figure 42—40. It involves quenching to the

FIG. 42—40. Schematic transformation diagram for austempering.

desired temperature in the lower bainite region, usually in molten salt, and holding at this temperature until transformation is complete. It is the usual practice to hold for a time twice as long as that indicated by the isothermal transformation diagram to insure complete transformation of segregated areas. The piece may be quenched or air cooled to room temperature after transformation is complete and may be tempered to a lower hardness level if desired.

Austempering has the tremendous advantage over conventional quenching and tempering that the bainite transformation takes place isothermally at a relatively high temperature so that the transformation stresses are very low, with a resultant absolute minimum of distortion and a practically complete assurance that quench cracking will not occur.

Austempering, on the other hand, has the disadvantage, which it shares with martempering, that, because of the slower cooling rates of the molten salt baths as compared with the usual water or oil quenches, a higher hardenability steel is required to prevent high temperature transformation during the cooling to the bainite temperature. Along with these higher hardenabilities also go longer times for complete transformation to bainite so that austempering may be considerably more time consuming than martempering or conventional quenching and tempering.

This hardenability limitation may be overcome to a certain extent by the introduction of a prequench in water or oil to a temperature just below the M_s temperature, so that some martensite transformation occurs prior to the final holding at the bainite transformation. The final product is then a mixture of tempered martensite and bainite and steel with this microstructure has good properties.

Largely because of this hardenability limitation, austempering has found its widest application in the heat treatment of plain high-carbon steels in small section sizes, such as sheet, strip and wire products. It is, however, also being used for the heat treatment of alloy steels and cast irons for applications in which it is essential that distortion be held to a minimum.

Normalizing—Normalizing involves reheating the steel above its critical temperature (A_{c3}) and air cooling. It has two primary purposes: to refine the grain, and to obtain a carbide size and distribution which will be more favorable for carbide solution on subsequent heat treatment than the as-rolled structure.

The as-rolled grain size depends principally upon the finishing temperature in the rolling operation. This is subject to wide variations and there is, therefore, a corresponding wide variation in the grain size of the as-rolled products. The normalizing operation, as the name implies, serves to refine a coarse grain size resulting from a high finishing temperature and to establish a uniform, relatively fine-grained microstructure.

In alloy steels, particularly if they have been slow cooled after rolling, the carbides in the as-rolled condition tend to be rather large and massive. These large carbides are difficult to dissolve on subsequent austenitizing treatments. This carbide size, likewise, will be subject to wide variations, depending on the rolling and slow-cooling practice. Here again, normalizing tends to establish a more uniform and finer carbide particle size which will facilitate subsequent heat treatment to a more uniform final product.

The usual practice is to normalize from 100° to 150° F above the critical temperature, but for some alloy steels with carbides that are soluble only with difficulty, considerably higher temperatures may be used to obtain carbide solution. Heating, in general, should be slow enough to insure uniform temperatures and low thermal stresses. It is now a very common practice to carry out this operation in continuous furnaces. Continuous normalizing is particularly well adapted to sheet and strip because it may be heated quickly, but it is also used for plates and bars. The heating operation may, however, be carried out in any type of furnace which will permit uniform heating and accurate temperature control.

Annealing—The principal purposes of annealing are to relieve cooling stresses or stresses induced by cold or hot working, and to soften the steel so as to improve its machinability or formability. It may involve only a subcritical heating to relieve stresses, to recrystallize cold-worked material, or to spheroidize the carbides or it may involve heating above the critical temperature with subsequent transformation to pearlite or directly to a spheroidized structure on cooling.

Full Anneal—As discussed above, the most favorable microstructure for machinability in the low- or medium-carbon steels is coarse pearlite. The customary heat treatment to develop this microstructure is a full anneal, illustrated diagrammatically in Figure 42-41. It consists of austenitizing at a relatively high temperature so that full carbide solution is obtained, followed by a slow cooling so that transformation occurs only and completely in the high-temperature end of the pearlite range. This is a simple heat treatment and is reliable for most steels. It is, however, rather time consuming since it involves a slow cooling over the entire temperature range from the austenitizing temperature to a temperature well below that at which transformation is complete.

Isothermal Annealing—This annealing to coarse pearlite can, of course, be carried out isothermally by cooling to the proper temperature for transformation to coarse

FIG. 42-41. Schematic transformation diagram for full annealing.

pearlite, and holding at this temperature until transformation is complete in a manner similar to the austempering procedure. This method is illustrated diagrammatically in Figure 42-42. Such an isothermal-annealing cycle may make possible a very considerable time saving over the conventional full-annealing treatment described above. Neither the time from the austenitizing temperature to the transformation temperature, or from the transformation temperature to room temperature is critical and these may be speeded up as much as is desired or is practical. Furthermore, if the extreme softness of the coarsest pearlite is not necessary, the transformation may be carried out at the "nose" of the curve where the transformation goes to completion most rapidly and the operation thereby further expedited; the pearlite is much finer and the hardness is higher.

Isothermal annealing is most practical for applications in which full advantage may be taken of the rapid cool-

FIG. 42-42. Schematic transformation diagram for isothermal annealing.

ing to the transformation temperature and from this temperature down to room temperature. Thus for small parts which can be conveniently handled in salt or lead baths, this isothermal annealing makes possible large time savings as compared with the conventional slow furnace cooling. It is also very conveniently adapted to continuous heat treatment, and continuous annealing by this method is commonly referred to as "cycle annealing." This is usually carried out in an especially designed furnace, incorporating an air-blast chamber in order to cool rapidly from the high-heat stages for austenitizing down to the lower-temperature stages in which the transformation to pearlite occurs. This permits an accelerated cooling down to the transformation temperature. On the other hand, the method offers no particular advantage for applications such as the batch annealing of large furnace loads in which the rate of cooling to the center of the load may be so slow as to preclude any rapid cooling to the transformation temperature. For such applications, the conventional full-annealing method usually offers a better assurance of obtaining the desired microstructure and properties.

Spheroidize Annealing—Coarse pearlite microstructures are too hard for optimum machinability in the higher carbon steels, and such steels are, therefore, customarily annealed to develop spheroidized microstructures. This may be accomplished by tempering the as-rolled, slow-cooled or normalized materials at a temperature just below the lower critical temperature. Such an operation is known as "sub-critical annealing." Full spheroidization of the carbides by this method may require long holding times at the sub-critical temperature and the method may, therefore, be slow, but it is a simple heat treatment and may frequently be more convenient than annealing above the critical temperature.

It has been found, however, that the procedures described above for annealing to produce pearlite, can, with some modifications, be applied to annealing methods that will result in spheroidized microstructures. If free carbide remains after the austenitizing treatment, transformation (in the temperature range at which coarse pearlite would ordinarily form) would proceed to spheroidized rather than to pearlitic microstructures. Thus, heat treatment to form spheroidized microstructures can be carried out in a manner completely analogous to heat treatment to form pearlite, except for the use of lower austenitizing temperatures. Spheroidize annealing may thus involve a slow cooling similar to the full-annealing treatment to produce pearlite or it may be an isothermal heat treatment similar to the isothermal annealing to form pearlite. An austenitizing temperature not more than 100° F above the lower critical temperature is customarily used for this super-critical annealing to produce spheroidized microstructures.

Process Annealing—Process annealing is the term used to describe the sub-critical annealing of cold-worked materials. It customarily involves heating at a temperature high enough to cause recrystallization of the cold-worked structure and to soften the steel.

The most important example of process annealing is the box annealing of cold-rolled low-carbon sheet steel; the sheets are packed in a large box which is sealed to protect them from oxidation. This annealing is usually carried out at temperatures of from about 1100° to 1300° F. The heating and holding at temperature usually takes about 24 hours after which the charge is slowly cooled in the box, the entire process taking about 40 hours.

The process and equipment are described in detail in Chapter 34.

SECTION 4

CARBURIZING

In carburizing, a high-carbon surface layer is imparted to low-carbon steel by heating it in contact with carbonaceous materials. On quenching after carburizing, the high-carbon "case" becomes very hard, while the low-carbon core remains comparatively soft. The result is a very wear-resistant exterior combined with an interior possessing great toughness, particularly suitable for gears, camshafts, etc.

Carburizing is most commonly carried out by packing the steel in boxes with carbonaceous solids, sealing to exclude the atmosphere and heating to about 1700° F for a period of time depending upon the case depth desired. This process is known as **pack carburizing**. Carburizing may also be carried out by heating the steel in direct contact with carburizing gases, in which case the process is known as **gas carburizing**; or, least commonly, in liquid baths of carburizing salts, in which case it is known as **liquid carburizing**.

Pack Carburizing—Although in pack carburizing, as described above, the parts are packed in a solid compound, the actual carburizing medium is carbon-monoxide gas. The carburizing compound usually consists of charcoal, coke and an energizer such as barium or sodium carbonate. The energizer is supposed to break down in the presence of carbon, forming carbon monoxide as follows:

but the precise behavior of the energizer is not exactly known. The CO then carburizes the steel:

The usual carburizing temperature is 1700° F, and a case depth of about $\frac{1}{16}$ inch is ordinarily obtained on carburizing 8 hours at this temperature. Where speed is a primary consideration, temperatures up to 1750° F may be used. The higher temperatures, however, require more careful control to assure uniform results. For some steels, especially the higher-nickel alloy steels, lower temperatures of 1625° to 1650° F are used, and these lower temperatures have the advantage of decreasing warpage.

The carbon content at the surface should ordinarily not be over 1.15 per cent and the gradation toward the core should be uniform. This can be controlled to a considerable extent by the composition of the carburizing compound; for example, reducing the amount of energizer and increasing the charcoal or coke content will lower the surface carbon. In general, the maximum surface carbon will increase as the carburizing temperature decreases because of the low diffusion rate of the carbon at the lower temperature.

Gas Carburizing—The principal carburizing agents in gas carburizing are methane and carbon monoxide; the reactions may be represented as follows:

The most common practice is to lead the gas into a heated retort in which the work is continuously tumbled by rotating the retort. Such carburizing is faster than

FIG. 42-43. Comparative case depths as a function of time and temperature in activated and cyanide baths. From "Metals Handbook," 1939 Edition (page 1061). Published by American Society for Metals.

pack carburizing since the time of heating the carburizer is saved, and the case depth can be held to close limits. Gas carburization has the further advantage that the carburizing cycle may be followed up by a diffusion cycle during which no carburizing gas is admitted, and thereby a lower surface carbon and a better gradation of the case obtained.

Natural gas, which consists largely of methane, with ethane varying from 5 to 10 per cent, is very satisfactory for gas carburizing. The carburizing gas may, however, be produced in a separate gas generator, or bottled propane may be used.

Liquid Carburizing—Immersion of steel parts in a molten-salt bath containing about 30 per cent sodium cyanide at 1600° F for ½ to 1 hour periods to obtain a light (0.010 inch) hard case for wear resistance has been practiced for many years. The case is a mixture of carbides and nitrides and its relatively high hardness reflects to a considerable extent the presence of iron nitride.

The above cyaniding process is now, however, largely being replaced by liquid carburizing in activated baths which employ a floating slag of calcium cyanide as the active agent and which produce deeper cases which are lower in nitrogen and higher in carbon than those obtained with the simple sodium-cyanide bath. A typical composition of an activated bath is as follows:

Calcium Cyanamide	CaCN ₂	2-5%
Calcium Cyanide	Ca(CN) ₂	43-48%
Sodium Chloride	NaCl	30-35%
Calcium Oxide	CaO	14-16%
Carbon	C	4-5%

The comparative case depths as a function of time and temperature in activated and cyanide baths are shown

in Figure 42-43. The cases obtained with activated baths range from 0.70 to 1.00 per cent carbon with about 0.2 per cent nitrogen concentrated mainly at the surface of the steel parts.

Heat Treatment of Carburized Parts—Since carburized articles have a high-carbon case and a low-carbon core, the proper heat-treating temperature for the case will be too low for the core, and vice versa. Thus a double treatment is desirable to obtain optimum properties of both case and core; the piece is first heated to above the critical temperature corresponding to the low-carbon core and suitably cooled to refine its structure. It is then reheated to just above the critical temperature of the case and quenched to harden the case. However, when the carburizing temperature is not too high, refining of the core may not be essential, and after cooling from the carburizing temperature, a single reheating and quench from above the critical temperature of the case is sufficient. Quenching directly from the carburizing temperature is sometimes employed, although this may lead to undue warpage.

Nitriding—The nitrogen case-hardening process which is termed "nitriding" consists in subjecting machined and preferably heat-treated parts to the action of a nitrogenous medium, commonly ammonia gas, under certain conditions whereby surface hardness is imparted to the material without necessitating any further treatment. Wear resistance, retention of hardness at elevated temperatures, and resistance to certain types of corrosion are other properties imparted to the steel by nitriding.

It has been found that chromium and aluminum are desirable in steels for nitriding and compositions especially adapted to nitriding have been developed. A typical composition is as follows:

Carbon	0.20-0.30%
Manganese	0.40-0.60%
Aluminum	0.90-1.40%
Chromium	0.90-1.40%
Molybdenum	0.15-0.25%

Usual conditions for the nitriding process consist of subjecting the articles to the action of ammonia gas at temperatures ranging from 930° to 1220° F. The range most commonly used is 950° to 1000° F. Nitrided cases are ordinarily light, case depth of 0.010 to 0.015 inch being obtained in 48 hours at 975° F. The surface hardness is, however, very high (900 to 1200 Vickers), and this hardness is retained even after reheating to temperatures up to 900° F.

Chapter 43

CARBON STEELS

SECTION 1

CLASSIFICATION AND APPLICATION

The plain carbon steels undoubtedly represent the most important group of engineering materials known. They represent by far the major percentage of steel production and the widest diversity of application of any of the engineering materials. These applications are so diversified that anything like a complete listing, or even a classification on the basis of application, is impossible. Many of the important classes of application have, however, been discussed in this book. These include castings, forgings, tubular products, plates, sheet and strip, wire and wire products, structural shapes, bars, tools, and such railway materials as rails, wheels and axles.

Although a classification by application is impossible, plain carbon steels may be generally classified in accordance with their method of manufacture as basic open hearth, acid open hearth or acid Bessemer steels. The basic open hearth steels, of course, represent the preponderance of the tonnage. This classification may be

extended to include the method of deoxidation used. For example, the basic open hearth steels may be rimmed, semi-killed or fully killed.

The plain carbon steels may also be classified on the basis of carbon content as hypo-eutectoid or hyper-eutectoid steels; the hypo-eutectoid steels are those in which the carbon content is below the eutectoid value of about 0.80 per cent, and the hyper-eutectoid steels those with carbon contents above this value.

The composition ranges for the plain carbon steels have been standardized by the American Iron and Steel Institute and these composition ranges are listed in Tables 43—I, 43—II, 43—III and 43—IV. Concerning these four tables, it should be noted that the prefix letters "B" and "C" are used to designate the two principle steel-making processes for carbon steels as follows: "B" denotes acid Bessemer carbon steel, "C" denotes basic open hearth steel.

SECTION 2

FACTORS AFFECTING CARBON-STEEL PROPERTIES

The principal factors affecting the properties of the plain carbon steels are the carbon content and the microstructure. The general relationships between microstructure and properties, and the factors governing microstructure, have been discussed in the preceding chapter on heat treatment, and need not be repeated here. Most of the plain carbon steels are, however, used without a final heat treatment and the factors affecting the microstructure and thereby the properties in such as-rolled or as-forged products will be emphasized in this chapter.

In addition to the predominant effects of carbon content and microstructure, the properties of plain carbon steels may be modified by the effects of residual elements other than the carbon, manganese, silicon, phosphorus and sulphur which are always present, or the properties of carbon steel may also be affected by the presence of gases, especially oxygen, nitrogen and hydrogen and their reaction products. These incidental elements are usually picked up from the scrap, from the deoxidizers, or from the furnace atmosphere. The gas content is largely dependent upon the melting, deoxidizing and pouring practice so that the final properties of the plain carbon steels are, to a very considerable extent, dependent upon the steelmaking practice used in their production.

Thus, the factors governing the properties of a plain carbon steel are primarily its carbon content and microstructure, with the microstructure being determined largely by the composition and the final rolling, forging

or heat-treating operation, and secondarily by the residual alloy, non-metallic and gas content of the steel which, in turn, depend upon the steelmaking practice.

Carbon Content and Properties—The average mechanical properties of as-rolled one-inch bars of carbon steels, as a function of carbon content, are shown in Figure 43—1. These values are based on statistical analyses made by several investigators and plotted by Sisco. This figure is illustrative of the general effect of carbon content when the microstructure and grain size are held reasonably constant. It will be seen that the hardness, tensile strength and yield strength increase with increasing carbon content, while the elongation, reduction of area, and Charpy impact values decrease sharply.

Effect of Microstructure and Grain Size—The general relationships between microstructure and properties have been discussed in Chapter 42 on heat treatment. The carbon steels, being of relatively low hardenability, are predominantly pearlitic in the cast, rolled or forged conditions. The constituents of the hypo-eutectoid steels are, therefore, ferrite and pearlite, and of the hyper-eutectoid steels, cementite and pearlite. As described in the previous chapter, the properties of such pearlitic steels are dependent primarily upon the interlamellar spacing of the pearlite and the grain size. Both the hardness and the ductility increase as the interlamellar spacing or the pearlite-transformation temperature decreases, and the ductility increases with decreasing grain size. The effect of grain size was discussed in some detail in the preceding chapter. The effect of the

interlamellar spacing of the pearlite was also discussed and illustrated for a eutectoid steel. The effect of this variable on tensile strength is further illustrated in Figure 43—2, which shows the approximate relationship between tensile strength and carbon content for a series of plain carbon steels isothermally transformed to fine

and coarse pearlitic microstructures. The line for the 1200° F transformation product in this illustration is generally similar to, although slightly above, the tensile strength line for as-rolled bars in Figure 43—1, indicating that these as-rolled bars have transformed during cooling at temperatures in the vicinity of 1200° F.

THE MAKING, SHAPING AND TREATING OF STEEL

FIG. 43-2. Relationship between tensile strength and carbon content of a series of plain carbon steels isothermally transformed to fine and coarse pearlitic microstructures.

SECTION 3

FACTORS AFFECTING MICROSTRUCTURE AND GRAIN SIZE

Composition—As explained in Chapter 42 on heat treatment, the microstructure of steel is determined by the temperature range in which transformation of the austenite takes place on cooling. This, in turn, is determined by the cooling rate employed and the transformation rate of the steel. This latter factor is dependent largely upon the composition; thus, for a given cooling rate after rolling, for instance, the resulting microstructure is largely dependent upon the composition. The composition will, of course, similarly control the microstructure for given cooling conditions in cast, as-rolled, or heat-treated carbon steels.

The austenite-transformation behavior in carbon steel is determined almost entirely by the carbon and manganese content; the effects of phosphorus and sulphur are almost negligible, and the silicon contents are normally so low that they are likewise ineffective. The carbon content is ordinarily chosen in accordance with the strength level desired and the manganese content then selected in order to produce suitable microstructure and properties at this carbon level under the given cooling conditions.

Microstructure of Cast Steels—The microstructure of as-cast steels is, of course, determined by the composition and cooling conditions in the same manner as in wrought steels. Cast steels are usually very coarse grained since the austenite forms at a high temperature, and the pearlite is usually coarse since the cooling through the critical range, particularly if the casting is cooled in the mold, is usually quite slow. In hypoeutectoid steels, ferrite is precipitated ordinarily at the original austenite boundaries during the cooling. In hyper-eutectoid steels, cementite is similarly precipitated. Such mixtures of ferrite or cementite and coarse-grained coarse pearlite have, as would be expected, poor properties both in respect to strength and ductility, and heat treatment is usually necessary to obtain suitable microstructures and properties in cast steels.

The dendritic segregation occurring during the solidification of steel castings also results in an irregular microstructure and correspondingly poor properties, and the homogenization of this segregated structure is another function of the heat treatment of cast steels.

A typical microstructure of an as-cast carbon steel is shown in Figure 43-3.

Effects of Hot Working—Most carbon steels are used in the form of as-rolled finished sections and the microstructure and properties of these sections are determined largely by the composition, rolling practice and cooling

FIG. 43-3. As-cast microstructure of 0.20 per cent carbon steel. Nital etch; magnification: 200X.

conditions after rolling. The rolling or hot working of these sections is ordinarily carried out in the temperature range at which the steel is austenitic and has four major effects, as follows:

1. Considerable homogenization that tends to eliminate dendritic segregation occurs during the heating for rolling.
2. The dendritic structure is broken up during rolling.
3. Recrystallization occurs during rolling so that the final austenitic grain size is determined by the temperature at which the last passes are made (the finishing temperature).
4. Dendrites and inclusions are reoriented in the rolling direction so that the final ductility in the rolling direction is markedly improved.

Thus, the homogeneity and grain size of the austenite is largely determined by the rolling practice. It should be pointed out, however, that, as discussed in earlier chapters, the recrystallization characteristics of the austenite and, therefore, the austenite-grain size characteristic of a given finishing temperature may be markedly affected by the steelmaking practice, particularly in respect to the deoxidation practice used.

The distribution of the ferrite or cementite and the nature of the pearlite is, however, as has been explained earlier, determined by the cooling rate after rolling. Since the usual practice is air cooling, the final microstructure and, therefore, the properties of these as-rolled sections will be principally dependent on the composition and section size.

Bars, rails or structural shapes are rolled in one direction only and this rolling tends to orient the grains along the direction of rolling. Inclusions which are plastic at the rolling temperature are also elongated. This elongation tends to improve the mechanical properties of the rolled steel as compared to the as-cast steel, when the material is subjected to stresses acting longitudinally, as in the case of tensile specimens cut in the direction of rolling. However, specimens cut transversely to the direction of rolling have lower values for elongation, reduction of area, and impact resistance than do the longitudinal specimens. This effect is minimized by cross

FIG. 43-4. Microstructure of full-hard cold-reduced black plate (85 per cent reduction). Nitral etch; magnification: 200X.

FIG. 43-6. Effect of cold working on the ductility of plain carbon steel.

rolling, i.e., by hot working in both directions, and this is frequently practiced in sheet and plate products.

Effects of Cold Working—The manufacture of wire, sheet and strip, and tubular products often involves a cold-working operation and the general effects of cold working will, therefore, be discussed in this chapter. The effects of this cold working may often be destroyed by a suitable annealing operation but some products, particularly wire, are used in the cold-worked condition.

A typical microstructure of a heavily cold-worked steel is shown in Figure 43-4. The elongation of the ferrite and pearlite grains and the generally distorted

microstructure are characteristic. The most pronounced effect of this cold work is an increase in strength and hardness and a decrease in ductility as represented by elongation and reduction of area. The effects of cold working on tensile strength and elongation are shown in Figures 43-5 and 43-6. Upon reheating cold-worked steel to the recrystallization temperature (750° F) or above, depending upon composition, amount of cold work and other variables, the original microstructure and properties may be restored. The annealing of cold-worked steels (process annealing) has been discussed in the chapter on heat treatment.

SECTION 4

HEAT TREATMENT OF CARBON STEELS

Although the majority of carbon steels are used without a final heat treatment, heat treatment may be employed to improve the microstructure and properties for specific applications. The principles of these heat treatments have been discussed in Chapter 42 and many of the heat-treating practices have been described in detail in the chapters of the various carbon-steel products. As mentioned earlier, the heat treatment of cast carbon steels improves the properties of the material by breaking up the dendritic structure and refining the grain size and microstructure. These treatments usually involve normalizing the castings at a high temperature to homogenize the dendritic structure, followed by annealing at a lower temperature for grain refinement. The use of a final quenching and tempering treatment to obtain optimum microstructure and properties in castings is, however, becoming an increasingly common practice. The heat treatment employed in processing wrought steel products are described in the following paragraphs.

Annealing—Annealing is practiced for applications requiring better machinability or formability than would be obtained with the as-rolled microstructure. This is usually a full anneal to form coarse pearlite, although a sub-critical anneal or spheroidizing treatment is occasionally practiced. Process annealing to obtain optimum formability in cold-rolled strip, sheet and tubing is, of course, a universal practice.

Normalizing—The grain size of as-rolled products is, as described above, largely dependent upon the finishing temperature in rolling and this is difficult to control.

Therefore, a final normalizing treatment from a relatively low temperature may be used to establish a fine uniform grain size for critical applications in respect to ductility or toughness.

Quenching and Tempering—The quenching and tempering of plain carbon steels to obtain optimum microstructures and properties is being increasingly practiced. Because of the relatively low hardenability of these steels, this type of treatment falls generally into two classifications, as follows:

1. Heat treatment to produce essentially tempered martensite for optimum properties. Hardenability restrictions limit the application of this type of treatment to section sizes of not more than $\frac{3}{8}$ to $\frac{1}{2}$ inch. It is, however, commonly practiced for small tools, sheet and strip, etc., which fall within this size limitation.

2. Heat treatment to form fine pearlite. Quite large sections of plain carbon steels may be quenched and tempered to produce fine pearlite microstructures, thereby making available the greatly improved strength and ductility associated with this microstructure as compared with the properties of the coarse pearlite of the usual as-rolled or normalized products.

Austempering—Thin sections (0.2-inch and below) of carbon steels are particularly suitable for austempering, since the times for transformation to bainite are relatively short and this heat treatment is likewise being increasingly practiced for applications requiring toughness at high hardness in such section sizes.

SECTION 5

AGING IN CARBON STEELS

Aging in steel is manifested as a spontaneous increase in hardness at room temperature, the process being accelerated by raising the temperature slightly. It is generally assumed to be caused by the disintegration of a supersaturated solid solution. In a system in which the solid solubility of the solute decreases sharply with temperature, the solute may be retained in supersaturated solid solution on rapid cooling, but it will tend to precipitate out on standing. Such incipient or complete precipitation is considered to be the cause of aging in steels. This precipitation is accelerated by straining, and straining frequently plays an important part in the aging of steel. To separate the effects of straining from the effects of precipitation in the absence of strain, aging in the absence of strain is referred to as quench aging, and aging after or during straining is known as strain aging.

The elements in carbon steel which seem most likely

to cause aging are carbon, oxygen and nitrogen. Curves for the change of solubility of these three elements in ferrite as a function of temperature, are shown in Figure 43-7. These curves are all of the type that can lead to aging. Probably all three of these elements play a part in the aging of steel, but it is very difficult to isolate their individual effects.

The general nature of the hardness increase from quench aging is shown in Figure 43-8. It will be noted that aging above room temperature results in a more rapid hardness increase, but that the maximum hardness attained is lower than in steel aged at room temperature. Aging for times beyond that corresponding to the maximum hardness results in a decrease in hardness. This is sometimes called overaging.

It has been found that steels which are drastically deoxidized with aluminum or aluminum and titanium are

FIG. 43-7. Effect of temperature upon the solubilities of carbon, oxygen, and nitrogen in ferrite. (From "Metals Handbook," 1948 Edition; American Society for Metals.)

FIG. 43-8. Changes in hardness of 0.06 per cent carbon steel quenched from 1325° F after aging at indicated temperatures. (From "Metals Handbook," 1948 Edition; American Society for Metals.)

FIG. 43-9. Effect of deoxidation practice on quench-aging characteristics of carbon steels. (From "Metals Handbook," 1948 Edition; American Society for Metals.)

essentially non-aging and that the rimmed and Bessemer steels are the most susceptible to aging. This effect is illustrated by Figure 43-9, which shows the increase in hardness resulting from quench aging in steels with three different deoxidation practices as a function of carbon content. It is perhaps significant that the maximum aging effect was found at 0.04 per cent carbon, which is approximately the maximum solid solubility of carbon in ferrite. In general, the changes in hardness on strain aging are somewhat less than those from quench aging, but there is some indication that strain aging may be more embrittling than quench aging.

The effects of strain aging on the impact properties of steels with different manufacturing practices are shown in Figure 43-10. The Izett steel is a strongly deoxidized "non-aging" steel. Since these tests were made immediately after straining, the embrittlement represents a combination of the effect of cold working and of precipitation occurring during the straining. Further embrittlement would result from aging, particularly accelerated aging, and a maximum embrittlement has been found in heating about ½ hour at 500° F.

The effect of aging is also reflected in the characteristics of the stress-strain curve. Most as-rolled carbon steels show a jog in the stress-strain curve or a drop of the beam at the yield point in tensile testing. This jog or drop of the beam disappears if the specimen has been subjected to a previous strain, but again reappears upon aging after this straining. This phenomenon does not occur, however, in a strongly deoxidized "non-aging" steel. This effect on the stress-strain curves is illustrated in Figure 43-11.

Still another manifestation of the strain aging phenomenon is the increased hardness and decreased ductility of steels aged at 400° to 500° F, as shown by tensile tests at this temperature. This phenomenon is illustrated in Figure 43-12 and the distinction between the stabilized and aging type of steel is apparent.

These aging phenomena are of importance for applications of carbon steels in which formability or toughness are of importance, and possible embrittlement from strain aging must be given careful consideration whenever a material is subjected to strain during fabrication or use. The yield point phenomenon discussed above is of importance in the stamping or drawing of sheet, since

the jog in the stress-strain curve will be reflected in a roughening of the surface, known as stretcher strains. Galvanizing embrittlement is also a reflection of strain

aging with the short time exposure at 850° F of the galvanizing treatment constituting an accelerated aging treatment.

SECTION 6

EFFECT OF RESIDUAL ELEMENTS

In addition to the carbon, manganese, phosphorus, sulphur and silicon which are always present, carbon steels may contain small amounts of other elements. These include gases, such as hydrogen, oxygen or nitrogen which are introduced during the steelmaking process, nickel, copper, molybdenum, chromium and tin which may be present in the scrap, and aluminum, titanium, vanadium, zirconium or boron which may be introduced during the deoxidation process.

The effects of oxygen and nitrogen have been discussed in the section on aging, and their effect on aging is their principal effect in carbon steel.

In steel, hydrogen has a definite embrittling effect, the mechanism of which is not well understood. Although hydrogen will diffuse out of steel at room temperature if sufficient time is allowed, tension tests on carbon steels will show low ductility if made soon after rolling and the ductility will increase on aging at room temperature or after shorter times at slightly elevated temperatures. This effect is, of course, more pronounced in larger section sizes because of the longer time required for the diffusion of hydrogen to the surface. Hydrogen contents of about 0.0005 per cent will give rise to this effect and such contents are common in as-rolled steels.

Hydrogen also plays an important role in the phenomenon known as **flaking** which is manifested as internal cracks or bursts, usually occurring during the cooling from rolling or forging. The phenomenon is more pronounced in heavy sections and in the higher carbon steels. In carbon steels, flaking may be prevented by slow cooling after rolling or forging. This slow-cooling operation presumably permits the hydrogen to diffuse out of the steel and thereby minimizes the susceptibility to flaking. Such a controlled slow-cooling operation after rolling is now standard practice in the manufacture of rails, and this practice has practically eliminated the

occurrence of flaking and resultant occasional "transverse fissure" failures.

The alloying elements, such as nickel, chromium, molybdenum and copper, which may be introduced in the scrap will, of course, increase the hardenability of carbon steels, although, since the percentages are ordinarily low, this effect will usually not be large. It may, however, change the heat-treating characteristics and for applications in which ductility is important, such as steels for deep drawing, the increased hardness from these residual elements may be serious.

Tin in relatively low amounts is harmful in steels for deep drawing, but for most applications the effect of tin in the amounts ordinarily present is negligible.

Aluminum, as described above, is generally desirable since it acts as a grain refiner and tends to decrease the susceptibility to strain aging. It has the disadvantage, however, that it tends to promote graphitization and is, therefore, undesirable in steels to be used for high-temperature applications. The other elements which may be introduced as deoxidizers, titanium, vanadium or zirconium, are, unless intentionally added, ordinarily present in such small amounts as to be generally ineffective.

Boron in amounts as low as 0.001 per cent may markedly increase hardenability, but the boron contents are ordinarily well below this value and are ineffective.

Chapter 44

ALLOY STEELS

Introductory—Alloy steels may be defined as those steels which owe their enhanced properties to the presence of one or more special elements or to the presence of larger proportions of elements such as manganese and silicon than are ordinarily present in carbon steel. The major classifications of steels containing alloying elements are as follows:

1. High-strength low-alloy steels
2. AISI alloy steels
3. Alloy tool steels

4. Stainless steels
5. Heat-resisting steels
6. Electrical steels (silicon steels)

The high-strength low-alloy steels, stainless steels, heat-resisting steels, and electrical steels are discussed in other chapters. This chapter covers the AISI alloy steels, often referred to commonly as "constructional alloy steels," and the alloy tool steels, with an introductory discussion of the functions of the alloying elements.

SECTION 1

FUNCTIONS OF THE ALLOYING ELEMENTS

As stated above, alloying elements are added to steel to enhance its properties. In the broadest sense, alloy steels may contain up to approximately 50 per cent of alloying elements, and the enhancement of properties may be a specific and direct function of the alloying elements, as in the instances of the increased corrosion resistance of the high-chromium steels and the enhanced electrical properties of the silicon steels. In the narrower and more technical sense, however, the term "alloy steels" refers to the heat-treatable alloy constructional and automotive steels which contain from about one to three or four per cent of alloying elements. The American Iron and Steel Institute definition of alloy steel is as follows: "By common custom steel is considered to be alloy steel when the maximum of the range given for the content of alloying elements exceeds one or more of the following limits: manganese, 1.65 per cent; silicon, 0.60 per cent; copper, 0.60 per cent; or in which a definite range or a definite minimum quantity of any of the following elements is specified or required within the limits of the recognized field of constructional alloy steels: aluminum, boron, chromium up to 3.99 per cent, cobalt, columbium, molybdenum, nickel, titanium, tungsten, vanadium, zirconium, or any other alloying element added to obtain a desired alloying effect."

Such steels have been standardized and classified jointly by the American Iron and Steel Institute and the Society of Automotive Engineers, and represent by far the largest tonnage of alloy steels. Alloy steels of this type are generally known as "AISI alloy steels" and will be so designated in this chapter. As previously stated, they are also commonly referred to as "constructional alloy steels." The composition of these steels is shown in Table 44—I.

As was emphasized in the chapter on heat treatment, the mechanical properties of steel are dependent upon its microstructure. In the AISI alloy steels the effect of the alloying is indirect; i.e., through their influence on the microstructure of the material. The AISI alloy steels make it possible to attain desirable microstructures and corresponding desirable properties over a very much

wider range of sizes and sections than is possible with the carbon steels.

Hardenability—The mechanism by which the alloying elements affect the microstructure obtained with a given heat treatment is discussed in the chapter on heat treatment. It is shown that the alloying elements in general decrease the rates of transformation of austenite at sub-critical temperatures, thereby facilitating the attainment of low-temperature transformation to martensite or lower bainite when these are the end products desired, without prior transformation to unwanted higher temperature products. It was pointed out that this function of the alloying elements could be evaluated and expressed in terms of the property known as hardenability. Alloying elements thus control microstructure through their effect on hardenability, and this hardenability effect is by far their most important function.

It was also shown in the chapter on heat treatment that the properties of tempered martensite, which represents the most desirable microstructure in respect to strength and toughness, were characteristic of the microstructure rather than of the composition. Thus, alloy steels of equal hardenabilities, but utilizing different combinations of alloying elements, are generally interchangeable for heat treatment to produce this microstructure. This principle permits an intelligent choice of alloy combinations which, for reasons of economy or availability, are best suited for particular applications. This principle was widely used during World War II to develop substitute compositions utilizing the alloying elements most available at the time, thereby conserving the scarcer alloying elements.

Effects of the Alloying Elements on Hardenability—**The Multiplying Factor Principle**—The effects of the alloys on grain size or hardenability may be quantitatively evaluated by hardenability measurements on a series of steels in which a single alloying element is the only variable. This method is illustrated by Figure 44—1 which shows the hardenabilities of two series of steels in terms of ideal diameter for a microstructure of 50 per cent martensite. These series were made by additions of phosphorus to successive ingots so that in each series

NOTE 1. Grades shown in the above list with prefix letter E generally are manufactured by the basic electric furnace process. All others are normally manufactured by the basic open hearth process but may be manufactured by the basic electric furnace process with adjustments in phosphorus and sulphur.

NOTE 2. The phosphorus and sulphur limitations for each process are as follows:

Basic electric furnace—0.025 maximum per cent

Basic open hearth —0.040 maximum per cent

Acid electric furnace—0.050 maximum per cent

Acid open hearth —0.050 maximum per cent

NOTE 3. Minimum silicon limit for acid open hearth or acid electric furnace alloy steel is 0.15 per cent.

NOTE 4. Small quantities of certain elements are present in alloy steels which are not specified or required. These elements are considered as incidental and may be present to the following maximum amounts: Copper, 0.35 per cent; Nickel, 0.25 per cent; Chromium, 0.20 per cent and Molybdenum, 0.06 per cent.

NOTE 5. Where minimum and maximum sulphur content is shown it is indicative of resulphurized steels.

NOTE 6. TS denotes tentative standard steels.

the composition was constant except for the phosphorus. It will be noted that the hardenability increases regularly with increasing phosphorus content, and that the rate of increase is more rapid for the steel of the higher base hardenability. In order to obtain a numerical evaluation of the effect of phosphorus on hardenability, the hardenabilities of the steels containing phosphorus may be divided by the base hardenability of the steel containing no phosphorus. This value expressing the effect of the element on hardenability is known as a **multiplying factor**, and the multiplying factors for phos-

phorus, derived from the series in Figure 44—1, are plotted in Figure 44—2. It will be seen that a steel with 0.020 per cent phosphorus will have 1.05 times the hardenability of a steel with no phosphorus, while a steel with 0.100 per cent phosphorus would have roughly one and one quarter times the base hardenability. Also, with this information, the effect of increasing the phosphorus content from 0.020 to 0.100 per cent can be evaluated by multiplying the hardenability of the 0.020 per cent phosphorus steel by $\frac{1.27}{1.05}$ or 1.21.

FIG. 44-1. Hardenability as a function of phosphorus content in two series of steels.

The pioneer work of this nature was done by Grossmann in 1941. Hardenability factors for many of the common alloying elements, as well as hardenability values for pure iron-carbon alloys and the effect of grain size, were evaluated at that time. These factors have, in some cases, been modified by the work of other investigators and the values as published by the American Iron and Steel Institute are shown for alloying elements in Figure 44-3, and for grain size in Figure 44-4.

FIG. 44-2. Multiplying factors for phosphorus.

Grossmann and his associates further found that the cumulative effects of alloying elements on hardenability could be evaluated by multiplying the base hardenability of the iron-carbon alloy progressively by the multiplying factors for the elements. Thus the chart of Figure 44-3 enables one to calculate the hardenability in terms of 50 per cent martensite microstructures of a given alloy combination.

The element boron increases the hardenability of steel but its effect differs from that of the other alloying elements since additions over a certain optimum amount produce no further increase in hardenability. Experience has shown that the optimum content is 0.0005 to 0.004 per cent boron. The multiplying factor for boron depends not on boron content, but on carbon content and varies from approximately 2.00 for 0.20 per cent carbon steels to nearly zero for 0.90 per cent carbon.

The multiplying factor principle is of importance not only as a means of predicting the approximate hardenability of a steel from its composition, but also since it shows that, in general, the addition of relatively small amounts of several alloying elements is more effective in increasing hardenability than a relatively large amount of a single element. This principle was also widely applied during World War II to the development of substitute compositions which would utilize to the

FIG. 44-3. Multiplying factors for a variety of alloying elements (American Iron and Steel Institute).

FIG. 44-4. Effect of grain size on the hardenability of pure iron-carbon alloys, expressed as ideal critical diameter, D_i .

fullest extent the hardenability effects of the alloying elements most available.

Effects of the Alloys in Tempering—While the martensitic microstructure has been stressed as a criterion of hardenability, it must of course be realized that martensite itself is very brittle, and that in order to realize the properties generally sought in machine parts, this martensite must be reheated or tempered. It is essential to an understanding of alloy steels, therefore, to consider the roles played by the alloying elements in this tempering process, and the manner in which they will affect the behavior on tempering.

The primary purpose of tempering is to impart a degree of plasticity or toughness to the steel to alleviate the brittleness of the martensite. Although this process may, and usually does, soften the steel, this softening is only incidental to the very important increase in toughness. This increase in toughness after tempering reflects two effects of tempering: (1) the relief of internal stresses set up by the quenching operation; and (2) a crystallization, coalescence and spheroidization of iron and alloy carbides, resulting in a microstructure of greater plasticity.

The addition of alloying elements which increase hardenability may be very helpful in decreasing the magnitude of the internal stresses resulting from the quench, since they will permit the attainment of a martensitic microstructure with a less drastic quench. For this reason, the use of an alloy steel and a mild quench for an application requiring high hardness, and, therefore, a low tempering temperature with an accompanying relatively low degree of stress relief, may be very advantageous. It should be noted, however, that this is only secondarily an effect of alloys in tempering; here again the primary function of the alloying elements is to increase hardenability.

FIG. 44-5. The effect of silicon on tempering rate of 0.50-0.55% carbon steel, tempered for 1 hour at indicated temperatures.

FIG. 44-6. The effect of chromium on tempering rate of 0.35% carbon steel, tempered for 1 hour at indicated temperatures.

The alloying elements will, however, have a direct and significant effect upon the second behavior, that of crystallization and coalescence of the carbides. In general, the effect of alloying elements will be to slow up the processes of crystallization and coalescence. This means that an alloy steel will customarily require higher tempering temperatures, or longer times at temperature, to obtain a given hardness.

The effects of some of the individual alloying elements on the tempering rate are illustrated in Figure 44-5 for silicon, Figure 44-6 for chromium, Figure 44-7 for molybdenum and Figure 44-8 for vanadium. These charts show the hardness of tempered martensite in these steels after tempering one hour at the indicated tempering temperature.

The effects of nickel and manganese, as in the case of silicon, while they are significant, are quite moderate, and the hardness changes are nearly a direct function of the tempering temperature. This type of behavior is characteristic of alloys which dissolve largely in the ferrite phase, and do not tend to form carbides.

Boron in the amount used to increase hardenability has no perceptible effect on hardness changes during tempering.

The carbide-forming elements, such as chromium, molybdenum or vanadium, however, have very marked effects on the tempering behavior. Elements of this type not only raise the tempering temperature to obtain a given hardness, but with the higher percentages of these elements, the rate of softening is no longer a continuous function of the tempering temperature. In steels of this type, such as the 0.5 per cent molybdenum steel of Figure 44-7, there is a tempering temperature range in which the softening is retarded or, with still higher alloy content as in the 2.0 per cent molybdenum steel, in which the hardness first decreases, then increases somewhat before continuing the decline with increasing tempering temperature. The retardation is also observed in steels containing more than one carbide-forming ele-

FIG. 44-7. The effect of molybdenum on tempering rate of 0.35% carbon, 0.30% chromium steel, tempered for 1 hour at the indicated temperatures.

FIG. 44-8. The effect of vanadium on tempering rate of steels tempered for 1 hour at the indicated temperatures.

FIG. 44-9. The combined effect of chromium and vanadium on tempering rate of 0.40-0.45% carbon steel tempered for 1 hour at the indicated temperatures. The 6140 steel contains both Cr and V; the 5140, only Cr.

ment, as illustrated by Figure 44—9, which compares the tempering curve for a 1 per cent chromium steel with that for a chrome-vanadium steel.

In order that a carbide forming element may manifest its full effect upon the tempering behavior, it must dissolve in the austenite at the heating temperature. This is illustrated by Figure 44—10, which shows the tempering behavior of a chrome-molybdenum-vanadium steel after quenching from 1500°, 1800° and 2100° F. It will be noted that the secondary hardening behavior is very marked in the steels quenched from

FIG. 44—11. The effect of time of tempering on the secondary hardening behavior in tempering.

the higher temperature, but is almost absent in the steel quenched from 1500° F in which a considerable proportion of the carbides is undissolved.

This secondary hardening effect is also evident in studies of the effect of time at a given tempering temperature on the hardness of alloy steels with carbide forming elements. As an illustration of this, Figure 44—11 shows the manner in which the hardness of a 2.0 per cent molybdenum steel varies with time at several different tempering temperatures. It will be noted that at the highest tempering temperature (1200° F), the secondary hardening effect occurs at times of from 10 seconds to 10 minutes, while at the lowest tempering temperature (660° F), there is no indication of this effect in 1000 hours.

This phenomenon can best be explained on the basis of a delayed precipitation of alloy carbide. Because of the relatively small number of alloy atoms in comparison to the iron atoms, and because of the slow diffusion rate of the alloying elements, the first precipitate to form on tempering will certainly be iron carbide, and the initially rapid drop in hardness represents the coalescence of these iron-carbide particles. However, with longer times and particularly with higher temperatures at which the diffusion rate of the alloys becomes more rapid, some alloy carbide will precipitate, and since this occurs after the coagulation of the iron carbide has progressed to a considerable extent, these fine particles will result in a reversal of the softening action. With relatively low alloy content, this may be manifested as only a decrease in the rate of softening while with high alloy content, an actual increase in hardness may occur as this secondary precipitation proceeds.

In the case of modern alloy steels which are of such a composition as to consist of a matrix of considerable plasticity with a dispersion of rather sizeable undissolved carbides after heat treatment, full advantage is taken of this secondary hardening effect. The composition and heat treatment of these steels is such that, although a number of the alloy carbides remain undissolved, enough are taken into solution to bring about a marked resistance to softening at temperatures up to 1100° F. Such tools can then be used for high-speed machining at relatively high operating temperature without softening.

It might further be mentioned that this effect of the alloying elements, and particularly the carbide-forming elements, on tempering may be reflected in an increased toughness of high-alloy steels. We have seen that the toughness of tempered martensite results from both the relief of internal stresses, and the formation of a desirable carbide dispersion. The higher tempering temperatures for a given strength level, characteristic of these high-alloy steels, will permit a greater degree of stress relief with an accompanying increase in toughness. Furthermore, as we have seen, a given hardness level in the tempered alloy steels reflects not only the state of dispersion and coagulation of the iron carbides, but also that of the alloy carbides, and thus coagulation and spheroidization of the iron carbides must progress further for a given hardness to offset the secondary hardening effect of the alloy carbides. This more completely spheroidized microstructure would also favor plasticity, particularly at hardness levels at which a moderate coalescence of the alloy-carbide dispersion has taken place.

The increase in plasticity on tempering has so far been considered as though it were a continuous effect, that is, as if the steel softened and became more ductile continuously as the tempering temperature is increased. However, this is not altogether true, as many steels ex-

Fig. 44-12. The loss of notch toughness in the Izod test in several alloy steels on tempering at about 600° F.

hibit a minimum toughness on tempering at temperatures of 500°–600° F. This behavior is illustrated in Figure 44-12, which shows the impact values of several alloy steels as a function of tempering temperature. This phenomenon is not fully understood, nor can the effects of the alloying elements on this behavior be evaluated. However, it should be realized that, in general, tempering temperatures in this range (500°–600° F) should be avoided wherever possible.

Temper brittleness in alloy steels is another common example of a discontinuous increase in plasticity on tempering. This phenomenon is manifested as a loss of toughness on slow cooling after tempering at temperatures of 1100° F or above, or on tempering in the temperature range of approximately 850° to 1100° F. Thus, a steel which is susceptible to this type of embrittlement may lose much of its ductility as indicated by a notched-bar impact test on slow cooling from a tempering temperature of 1150° F, although the same steel will be very tough if it is quenched from the same tempering temperature, and this expedient of quenching from the tempering temperature is a common practice to insure freedom from this embrittlement. However, in such steels, embrittlement will also occur on tempering at 850°–1050° F, particularly if the tempering times are protracted and quenching from the tempering temperature will, in such cases, never completely restore the toughness. This phenomenon also is not completely understood, although the behavior suggests that something which dissolves at temperatures of 1100° F and above precipitates in a damaging form at the lower temperatures, either during slow cooling or on reheating to these temperatures. High manganese, phosphorus and chromium contents appear to accentuate this behavior, and molybdenum seems to have a definite retarding effect.

OTHER FUNCTIONS OF THE ALLOYING ELEMENTS

The primary function of the alloying elements in alloy steels has been seen to be that of enhancing the properties through control of the microstructure, particu-

larly in conjunction with suitable heat treatments, and this function has been discussed in considerable detail. However, the alloying elements may exert other useful influences, particularly in steels which may be classed as special purpose steels. These functions will now be briefly discussed.

Ferrite Strengthening—Alloying elements dissolved in pure iron will increase its hardness, and this furnishes a method of increasing the strength of steels in the unhardened state. This ferrite-strengthening function of the alloys is, thus, independent of the effect of the alloys on microstructure, and may be utilized to increase the strength of steels which essentially receive no heat treatment, except for the cooling after the hot-working operation. This hardening effect is, of course, small as compared with that obtainable by changes in the dispersion of the carbide. This is illustrated by Figure 44-13, which shows the hardness of chromium steels as

Fig. 44-13. The minor effect of chromium in furnace-cooled steels compared with its strong effect as a strengthener through its influence upon structure in air-cooled steels.

a function of chromium content in a series of steels which have been very slowly cooled, in which the ferrite-strengthening effect will be predominant, as compared with a rapidly cooled series in which the effects of microstructural changes will be predominant. Each of the alloying elements will exert its individual effect in ferrite strengthening. The relative effectiveness of the alloying elements in this respect is indicated by Figure 44-14. The order of increasing effectiveness of these elements appears to be as follows: chromium, tungsten, vanadium, molybdenum, nickel, manganese, silicon, phosphorus. Significant increases in strength may be

FIG. 44-14. The relative effectiveness of the alloying elements as ferrite strengtheners.

obtained by the use of several elements in a single composition. In general, the higher strength levels obtained by this method of ferrite strengthening will be accompanied by a relatively small loss in plasticity, as compared with the considerable loss in ductility accompanying the hardness increases resulting from microstructural changes.

As discussed in the chapter on the low-alloy high-strength steels, these ferrite-strengthening effects have been utilized to their fullest extent in such steels.

Corrosion Resistance—Another function of some of the alloying elements in steel is to increase its resistance to corrosive attack. This function is also utilized in the low-alloy high-strength steels, in which chromium, copper, and phosphorus have been found very effective in increasing resistance to atmospheric corrosion, thereby permitting the use of the lighter sections made possible by their higher strengths, without decreased life from corrosion.

Chromium in high percentages imparts an extraordinary corrosion resistance to steel, and the stainless steels are largely based on this effect of chromium. This effect is discussed in detail in Chapter 47 on the stainless steels and need not be elaborated on here.

Abrasion Resistance—The compositions of alloy tool steels are such that at the heat-treating temperature many of the alloy carbides remain undissolved in the

austenite. These hard carbide particles serve to increase the abrasion resistance of the steel, and this represents another function of the alloying elements. The elements commonly used for this purpose are tungsten, molybdenum, vanadium, titanium and chromium.

The Hadfield manganese steels represent another class of abrasion-resistant steels in which the function of the element is to stabilize austenite in order to produce austenitic steels which harden on cold working.

Magnetic (Electrical) Characteristics—The addition of alloying elements may greatly modify the characteristics of steel used for electrical equipment. Improved electrical characteristics for a desired application may be obtained by utilizing these effects (see Chapter 46).

One example of this function of the alloying elements is represented by the silicon steels used for transformer cores. These steels, containing silicon up to 5 per cent, have a greatly increased electrical resistivity and, as annealed, high permeability. When used as transformer cores, these properties result in greatly reduced core losses.

The magnet steels, for permanent magnets, are another example of alloy electrical steels. The outstanding property of these steels is their retentivity or ability to retain magnetism. Cobalt, chromium, and tungsten are the alloying elements commonly used to enhance this characteristic.

SECTION 2

THE AISI ALLOY STEELS

Classification and Standardization of the AISI Steels

—The alloy steels most commonly used for heat-treated parts have been classified by the American Iron and Steel Institute and the Society of Automotive Engineers. The composition ranges of these steels have been listed in Table 44-I.

These steels are identified by a numerical index system that is partially descriptive of the composition. The first digit indicates the type to which the steel belongs; thus "1" indicates a carbon steel; "2" indicates a

nickel steel; "3" indicates a nickel-chromium steel. In the case of the simple alloy steels, the second number usually indicates the percentage of the predominating alloying element. Usually the last two or three digits indicate the average carbon content in "points," or hundredths of a per cent. Thus, "2340" indicates a nickel steel of approximately 3 per cent nickel (3.25 to 3.75) and 0.40 per cent carbon (0.35 to 0.45).

The basic numerals for the various types of AISI steels (including plain-carbon steels) are:

Series Designation	Types
10xx	Nonresulphurized basic open hearth and acid bessemer carbon steel grades
11xx	Resulphurized basic open hearth and acid bessemer carbon steel grades
12xx	Rephosphorized and resulphurized basic open hearth carbon steel grades
13xx	Manganese 1.75 per cent
23xx	Nickel 3.50 per cent
25xx	Nickel 5.00 per cent
31xx	Nickel 1.25 per cent—Chromium 0.65 per cent
33xx	Nickel 3.50 per cent—Chromium 1.55 per cent
40xx	Molybdenum 0.25 per cent
41xx	Chromium 0.50 or 0.95 per cent—Molybdenum 0.12 or 0.20 per cent
43xx	Nickel 1.80 per cent—Chromium 0.50 or 0.80 per cent—Molybdenum 0.25 per cent
46xx	Nickel 1.55 or 1.80 per cent—Molybdenum 0.20 or 0.25 per cent
47xx	Nickel 1.05 per cent—Chromium 0.45 per cent—Molybdenum 0.20 per cent
48xx	Nickel 3.50 per cent—Molybdenum 0.25 per cent
50xx	Chromium 0.28 or 0.40 per cent
51xx	Chromium 0.80, 0.90, 0.95, 1.00 or 1.05 per cent
5xxxx	Carbon 1.00 per cent—Chromium 0.50, 1.00 or 1.45 per cent
61xx	Chromium 0.80 or 0.95 per cent—Vanadium 0.10 per cent or 0.15 per cent min.
86xx	Nickel 0.55 per cent—Chromium 0.50 or 0.65 per cent—Molybdenum 0.20 per cent
87xx	Nickel 0.55 per cent—Chromium 0.50 per cent—Molybdenum 0.25 per cent
92xx	Manganese 0.85 per cent—Silicon 2.00 per cent
93xx	Nickel 3.25 per cent—Chromium 1.20 per cent—Molybdenum 0.12 per cent
98xx	Nickel 1.00 per cent—Chromium 0.80 per cent—Molybdenum 0.25 per cent
TS	denotes Tentative Standard Steel, as in TS 4130 and others.
B	denotes Boron Steel, as in 46B12 and others.
BV	denotes Boron Vanadium Steel, as in TS 43BV12 and TS 43BV14.

Needless to say, this list, representing as it does, a standardization and simplification of thousands of alloy-steel compositions, is a very valuable aid to the specification and choice of alloy steels for various applications. Many of these steels were developed for specific applications, and their continued satisfactory performance has resulted in a considerable degree of standardization of application among these compositions.

Applications of the AISI Alloy Steels—The low-carbon steels (0.10-0.25 per cent carbon) in this classification are designated as carburizing steels and they are applied almost exclusively to carburized parts. However, the choice of a steel within this group is determined largely by the core properties desired for the specific application. The lower alloy combinations, such as 4023, 4118 or 5015 are used where somewhat better core properties than those obtainable with the plain carbon compositions such as C1018 or C1117 are desired. They have the further advantage of being hardenable in oil in moderate

sections, and therefore can be heat treated with less distortion than the types requiring water quenching. The higher manganese and sulphur steels are used where superior machinability is required. Typical applications of these low-alloy carburizing grades would be for the production of cam shafts, wrist pins, clutch fingers, and other automotive parts in which high strength and optimum core properties are not required.

The higher alloy carburizing steels, such as 3120, 3310, 4320, 4620, 4815, 5120, 6120, 8620, 9310 or 94B17 are used where superior case hardness or core properties are desired. The choice of steels within this group is determined primarily by the hardenability necessary to obtain the desired core properties under the given conditions of section size and heat treatment. The low nickel-chromium (3120), nickel-molybdenum (4620), plain chromium (5120), chromium-vanadium (6120) or low nickel-chromium-molybdenum (8620) steels are customarily used for such applications as automotive gears, universal joints, small hand tools, piston pins, and similar parts of moderate section for relatively severe service. The higher alloy steels 3310, 4815, 9310 or 94B17 are used for severe service applications or heavy sections. Typical applications of these steels are aircraft-engine parts, truck transmissions and differentials, rotary rock-bit cutters and large antifriction bearings.

Similarly, the choice of the higher carbon alloy steels is based largely on the hardenability requirements of the specific applications. This will, of course, be a function of the heat treatment and section size. Intricate sections or higher carbon materials (over 0.40 per cent carbon) which must be oil quenched to prevent danger of quench cracking may frequently require higher alloy compositions than the simpler sections or low-carbon materials which can be safely heat treated under more drastic quenching conditions.

As with the carburizing steels, the lower alloy higher carbon steels, such as the manganese (1330-45), plain molybdenum (4037-47), plain chromium (5130-50), or the low nickel-chromium-molybdenum (8630-50), are used for applications involving relatively small sections, but which are subject to severe service conditions, or in larger sections which may not necessitate optimum properties, but in which advantage is taken of the weight saving derived from the higher strength of the alloy steels. Typical applications are the use of the manganese steels for automotive axles and high-strength bolts, molybdenum steels and chromium steels for automotive steering parts and low nickel-chromium-molybdenum steels for small machinery axles and shafts. These lower alloy steels are also widely used for high-quality small tools.

The higher alloy AISI steels, such as the 4137-50, 4337-40, 9840-50 or 86B45 compositions are used for heavy sections or for parts subject to particularly severe service conditions or for which very mild quenches must be used to prevent distortion. Typical uses would be for relatively heavy aircraft or truck parts or for ordnance materials.

In addition to the more or less general uses described above, some of the AISI steels have quite specialized applications. Thus the 52100 steels are used almost exclusively for ball- and roller-bearing applications, and the chromium steels (5155 and 5160) were developed for and are used almost entirely for spring-steel applications.

Hardenabilities of the AISI Alloy Steels—Hardenability has been stressed as the most important function of the alloying elements in these steels, and the above discussion of their applications has shown that the choice of the alloy steel to be used for a given applica-

FIG. 44-15. Typical hardenability band (4140H steel).

FIG. 44-16. Minimum hardenability limits for 4140H, 4340H, 5140H, 8640H and 9840H, comparing minimum hardenabilities for steels of different alloy content but of the same carbon content.

FIG. 44-17. Minimum hardenability limits of a group of steels of the 8600 (nickel-chromium-molybdenum) series, showing the increase in minimum hardenability with increasing carbon content.

tion is largely based on its hardenability. Realizing the importance of hardenability, the American Iron and Steel Institute, together with the American Society of Automotive Engineers, have established minimum and maximum end-quench hardenability curves, known as hardenability bands, for most of these alloy steels. These bands or hardenability limits, typified by Figure 44-15, are based on the analysis of data collected from hundreds of heats of each grade of steel. Such information permits these steels to be sold on the basis of this most important property, hardenability, and steels sold to such

a hardenability specification are known as "H" steels.

Since, for application purposes, the minimum hardenability values for a given steel are usually the most pertinent, the minimum hardenability limits for numerous "H" steels are shown in Figures 44-16 and 44-17. Figure 44-16 also compares the minimum hardenability limits for a group of steels of different alloy content but having essentially the same carbon content. Figure 44-17 shows the effect on the minimum hardenability limit of increasing carbon content in steels of the 8600 (nickel-chromium-molybdenum) series.

SECTION 3

ALLOY TOOL STEELS

Compositions and Applications—The principal functions of the alloying elements in tool steels are to increase hardenability, to form hard, wear-resisting alloy carbides, and to increase resistance to softening on tempering. The alloy tool steels may be roughly classified according to the extent of their utilization of these three functions. On this basis, the three classes would be as follows:

1. **Relatively low-alloy tool steels.** These are of higher hardenability than the plain carbon tool steels in order that they may be hardened in heavier sec-

tions or with less drastic quenches and thereby less distortion.

2. **Intermediate alloy tool steels.** These steels usually contain elements such as tungsten, molybdenum or vanadium, which form hard, wear-resisting carbides. They are employed in the manufacture of fast-finishing tools in which the retention of a smooth cutting edge is of particular importance.
3. **High-speed tool steels.** These contain large amounts of the carbide-forming elements which serve not only to furnish wear-resisting carbides but also to

Table 44—II. Compositions of Some Tool Steels (Per Cent)

Class	Type	C	Mn	Si	Ni	Cr	Mo	W	V	Co
1	Non-Deforming ...	0.90	1.60

2	Tungsten Finishing.	1.35	0.25	0.25	0.50-1.00	3.0-4.0
2	Tungsten Finishing.	1.35	0.25	0.25	0.50-1.00	3.0-4.0
2	Tungsten Chisel ...	0.50	0.25	0.25	1.50	2.10	0.25
3	18-4-1 High Speed .	0.50-0.80	0.25	0.25	4.00	18.00	1.00
3	18-4-3 High Speed .	0.95	0.25	0.25	4.00	18.00	3.00
3	Tungsten Cobalt ...	0.75	0.25	0.25	4.00	18.00	1.00	5.00
3	Molybdenum High Speed	0.75	0.25	0.25	4.00	8.50	1.50	1.00
3	Tungsten-Molybdenum High Speed	0.80	0.25	0.25	4.00	4.75	5.75	1.50

promote secondary hardening and thereby to increase resistance to softening at elevated temperature.

Typical compositions of these three classes of tool steels are given in Table 44—II. More detailed information on types of tool steels, their composition, treatments and applications, may be found in the 1948 Edition of the American Society for Metals' Handbook, pages 653-676, and in "Tool Steels" by Gill, Rose, Roberts, Johnston and George, published by the American Society for Metals.

Table 44—II is illustrative of the types of compositions used for alloy tool steels, of which there are hundreds of variations. The uses of tool steels are so diversified and the compositions and types that may be used for a single application overlap to such an extent that a satisfactory general classification on this basis is impossible. However, the high-speed steels obviously are used for application requiring long life at relatively high operating temperatures such as for heavy cuts or high-speed machining, the intermediate alloy types are used for finishing operations in which extreme wear resistance and the ability to retain a smooth cutting edge on light cuts is necessary, and the first class of steels are general purpose tool steels, the choice of which is based primarily on section size, permissible distortion, intricacy of design, and the hardness and toughness requirements of the application; all of which are, to a considerable extent, functions of the hardenability. The higher hardenability steels are used in cases where a low "movement" (change of dimension) in hardening is required, since relatively slow oil or even air quenches may be used. These steels are also designed to be capable of hardening from relatively low quenching temperatures which also tends to decrease distortion and danger of quench cracking. Within this class, the higher carbon steels are used for applications requiring high resistance to wear or abrasion and the lower carbon steels for applications in which resistance to shock or impact is of particular importance.

HEAT TREATMENT OF ALLOY TOOL STEELS

General—The general principles of heat treatment, as described in Chapter 42, naturally apply to the heat treatment of the alloy tool steels. The alloy tool steels are generally high carbon, and many of them are relatively high-alloy steels so that their heat treatment necessarily involves special precautions to avoid distortion, cracking, and decarburization. The heating operation must be conducted at a slow rate to minimize thermal stresses, and relatively low austenitizing temperatures are usual to minimize distortion and cracking. It is a common practice to carry out the heating in two stages: a preliminary preheat to an intermediate temperature preceding the heating to the final temperatures. Decarburization is usually particularly harmful in tool steels, and the practices mentioned in the chapter on heat treatment, such as use of controlled atmospheres, packing in cast-iron chips, or heating in neutral liquid baths, are very commonly employed.

Because of their sensitivity to cracking and the dangers of distortion, relatively mild quenches are commonly used in the heat treatment of alloy tool steels, and many of them are of high enough hardenability to permit air quenching.

Since the residual stresses are high in these high-carbon steels after quenching, the stress-relieving function of the tempering operation is of particular importance. Tempering to relieve these stresses and

toughen the steels is therefore an essential part of the heat-treating operation and should immediately follow the quench. Since high hardness is usually desired, the tempering temperatures are generally low (250° to 450° F), although in cases such as some of the die applications, in which resistance to shock and impact are important, higher temperatures may be used. Tempering in the temperature range of 500° to 600° F should generally be avoided.

High-Speed Steel—As mentioned above, the high-speed steels, typified by the 18 per cent tungsten, 4 per cent chromium, 1 per cent vanadium composition, differ from the lower alloy tool steels, not only in the presence of higher percentages of carbide-forming elements, but also in the fact that the secondary hardening effects of these elements are much more fully realized and a high resistance to softening at elevated temperature is obtained. These steels require a special heat treatment in order that their unique properties may be fully realized. In outline, this procedure consists of heating to a high temperature (2150° to 2400° F) to obtain solution of a substantial percentage of the alloy carbides, quenching to room temperature, at which stage a considerable amount of austenite is retained, tempering at 1000° to 1150° F, and again cooling to room temperature. During the tempering operation, alloy carbides are precipitated, resulting in a marked secondary hardening and in a reduction of alloy content in the retained austenite, which then transforms to martensite on cooling to room temperature and results in a still greater hardness increase. It is often desirable to temper a second time to temper the martensite formed on cooling from the original tempering.

In order to prevent excessive grain growth and decarburization, the steels are held at the high quenching temperature for only a few minutes before quenching. Steels are customarily preheated to between 1400° and 1600° F before transferring to the high-heat furnace. This serves the dual purpose of eliminating the severe thermal shock of placing the cold tool into the high-temperature furnace, and of decreasing the decarburization because of the shorter time of exposure to the high temperature. The use of controlled-atmosphere furnaces, or of neutral liquid baths for the high-heat treatment is also very desirable, and in many cases essential, to minimize decarburization. The time in the high-heat furnace will, of course, vary with the heating rate and size and shape of the piece. Typical hardening temperatures are 2250° to 2350° F for the tungsten types, 2150° to 2250° F for the molybdenum types, and 2325° to 2400° F for the cobalt types.

Quenching may be in air, oil, or in liquid baths. Air cooling has the disadvantage of the formation of a tightly adherent scale during cooling. Oil quenching, while it facilitates the removal of this scale, results in higher stresses. These may be minimized, however, by removing the piece from the oil at the flash point and then air cooling. By this method, the tools will be air cooled through the temperature range in which transformation to martensite occurs. The third method, which is very commonly practiced to insure low quenching stresses, is to quench into a liquid bath at 1000° F, hold until equalized, and then slowly air cool to between 200° and 300° F and immediately temper. This procedure is particularly applicable to the hardening without undue distortion or cracking of intricate tools.

Tempering may be carried out in salt baths, lead baths, or circulating-air furnaces. The latter are particularly desirable because of their adaptability to close control of temperature and uniformity of heating the work. The rapid heating of high-speed tool steels im-

mersed in lead baths is undesirable since it may set up stresses which would lead to cracking. The maximum hardness will usually be developed at temperatures of 1000° to 1100° F, and the holding times in this temperature range usually are from 1 to 4 hours. The specific time and temperature will vary with the hardness and toughness desired.

As mentioned above, a second tempering at a relatively low temperature (600° to 650° F) will temper the martensite formed in cooling from the first tempering operation and will serve to increase the toughness of these steels without causing appreciable softening.

Chapter 45

HIGH-STRENGTH LOW-ALLOY STEELS

The steels which are the subject of discussion in this chapter are categorized upon the basis of their mechanical properties. This is in contrast to the usual method of classification, which is generally based on chemical composition; for example, the designations "plain carbon steels," "alloy steels" and "stainless steels" are based upon the presence (or absence) of added alloying elements in the particular steel. Thus steels of a particular range of composition may be specified so that the purchaser will be able to obtain certain desired properties in a part that may be heat treated by him. On occasion, plain carbon, alloy and stainless steels are furnished to specifications involving a prescribed combination of mechanical properties; since, however, chemical composition is the primary controlling factor in obtaining these required properties, such steels automatically fall into one of the above compositional classifications.

The steels classified as "high-strength low-alloy steels" have strengths somewhat greater than those exhibited by the structural carbon steels and, since enhanced mechanical properties can be obtained with a number of different combinations of alloy contents (other than carbon), this group of steels consists of various chemical compositions, but each steel in the group meets essentially the same minimum mechanical-property requirements. For the sake of brevity, they are referred to in the text only as high-strength steels.

Engineering Function of the High-Strength Steels—Modern trends toward larger and larger structures have made design and construction engineers aware of the advantages to be gained from a steel inherently stronger than structural carbon steel in order that excessively large sections might be avoided. It was realized that the advantages would be greatest in the transportation field since thinner sections with increased strength could be employed to eliminate the hauling of excess dead weight. Since carbon and manganese are the main strength-producing elements in structural carbon steel, it is obvious that the desired increase in strength could be obtained simply by increasing the amounts of either or both of these elements in the steel. It has been found, however, that while these additions will produce the higher strength, the resulting steels often cannot be handled so readily by ordinary methods of fabrication (including welding) and even when successfully fabricated, the utility of the finished part may be seriously impaired. It was found that other alloying elements, such as copper, phosphorus, nickel, chromium, vanadium and silicon, could be added in such amounts that, with a lower carbon content, the desired increase in strength was obtained, at relatively low cost, without greatly decreasing the ductility of the steel. The result of this experience has been the development of a group of steels which possess the required high strengths and which can still be fabricated by standard shop processes on conventional equipment.

The use of thinner sections to eliminate excess weight, and the desire for longer life with decreased mainte-

nance emphasized the need for improved resistance to corrosion. Materials which are exposed to corrosive environments, of which the atmosphere is one, are subject to loss of thickness and, consequently, to a decrease in their capacity to carry load. It may readily be seen that, if the high-strength low-alloy steels corroded at the same rate as structural carbon steel, thinner sections of high-strength steel would be reduced to the permissible minimum thicknesses in less time than would the thicker structural carbon steel sections. It is, therefore, necessary that the improvement in the atmospheric-corrosion resistance of the high-strength steels at least be in proportion to the increase in their strength so as to obtain satisfactory performance from the thinner sections. Similarly, increased resistance to corrosion is required to improve the service life of equipment made from sections of standard thicknesses.

As the foregoing discussion intimates, the high-strength low-alloy steels are intended for general structural applications. They should not, therefore, be considered as special-purpose steels nor as steels requiring, or adapted for, heat treatment.

Historical Background—Before 1900, the only widely available ferrous construction material, such as used in buildings and bridges, was mild carbon steel having an ultimate tensile strength of about 60,000 pounds per square inch. In 1902, the design engineers of the Queensboro Bridge, which was to span the East River in New York City, requested the development of a stronger steel so that the number and size of supporting members could be held within the space and weight limitations of their design. Carnegie Steel Company, which now is part of the United States Steel Corporation, supplied 3.25 per cent nickel steel for this application. Because of the satisfactory results obtained on the Queensboro Bridge, nickel steel was used for the stiffening trusses of the Manhattan Bridge in 1906. Although this material was satisfactory for riveted structures from the standpoint of strength, it was an expensive material, economical for use only in structures in which reductions in the weight or size of members was a necessity.

Silicon steel containing about 1.00 per cent silicon and 0.25 per cent carbon, cheaper than the nickel steel, was suggested for ship construction as early as the 1880's. However, the first application of this steel in ship-hull construction was in 1907 as plates in the S. S. MAURETANIA. The manufacture of this steel was ultimately discontinued because of the many difficulties encountered. Later on, a so-called "silicon structural steel" was used which, however, contained only a nominal amount of silicon. This material depended for its strength mostly on its high carbon content, usually 0.30 per cent minimum. It was first used in 1915 in a bridge spanning the Ohio River at Metropolis, Illinois. This grade, under the misnomer Silicon Structural Steel, has been one of the most widely used materials for riveted structures, but it is rapidly being superseded by carbon structural steel and high-strength steel.

In 1927, as an alternate for expensive nickel steel, the American Bridge Company, now a division of United States Steel, used a 1.60 per cent manganese steel for the lower chord members of the Kill van Kull Bridge connecting Staten Island with the mainland at Bayonne, New Jersey.

Similar developments had taken place in other countries. Engineers in Great Britain attempting through weight reduction to effect economies in ocean freights and handling charges, had used carbon steels containing generous amounts of silicon and manganese. Engineers on the Continent made use of similar steels, and early in 1933 the Germans completed the construction of "The Flying Dutchman," the first light-weight "streamlined" train built of high-strength steel. This composition contained additions of silicon, manganese and copper and was known as ST. 52.

Two New Problems: Corrosion and Welding—Each of the high-strength steels which had been developed before the year 1930 was found to lack one or more of the qualities required for most constructional applications. The potential benefits to be derived from the use of such materials, however, were indicated by these early steels, and the experience gained in their use had pointed out the specific characteristics needed in steels for this field of application. It had been discovered that improved resistance to corrosion was required if section thicknesses were to be reduced without the sacrifice of serviceability, or if increased service life were to be obtained. This discovery led to the addition of elements for the express purpose of improving the atmospheric corrosion resistance. A great deal of corrosion testing followed, which in turn led to the evaluation of the effects of the individual elements and of combinations of the elements on resistance to corrosion.

At about the same time, it was realized that good weldability of the high-strength steels was required to permit the greatest possible weight reduction, and to thus enhance the economical use of this type of material. The development of the present day high-strength low-alloy steels has paralleled the adoption of the various welding processes and much metallurgical ingenuity has been shown during the development of these steels to make certain that they possessed good welding characteristics.

The earliest of the present-day high-strength steel brands was "COR-TEN," which was introduced by United States Steel in 1933. This brand of steel has been continuously improved to meet the increasingly severe demands of fabricators, an experience common with most new steels. The great demand for steels of this type is indicated by the fact that, since "COR-TEN" steel was introduced, many other steel-producing companies have developed their own grades and there are at present a considerable number of high-strength low-alloy steels. These steels have found wide acceptance in the metal-working industry and have come into general production and almost universal use for many applications.

Definition—This group of steels has been termed "High Tensile Steels" and "Low Alloy Steels" but the name "High-Strength Low-Alloy Steels" is gradually being adopted as its designation.

There have been numerous attempts to write suitable definitions for this class of steels and the following is one that has been adopted by the American Iron and Steel Institute for its product manual on this grade of steel:

"High strength low alloy steel comprises a specific group of steels with chemical compositions specially developed to impart higher mechanical-property values

and greater resistance to atmospheric corrosion than are obtainable from conventional carbon structural steels containing copper. High strength low alloy steel is generally produced to mechanical property requirements rather than to chemical composition limits.

"High strength low alloy steel is generally intended for application where savings in weight can be effected by reason of its greater strength and atmospheric corrosion resistance and where better durability is desired."

These steels are normally furnished in the hot-rolled (as rolled) or cold-rolled, annealed or normalized condition, and are intended for use without further heat treatment, particularly not by quenching and tempering.

These steels are readily adaptable to fabrication by forming, riveting and welding; in the latter case no preheat or postheat is required. In certain complex structures, stress relieving after welding may be desirable.

Fundamental Characteristics—Steels of the high-strength low-alloy type, to be of interest as construction materials, must have characteristics and properties which result in economies to the user when the steels are properly applied. Such materials should be considerably stronger and, in many instances, tougher than structural carbon steel. They must have sufficient ductility, formability and weldability to be successfully fabricated by customary shop methods. In addition, high-strength steel should have sufficient resistance to corrosion so that equal life in a thinner section or longer life in the same section obtains when compared to that of a structural carbon steel member. Table 45—I lists the combination of important characteristics which an all-purpose high-strength steel should possess, and indicates the methods by which these characteristics are commonly determined.

Table 45—I. Important Characteristics of an All-Purpose High-Strength Steel

Property	Method of Determination
High strength ..	.Yield point in tension test.
Good corrosion resistanceAtmospheric-corrosion resistance judged from weight loss in exposure rack test, and useful life judged from service performance.
Good formability.	.Bend test, tensile elongation and fabrication performance.
Good weldability.	.Weldment performance judged by various weld-bending tests.
Good toughness under adverse conditionsTemperature of transition from tough to brittle behavior in notched-bar impact test.
Good resistance to repeated loadingEndurance tests on simple specimens or on built-up structures.
Good abrasion resistance ..	.Service performance.

Since the yield point of the constructional material determines the stress to which a structure may be subjected without permanent deformation, the unit working stresses of each structure are based upon this important property. The minimum yield point of structural carbon steel is 33,000 lb. per sq. in.; that of high-strength steel is generally 50,000 lb. per sq. in. Hence, on the basis of the proportionality of their yield points, the unit working stress employed with high-strength steel may

be increased to one and one-half times that used with structural carbon steel. The use of higher unit working stresses permits reductions in the thicknesses of section in the structure and this results in a decrease in weight. This saving in weight is of utmost importance in mobile structures, both in the economy and speed of transportation, and in the ability of these structures to carry greater payload. Frequently high-strength steels are substituted for structural carbon steel without change in section, the sole purpose being to produce a stronger and more durable structure with no increase in weight.

Corrosion Resistance—When high-strength steels are employed to save weight, it is desirable to make the maximum reduction in section. The engineer, however, must consider the structure not only at the time it is built but also as it will exist perhaps twenty years later when the members have been thinned by corrosion. Since the structural members are already relatively thin by virtue of the desired weight-saving, it is necessary that further thinning from the ravages of corrosion be prevented, at least in so far as possible, else the structure will become too weak to serve its intended purpose. Similarly, when high-strength steels are employed to obtain increased service life, corrosive attack must be retarded. Thus, it may be said that improved corrosion resistance is equal in importance to higher strength and that the corrosion resistance of the high-strength steels should be as high as is economically feasible without, at the same time, adversely affecting the other properties and characteristics to a marked extent. Unfortunately, the corrosion resistance of a material cannot be expressed quantitatively (as the yield point is described, for instance) because it is only a relative term. Furthermore, no material is equally resistant to all the corrosive conditions to which it might conceivably be exposed. Its performance can only be compared with that of other materials under similar conditions. A large number of corrosion tests under many conditions of exposure, particularly atmospheric rack tests, have been conducted for the purpose of determining these relative values. Such tests differentiate between the performances of various steels and permit a close evaluation of the trends in weight loss due to corrosion. The atmospheric-corrosion resistance of high-strength steels varies with the combination and content of those alloying elements most effective in building up this resistance. Several steels of this type possess four to six times the atmospheric-corrosion resistance of structural carbon

steel having a low copper content. The superior atmospheric corrosion resistance which most of the high-strength steels have shown in rack tests has been confirmed by their performances in many different kinds of service. This superiority is particularly evident in those applications in which the materials are subjected principally to atmospheric corrosion. Much has been written concerning the details and results of corrosion tests and a number of references are included in the bibliography for the use of those who wish to pursue the subject further. Figure 45-1 shows time-corrosion curves for plain carbon steel, structural copper steel, and three high-strength, low-alloy steels exposed to an industrial atmosphere.

Formability—High-strength, low-alloy steels must have suitable plastic properties so that they can be hot or cold worked readily and economically into various commodities for use in engineering structures. These materials must also be capable of being readily hot formed, cold formed, sheared, punched, reamed, coped, sawed, milled, drilled, riveted and welded by the fabricator. These operations can be performed on high-strength steels with almost as much ease as on regular structural carbon steel. High-strength steels, despite their high yield points, can be satisfactorily worked in pressbrakes, drawbenches, presses and other equipment used for cold forming, even when these forming operations are quite severe.

There are some inherent differences between the cold-forming characteristics of high-strength and plain carbon steels. First of all, more force is required to produce a given amount of permanent set in a high-strength steel section than in a plain carbon steel section of the same thickness. This is attributable to the greater strength of the high-strength steel, and the difference in force is approximately proportional to the difference in the yield points of the two materials.

Another difference is in the amount of springback encountered after forming the two materials. When like parts are formed from the same thickness of a high-strength steel and of a plain carbon steel, the relative springback of the two materials will be about proportional to the amount of force required to produce the part; therefore, a somewhat greater allowance for springback should be provided when forming the high-strength steel. When the high-strength steels are employed in thinner sections, the effect of reductions in thickness upon the springback allowance must also be

FIG. 45-1. Comparative reductions of thickness by atmospheric corrosion of steels exposed to an industrial atmosphere.

considered. In bending operations, the amount of elastic deformation is increased considerably by reductions in section thickness. Therefore, when lighter sections of high-strength steel are used, more springback is obtained even though the force to produce the part is little or no greater than that required for the original part of plain carbon steel.

Experience has shown that more liberal radii of bend must be used with a high-strength steel than with plain carbon steel for successful cold forming. This again is ascribed to the greater strength of the high-strength steel.

Weldability—Since welding is generally employed in fabricating structural steel, it is important that high-strength steels be readily weldable by metal-arc welding and by gas welding in plate thicknesses and by all the resistance welding processes in sheet and strip thicknesses. It is equally important that the welds in fabricated structures have the required strength and ductility to withstand the most adverse conditions in the contemplated service. As mentioned before, the development of the present-day high-strength steels has paralleled the adoption of the various welding processes and particular care was exercised to make certain that these steels possessed good welding characteristics. Suffice it to say that the high-strength low-alloy steels are considered readily weldable by the usual processes.

Notch toughness, measured in a notched-bar impact test, is of interest because it reflects the behavior of the materials at notches in actual structures. High-strength steels exhibit notch toughness superior to that of structural carbon steels, whether the notch toughness be considered in terms of the amount of energy absorbed in breaking a specimen at room temperature or in terms of the refrigerated temperature to which they preserve their toughness.

These advantages in notch toughness are reflected in superior performance of actual structures under adverse conditions of stress.

Fatigue Resistance—The resistance to repeated loading, or the fatigue resistance, of materials is generally determined by testing polished specimens. The endurance limit determined by this method of testing, therefore, is considered to have little bearing on the fatigue resistance of full-size structures since failures of structural members, subject to alternating or pulsating stresses, generally originate at some surface notch or discontinuity acting as a stress raiser. Laboratory tests of polished specimens do, however, indicate that the high-strength steels are superior to structural carbon steels. The ratio of endurance limit to tensile strength is greater for high-strength steels than for structural carbon steel.

Abrasion Resistance—There is general agreement that the resistance of various steels to abrasive action increases with strength or hardness and, to some extent, with carbon content. Service tests have demonstrated that the abrasion resistance of the high-strength steels, with their inherently greater strength, is somewhat higher than that of structural steel containing 0.15 to 0.20 per cent carbon.

Composition, Properties and Characteristics, and Applications—In the development of a chemical composition to obtain the desired properties in a steel, it was, of course, imperative that strength be given first consideration. Since increased strength can be obtained with various combinations of alloying elements, a number of different compositions have been produced which offer interesting combinations of other properties and characteristics in addition to the required minimum strength. This is well illustrated by the compositions of a representative group of current high-strength steels

Table 45—II. Composition Ranges of Some Representative High-Strength Low-Alloy Steels.

shown in Table 45—II, and by the comparison of the properties of a typical high-strength steel with those of two plain carbon steels given in Table 45—III.

EFFECT OF CHEMICAL COMPOSITION ON PROPERTIES AND CHARACTERISTICS

Carbon—It will be noted that a number of features are common to the compositions of many of the current high-strength low-alloy steels. For example, the carbon contents are generally lower than those found in structural carbon steels. Carbon is one of the more potent strengthening elements, but the increase in strength which it produces is accompanied by a marked decrease in ductility, notch toughness, and weldability.

In so far as metal-arc welding is concerned, it is generally desirable to keep the carbon content below certain maximum values because of the high rates of cooling which obtain in the heat-affected zone of a weldment and the consequent danger of embrittlement if the carbon content becomes too high. Carbon has two distinct effects in this connection: (1), an increase in carbon increases the hardenability and therefore increases the tendency for hard, brittle martensite to form adjacent to the weld; and (2), when martensite does form, the steel is much more brittle if the carbon content is high than if it is low. Thus, if other alloying elements are added, for example, to increase the corrosion resistance or strength, and the hardenability is consequently increased, the carbon content must be reduced to avoid embrittlement.

For satisfactory metal-arc welding of plain carbon steels with manganese contents below about 0.60 per cent, the upper limit of carbon content is about 0.30 per cent. With high-strength steels, in which hardenability is increased by addition of other elements, this upper limit is reduced; for example, to 0.12 per cent carbon in a steel for metal-arc welding containing 0.80 per cent chromium, 0.50 per cent nickel, 0.40 per cent silicon, 0.40 per cent copper and 0.10 per cent phosphorus. Of course, with less alloy content, the carbon content may be somewhat higher.

In the case of spot welding, where quenching rates are even more drastic than in metal-arc welding, the maximum carbon content in plain carbon steel is still further reduced and would, for example, be approxi-

mately 0.15 per cent. Spot welds made in high-strength steels have considerably less ductility than spot welds in plain low-carbon steels, even when the former contain only a maximum of about 0.10 per cent carbon.

The addition of carbon improves the endurance limit in direct proportion to the amount it raises the tensile strength. It is reported that variations in carbon content or conditions of heat treatment have little effect on the rates of corrosion of steels.

Manganese—The manganese contents of most of the high-strength steels, as is shown in the table, are somewhat higher than those of carbon structural steel. The effect of manganese on the mechanical properties of these types of steel is very much like that produced by carbon, but to a milder degree. The addition of manganese to steel results in an increase in strength accompanied by a decrease in ductility. There appears to be a slight improvement in notch toughness and a slight impairment in weldability with increase in manganese content.

In regard to metal-arc welding, it is desirable to keep the manganese content below certain values. These vary considerably, depending on the amounts of other elements present, particularly the carbon content. Thus, if the carbon content is about 0.25 per cent, manganese contents up to about 1.00 per cent are acceptable, whereas, if carbon is 0.20 per cent or lower, manganese somewhat over 1.00 per cent would be satisfactory. These permissible maximum amounts of carbon and manganese will be further reduced by approximately the extent to which the hardenability is increased by the addition of other alloying elements used to obtain the desired type of high-strength steel composition.

In the case of spot welding, the maximum permissible manganese content is again dependent upon the amount of carbon present. As mentioned previously, a carbon content of about 0.15 per cent can be tolerated in a steel having a manganese content below about 0.60 per cent. However, if the carbon content is reduced to 0.10 per cent or lower, the permissible manganese content may be 1.00 per cent or a little higher.

The addition of manganese, as is the case with carbon, increases the endurance limit in direct proportion to the amount it raises the tensile strength. It is reported that an increase in the manganese content has a very

small beneficial effect on the atmospheric corrosion resistance of steel.

Phosphorus—Many of the present day high-strength low-alloy steels have phosphorus contents in the range of 0.04 to 0.15 per cent. Additions of phosphorus markedly increase the strength properties of steel but this increase is accompanied by a decrease in ductility. Phosphorus was formerly considered to cause embrittlement in steels when present in amounts exceeding about 0.10 per cent. It has been found, however, that the embrittling effect of phosphorus is influenced markedly by the carbon content and that this effect is not pronounced in the low range of carbon content generally employed in the manufacture of high-strength steels. It has been further shown that grain-refining additions of aluminum improve somewhat the toughness of phosphorus-bearing steels. Thus added benefit is gained from the silicon-aluminum deoxidation practice employed in the manufacture of many high-strength steels. With respect to metal-arc welding, the effect of phosphorus is similar to that of manganese except that the influence of phosphorus is greater. Since the heat-affected parent metal is of principal concern when a steel is welded, the carbon content must be kept low enough so that the phosphorus which is present will not increase the hardenability of the steel by an amount sufficient to produce martensite. The results of several investigations indicate that a permissible upper limit of 0.20 per cent phosphorus may be set for a plain carbon steel containing 0.10 per cent carbon. These maxima will, of course, be reduced by approximately the extent to which the hardenability is increased by the addition of other alloying elements used to obtain the desired type of high-strength steel composition. The results of a few investigations to determine the effect of phosphorus content on the spot-welding characteristics of low-carbon steel indicate that cracking occurs in the welds if the phosphorus content is 0.20 per cent or higher. Addition of phosphorus, as in the case of carbon and manganese, increases the endurance limit in approximately direct proportion to the increase in the tensile strength. The atmospheric corrosion resistance of steel is considerably increased by the addition of phosphorus alone, and it has been shown that, when small amounts of copper are present in the steel, the effect is greatly enhanced. In other words, a given amount of phosphorus and copper has a beneficial effect which is greater than the effect produced by the corresponding amount of either of the individual elements alone.

Copper—Copper in limited quantities is beneficial to steels of the high-strength low-alloy type. Most present-day high-strength steels contain copper in amounts ranging from 0.20 to 1.30 per cent. Copper markedly increases the strength properties and the hardness of low- and medium-carbon steels with only a slight accompanying decrease in ductility. In contrast to the usual effect of alloying elements on strength properties, copper additions cause a more rapid rise in yield point than in tensile strength. The relative rates of increase are such that at about 3.00 per cent copper the yield point would closely approach the tensile strength. The endurance limit of steel is improved by the addition of copper, at least in proportion to the increase produced in the tensile strength. Copper up to at least 0.75 per cent is considered to have little effect on notched-bar toughness or welding performance. Steels containing over about 0.60 per cent are susceptible to precipitation hardening. This type of hardening is most pronounced in the range from 1.20 to 1.50 per cent copper, where increases of some 20,000 lb. per sq. in. in both yield point and tensile strength are possible. Steels containing

about 0.50 per cent or more of copper frequently exhibit "hot shortness" during hot working. This is evidenced by the occurrence of cracks or extremely roughened surfaces, sometimes referred to as "checking," which may develop during hot deforming at too high a temperature or during hot working after overheating. These defects are caused by preferential oxidation of the iron and by penetration of the remaining copper-rich alloy into the grain boundaries of the steel beneath the scale. The occurrence of these undesirable surface conditions can be minimized by careful control of oxidation during heating and by hot working below the melting temperature of the copper-rich solid solution. There has also been considerable experience which indicates that the addition of nickel in an amount equal to at least one-half the copper content is very beneficial to the surface quality of steels containing copper. Copper, in the concentrations used, is by far the most potent of all the common alloying elements in improving atmospheric corrosion resistance. Copper is especially effective in small amounts—as low as 0.10 per cent or less—in regular carbon steel. Continued improvement may be obtained up to 1.00 per cent copper, but the effect is not nearly so marked with additions over about 0.20 per cent copper.

Other Elements—Examination of Table 45—II discloses that other elements besides those discussed above are added to the various proprietary high-strength steels. Space does not permit a full discussion of the effect of the individual elements, but the amount of each element present in the steels listed in Table 45—II has been added to obtain a desired improvement in one or more of the essential characteristics and properties. From an examination of the compositions shown in Table 45—II and of the properties shown in Table 45—III, it will be seen that the high strength has been obtained in these steels by the use of alloying elements other than carbon. In spite of the fact that an increase in strength is usually accompanied by a decrease in toughness, the high-strength steels, having a lowered carbon content, are both stronger and tougher than structural carbon steels. Generally, some sacrifice has been made in weldability, and even occasionally in formability, in order to obtain this higher strength and increased resistance to atmospheric corrosion, along with higher endurance limit and greater abrasion resistance. The specific combinations of elements employed in the individual high-strength steels have resulted in various compromises of the properties and characteristics previously discussed.

Many articles and papers have been published which deal with the properties, characteristics and fabrication of the various steel compositions which are termed high-strength low-alloy steels, and a number of references which cover the subject in greater detail will be found at the end of this chapter.

Applications—While high-strength low-alloy steels find application in all recognized market classifications, the largest single field of application has been in the construction of transportation equipment. From 1934 to 1954 more than 190,000 railroad freight cars and 6,000 railroad passenger units have been constructed with but one of the leading grades of high-strength steel. If all of the prominent grades are considered, the number of high-strength steel freight cars in service would doubtless exceed 300,000 or 17 per cent of the current car ownership by American Class I railroads. Until quite recently, the emphasis, in railroad freight car usage, was on the substantial economies in operating costs obtained by using high-strength steels in somewhat reduced thicknesses to decrease the dead weight

of the cars. In some instances, the railroads were also able to increase the revenue per car trip by enlarging the capacity of the lightweight car so that it could carry an additional amount of pay load equal to the reduction made in the dead weight.

Similar benefits from weight reduction and some increase in capacity have been obtained with other mobile equipment, such as various types of trucks, trailers and buses.

In recent years, however, the emphasis has been shifted, in many types of applications, from weight reduction to stronger, more durable equipment, with no appreciable decrease in weight.

In addition to decreased maintenance costs, utilization of this principle has resulted in improved service performance. Examples are found in railroad freight cars, mine cars, power shovels and many other types of earth-moving equipment, off-highway trucks, and many other types of material-handling equipment, all of which are subjected to severe abuse in service.

High-strength steels, surface ground while hot and subsequently cold formed into the more elaborate types of automotive bumpers prevalently in use, have largely supplanted high- and medium-carbon steels previously used in making bumpers by hot forming which required costly hand grinding of the formed bumper before plating.

In bridges, designers are giving increased recognition to the importance of reducing dead load by using high-strength steels, particularly when long spans are involved and where a reduction of weight at the center permits additional saving in the weight of the supporting members. High-strength steels also lend themselves to economical tower construction where their properties permit the use of smaller sections than would be required in plain carbon steel. This advantage is important in tall television towers where wind resistance is lessened by use of smaller sections, and in transmission towers where lighter weight is a substantial advantage in reducing freight and handling costs.

Multistory building construction does not generally provide a suitable field of application for high-strength steel because weight reduction in the structural members is not usually important or economical. However, lightweight cold-formed sections of high-strength steel are being used to advantage in the framing members of industrial and farm buildings.

The weight of portable and semi-portable containers for liquefied petroleum gas has been reduced substantially by the use of high-strength steel, making them easier and less costly to handle and ship. Almost all such containers are now made of high-strength steel.

Other applications of high-strength steels include: the inner bottoms, floors, tanks and hatch covers of ore boats; hulls and other structural members and accessories of small tankers, barges, tugs, launches and river boats; coal bunkers, street-lighting poles, portable oil-drilling rigs, cable reels, pole-line hardware, air-conditioning equipment, oil-storage tanks, stokers, agricultural-machinery parts, military shipping containers, and air-preheater heating elements.

Chapter 46

SILICON-STEEL ELECTRICAL SHEETS

Introductory—When an alternating electric current is passed through a wire coiled around an iron bar, a magnetic field is induced in the bar, or core as it is commonly called. This magnetic field will, in turn, induce an electric current in a second wire coiled around the same bar or core, but not connected to the first wire. During this process, some of the electrical energy is converted to heat which is wastefully dissipated. If the core is constructed of thin laminations insulated from each other, the amount of energy lost as heat will be considerably reduced because the stray magnetic fields that cause part of the energy loss cannot flow as freely in a laminated structure as they do in a solid bar. An additional, and far greater, reduction in energy loss can be obtained, however, by replacing the iron in the core with silicon steel. The relatively high permeability, high electrical resistance, and low hysteresis loss of the silicon steels, which contain $\frac{1}{2}$ per cent to 5 per cent silicon, account for the beneficial reduction in energy loss.

The silicon steels (first patented by Sir Robert Hadfield about 1900) have made possible the development of more efficient and more powerful electrical equipment and have played an important role in the rapid growth of the electrical power industry. It has been estimated that this industry uses approximately 750,000 tons of silicon steel sheets annually.

In this chapter, reference is made only to steels produced in sheet form for the magnetic cores of electrical equipment and containing up to approximately 5 per cent silicon, which is the upper limit for commercial materials. Such products are referred to in the industry as electrical sheets.

CLASSIFICATION AND USES OF ELECTRICAL SHEETS

Silicon-steel electrical sheets may be divided into two general classifications, (1) grain-oriented steels, and (2) non-oriented steels. The grain-oriented steels, containing about $3\frac{1}{4}$ per cent silicon, are used in the highest-efficiency distribution and power transformers and in large turbine-generators. The non-oriented steels may be further subdivided into three classes on the basis of composition and application.

1. **Low-silicon steels** containing about $\frac{1}{2}$ per cent to $1\frac{1}{2}$ per cent silicon. These steels are used principally in the rotors and stators of motors and generators. Steels containing about 1 per cent are also used for reactors, relays, and small intermittent-duty transformers.
2. **Intermediate-silicon steels** containing about $2\frac{1}{2}$ per cent to $3\frac{1}{2}$ per cent silicon. These steels are used in motors and generators of average to high efficiency and in small to medium-sized intermittent-duty transformers, reactors, and motors.
3. **High-silicon steels** containing about $3\frac{3}{4}$ per

cent to 5 per cent silicon. This class is used in power transformers and the highest-efficiency motors, generators, and radio-transformers, and in other communications equipment.

There are a number of grades of electrical sheets in each of the above classifications. Specifically, there are three grain-oriented grades, typified by USS Transformer 80, 73, and 66, and eight non-oriented grades, USS Armature, USS Electrical (low-silicon), USS Motor, USS Dynamo (intermediate-silicon), USS Transformer 72, 65, 58, and 52 (high-silicon). The sheets are "graded" on the basis of a maximum specified core loss * at an induction of either 10 or 15 kilogausses. Specified maximum values for the grain-oriented grades have been established only at 15 kilogausses. Core loss values are expressed as watts per pound at 60 cycles and vary for each grade and thickness as shown in Table 46—I. It can be seen that the core loss of the non-oriented grades decreases (improves) as silicon content increases and thickness decreases.

PROCESSING OF ELECTRICAL SHEETS

Grain-Oriented—These grades are made from open hearth steel containing about $3\frac{1}{4}$ per cent silicon. The selection of the charge for the heats, and the melting and refining are under very close controls to insure the cleanest and purest steel possible. Otherwise, the furnace practice is similar to that used for other low-carbon steels. The alloying addition of silicon in the form of ferrosilicon is made to the steel in the ladle. Pouring practices are much like those used for other fully-killed steels and the ingots are rolled to slabs by common practices.

The slabs are next hot rolled and coiled in continuous hot strip mills. After rolling, the coils are pickled in continuous, single-strand picklers to remove the surface oxides formed during hot rolling. Subsequent steps in the processing may vary somewhat among the various manufacturers, but generally they consist of two cold reductions, each followed by a suitable continuous anneal, and a final high-temperature box anneal. The steel may be used directly from the coil after box annealing for wound-core distribution transformers in spite of slight curvature ("coil-set") caused by annealing in coil form. If the steel is to be used for laminations in power transformers or turbine-generators, where even this slight curvature is undesirable, the coil-set must be removed by continuous annealing.

Non-Oriented—Two general processing methods are used in the production of non-oriented electrical sheets. The older method consists of hot rolling the sheets on hand mills; it is being supplanted by the newer continuous cold-reduction method. The inherent brittleness

*Definitions for core loss and other magnetic terms are given at the end of this chapter.

of silicon steel at room temperature, however, normally limits the grades that can be cold reduced to those containing less than 3½ per cent silicon. Thus, it appears that production of high-silicon sheets in the hand mills will be continued until such an operation becomes uneconomical, or these grades can be made by the cold-reduction method.

The same grades of steel, with the exception noted above and also with some minor adjustments in composition, are used in both the hot-rolling and the cold-reduction methods. The practices for steelmaking, pouring, slabbing and rolling on a hot-strip mill are practically the same for both methods and are similar to those previously described for the grain-oriented grades. Beyond the hot-strip-mill rolling stage, however, the hot-rolling method and the cold-reduction method differ materially.

Hot-rolled strip coils intended for processing into sheets by the hot-rolling method are uncoiled and sheared into suitable lengths. The sheared pieces are doubled, reheated, and hot rolled in packs on hand-mills to a predetermined length. The length is such that the thickness of the individual sheets comprising the pack is reduced to the ordered thickness during the hot-rolling. After rolling, the packs are sheared to the ordered length and width and the sheets in the packs are separated from each other. Subsequent processing of

the sheets may vary somewhat, depending on the magnetic quality desired, but generally the treatments will include pickling, cold-rolling to flatten (no substantial reduction in thickness), and box annealing at a suitable temperature to develop the required magnetic properties.

The hot-rolled coils that are to be processed by the cold-reduction method are pickled (continuous) and then cold-reduced to the ordered thickness. The cold-reduction operation is accomplished in tandem mills or in single-stand reversing mills. The processing subsequent to cold-reduction includes suitable continuous-annealing and box-annealing treatments to develop the required magnetic properties. If the steel has been box-annealed in the form of coils, it is usually "thermally flattened" by continuous annealing.

The processing of grain-oriented and non-oriented electrical sheets described above may be followed by core plating if this is desired by the customer. The core plating operation is discussed in the following paragraphs.

CORE PLATING

The cores of transformers and other electrical structures are constructed of laminations to restrict the flow of eddy currents and thereby reduce this component of the core loss. For this to be successful, however, it is

necessary that each lamination be insulated from the others so that the eddy currents will not flow readily from one lamination to another. The normal surface oxide on fully-annealed silicon-steel sheets provides a certain amount of this necessary insulation or inter-lamination resistance, but in many cases it must be supplemented. The additional insulation is supplied by coating the sheets or laminations with a thin coating of varnish or core plate, which has good electrical resistance and which is capable of maintaining this resistance under normal operating conditions of temperature and pressure. When used in oil-immersed transformer cores, the core plate must not react with the oil because the products of this reaction would interfere with the circulation of the oil and thus cause excessive heating of the transformer.

There are two main types of core plate in common use, organic and inorganic, although there are many different classes of these two types. The usual method of applying either type is to pass the sheets or laminations through rolls coated with the core plate, and then through a combination flashing and baking oven. The thickness of the coating must be controlled, since the heavier the coating the greater will be the insulating properties. The coating cannot be too thick, however, because this will in effect reduce the amount of steel in a core of a specific height. Baking temperatures differ, depending on the composition and type of coating used. In general, the organic varnishes require more care in baking, since it is essential to volatilize off most of the vehicle and thus obtain a coating free from tackiness. Under-baking results in a soft, tacky coating which will not have satisfactory insulating properties at the pressure present in the core after assembling. Care also must be taken to prevent over-baking because the varnish will become carbonized and the insulation characteristics of the coating will be thereby impaired.

The inorganic type core plates are relatively free of volatile oils and organic matter and therefore require less exacting baking conditions. One of the requisites of an inorganic core plate is that it must be capable of withstanding annealing temperatures up to about 1500° F. Transformer manufacturers specify this type of core plate when they anneal the laminations before assembling the core.

FACTORS AFFECTING MAGNETIC PROPERTIES

Among the many factors that affect the magnetic properties of silicon-steel electrical sheets, the most important are (1) composition, (2) internal stress, and (3) grain orientation.

Composition—Electrical sheets composed of pure silicon ferrite, if obtainable, would be superior to the best commercial grades of silicon steel manufactured today. Practically all elements other than silicon and aluminum, when added to iron, adversely affect the magnetic properties desired in these "soft" magnetic materials. The absolute influence of each element is masked by the effects of other elements, but it is generally agreed that carbon is the most detrimental, followed in order by sulphur, oxygen, and nitrogen. Manganese and phosphorus apparently have little or no effect on magnetic properties, at least in the quantities normally present in commercial silicon steels. Consideration must be given to the state or form in which the impurity is present, however, as this may greatly alter its effect on magnetic properties. For example, widely-dispersed, fine particles of an impurity are more harmful than an agglomeration of the same impurity into a few relatively large particles.

Internal Stress—Three of the more important mag-

netic properties, permeability, coercive force, and hysteresis loss, are adversely affected by internal stress. For that reason, every effort is made in the processing of electrical sheets to produce a stress-free product. There are two main sources of internal stresses, (1) impurities that cause dislocations in the crystal lattice, and (2) mechanical stresses introduced during the rolling operations that are not completely removed during subsequent annealing or that are introduced by cooling too rapidly from the annealing temperature. Precautions are taken throughout the processing to reduce impurities such as carbon, sulphur, nitrogen, and oxygen to the lowest possible level to avoid internal stresses from this source. Mechanical stresses are minimized by annealing at high temperatures to completely remove the stresses introduced during working and by cooling very slowly from the annealing temperature.

Grain Orientation—Most magnetic properties are markedly affected by crystal orientation. That is, such properties are better in one of the three principal crystallographic directions of the unit cubes* than they are in the other two directions. This directionality of magnetic properties is undesirable in many applications such as in rotating machinery, but it has definite advantages in other applications. The cores of distribution and power transformers can be wound or constructed from laminations cut from the sheets to take advantage of such directionality. Consequently, the manufacturers of grain-oriented electrical sheets strive to develop this characteristic to a high degree. The processing of grain-oriented sheets was described in an earlier section of this chapter.

FIG. 46-1. Effect of orientation on the magnetic properties of a crystal, showing relative ease with which the cubes comprising the iron-silicon space lattice can be magnetized in different directions.

*A discussion of crystallography is found in Chapter 2 of this book.

FIG. 46-2. (Left) Section of the ternary iron-silicon-carbon diagram at the 0.01 to 0.02 per cent carbon level; (right) same at the 0.05 to 0.08 per cent carbon level.

After completion of this processing, most of the grains are so arranged that edges of the unit cubes comprising each grain are aligned parallel to the rolling direction and face diagonals are aligned in the transverse direction. Because each cube is most easily magnetized along its edge, the [100] direction, the magnetic properties of grain-oriented sheets are best in the rolling direction. As shown in Figure 46-1, the face diagonal, [110] direction, of each cube is more difficult to magnetize than the cube edge, and the cube diagonal, [111] direction, is the most difficult to magnetize. The magnitude of these differences is also illustrated in Figure 46-1. Thus, the magnetic properties of grain-oriented sheets are best in the rolling direction, poorer at 90 degrees to the rolling direction, and poorest at 55 degrees.

Consumers of grain-oriented sheets take advantage of this directionality effect by constructing magnetic cores in such a manner that the main flux path is in the rolling direction. As examples of the extent of the directional effect, the core loss and permeability at 15 kilogausses in the rolling direction may be as much as $2\frac{1}{2}$ and 50 times better, respectively, than the same properties in the transverse direction.

EFFECTS OF SILICON ON IRON-CARBON ALLOYS

In addition to improving magnetic properties by decreasing eddy-current and hysteresis losses and by increasing permeability, silicon also has the following effects on metallographic, physical, and mechanical characteristics:

1. Alloys of iron and silicon form a metallographic gamma loop which is closed at a silicon content of about $2\frac{1}{4}$ per cent. In the complete absence of carbon, only alpha iron (or delta iron at high temperatures) is present in alloys containing more than $2\frac{1}{4}$ per cent silicon. The addition of even as little as 0.05 per cent carbon, however, causes some gamma iron (austenite) to be present up to at least 5 per cent silicon, as shown in Figure 46-2.

2. The magnetic transformation (A_s) is depressed about 9°C (16°F) for each per cent of silicon up to about 4 per cent silicon. At a silicon content of about 4 per cent, the magnetic transformation (A_s) occurs at approximately 730°C (1346°F).
3. Silicon increases the electrical resistivity of iron 11.4 microhms per cubic centimeter for each added per cent of silicon.
4. The addition of silicon to iron reduces the density of the resulting alloy.
5. The addition of silicon to a low-carbon steel decreases the tendency for the material to age (impairment of magnetic properties with increased time and temperature), provided other factors are normal and properly controlled.
6. Brittleness, or lack of ductility, increases as the percentage of silicon increases.

MECHANICAL PROPERTIES

Although no appreciable drawing operations are involved in fabricating articles from silicon-steel sheets, the material must have good punching and shearing qualities and must be reasonably flat so that motor, generator, and transformer laminations may be punched or sheared therefrom without difficulty. Typical mechanical properties of the various silicon-steel grades are listed in Table 46-II.

In general, as the silicon content increases, elongation, Erichsen ductility, and Amsler bend values decrease, and hardness, yield point, and tensile strength increase. In the transformer grades, however, differences in processing treatments may alter these trends to some extent.

DEFINITIONS OF TERMS AND METHODS OF TESTING

The practical value of electrical sheets is determined principally by their magnetic characteristics. The most

THE MAKING, SHAPING AND TREATING OF STEEL

important characteristics that are used to evaluate this product are defined as follows:

Magnetic Aging is defined as the deterioration of magnetic properties of a material with increased time and temperature. Thus, as a material ages magnetically, its core loss increases and its permeability decreases. The American Society for Testing Materials Standard Aging Test consists of measuring the magnetic properties of a sample before and after heating it to 100° C for 600 hours and then determining the change in properties.

Core Loss is defined as the energy expended in magnetizing a material with an alternating electric current. The core loss of a low-loss material such as grain-oriented steel is composed of hysteresis, eddy-current and residual losses. Only the hysteresis and eddy-current losses are present in higher-loss material.

Core loss is measured on 3 by 50 centimeter specimens assembled with butt joints, or on 3 by 28 centimeter specimens assembled with lap and butt joints in the standard Epstein testing apparatus. The resulting values are expressed as watts per pound at a given flux density (usually 10 or 15 kilogausses) at a frequency of 60 cycles per second.

Eddy-Current Loss is that portion of the core loss caused by the circulation of stray magnetic currents in the magnetic material. These stray or eddy currents are generated in the core by the oscillation of the magnetic field in phase with the alternating electric current in the coil surrounding the core.

Eddy-current loss can be calculated from Maxwell's equation, or it can be determined by "separating" core loss into its components by the graphical method.

Hysteresis Loss is the power expended in a magnetic material, as a result of magnetic hysteresis, when the magnetic induction is cyclic. Hysteresis loss is proportional to the area of the hysteresis loop and can be determined by measuring the area of a hysteresis loop plotted from data obtained in a permeameter.

Permeability is a measure of the ease with which the magnetic lines of force can pass through a substance magnetized with a given magnetizing force. Quantitatively, it is expressed as the ratio between the magnetic flux density (B) produced and the magnetizing force (H) producing this flux density. The Greek letter μ (mu) is used to designate this ratio. Thus,

$$\text{Permeability, } \mu = \frac{B}{H}$$

Alternating-current permeability is measured in the Epstein apparatus on 3 by 28 centimeter specimens assembled with lap and butt joints. Direct-current permeability is measured in a permeameter, such as the

Fahy Simplex Permeameter in which the specimen size is 3 by 25 centimeters or longer.

Magnetic Flux Density, or Induction is the number of lines of magnetic flux per unit area at right angles to the direction of the flux.

When a magnetic core having a closed magnetic circuit is magnetized by current flowing in the windings of the coil which enclose the core, magnetic lines of force are generated which are designated as magnetic flux. The total magnetic flux in the core, designated as ϕ (phi), divided by the cross-sectional area of the core in square centimeters, gives the flux density (B), in lines per square centimeter, or gauss.

Magnetomotive Force is defined as the force which tends to produce a magnetic field. This force, when generated by an electric current flowing through a coil of wire, is proportional to the current and to the number of turns of wire in the coil. The term is not commonly used except in defining magnetizing force.

Magnetizing Force is defined as the magnetomotive force per unit of core length and is designated by the letter H. When the length of the core is expressed in centimeters, the unit of magnetizing force is the oersted. Another unit of magnetizing force sometimes used is ampere turns per inch which is 2.02 times greater than an oersted.

Saturation is the maximum flux density that can be obtained in a magnetic material. Further increases in magnetic force over that necessary to achieve this saturation flux density will not cause the generation of any additional flux within the material. Saturation occurs at a flux density of about 21,500 gauss in low-silicon steels and about 19,500 gauss in high-silicon steels.

Interlamination Resistance is the term applied to the electrical resistance measured perpendicular to the lamination plane in a stack of laminations under pressure. It indicates the effectiveness of surface oxides or core-plate coatings on the laminations in reducing interlamination (eddy-current) losses. Interlamination resistance values are generally expressed as ohms per square centimeter per strip at a given pressure in psi.

Lamination Factor or Space Factor is the ratio of the volume of a stack of laminations under a given pressure to that of the solid material of the same mass, assuming a definite density based on the chemical composition. Thus, the factor indicates the deficiency of effective steel volume due to the surface roughness and lack of flatness of the laminations, or to the presence of oxides and core-plate coatings on the surface of the laminations. Space factor values are generally expressed as a percentage which is obtained by multiplying the volume ratio by 100.

Chapter 47

STAINLESS STEELS

General—As the name implies, stainless steels are more resistant to rusting and staining than are plain carbon and lower alloy steels. This superior corrosion resistance is brought about by addition of the element chromium to alloys of iron and carbon. Although other elements, such as copper, aluminum, and silicon, nickel and molybdenum, also increase the corrosion resistance of steel, they are limited in their usefulness, and the discussion in this chapter will be confined to the iron-chromium and iron-chromium-nickel steels in which chromium is the major element for conferring corrosion resistance.

The minimum amount of chromium necessary to confer this superior corrosion resistance depends upon the corroding agent. The American Iron and Steel Institute has chosen 4 per cent chromium as the dividing line between "alloy" steel and "stainless" steel and for this discussion, the AISI views will be adopted. The standard types of stainless steels listed by the AISI in Supplementary Information (dated April, 1955) to Section 24 of the "Steel Products Manual" are shown in Table 47—1. (The information in these manuals is revised from time to time.) Most of these types are available in the main product forms such as plates, bars, shapes, sheet, strip, and tubes. A detailed list of the products and sizes available for each type of stainless steel is given in the AISI Steel Products Manual.⁽¹⁾

As is true of all scientific developments, no single nation can claim credit for the stainless steels; Germany, England, and the United States shared alike in the development of these materials.

In 1912 Harry Brearley, head of the Brown-Firth Research Laboratory in England, while attempting to develop steels to resist the fouling and corrosion encountered in gun barrels, reported that a composition of 12.8 per cent chromium and 0.24 per cent carbon was quite resistant to corrosion. Brearley suggested that this composition be used for cutlery. In fact, our present cutlery steel, AISI Type 420 (12 to 14 per cent chromium, over 0.15 per cent carbon), is similar to the steel suggested by Brearley.

The development of the higher chromium-iron alloys was due to the work of F. M. Becket in the United States who, from 1903 on, was continuously attacking the problem of producing low-carbon ferrochromium from chromium ores. While investigating the effect of chromium on oxidation resistance at 2000° F (1095° C), Becket noted a marked increase in resistance as the chromium content was raised above 20 per cent. It is significant that even now and with steels containing appreciable quantities of nickel, 20 per cent seems to be the minimum amount of chromium necessary for oxidation resistance at 2000° F (1095° C).

The austenitic iron-chromium-nickel alloys were developed in Germany during the years 1909-1912 by Benno Strauss and Edward Maurer while searching for

materials for use in pyrometer tubes. Further work by Strauss and others ultimately led to the versatile 18 per cent chromium, 8 per cent nickel steels (popularly called 18-8) which are used so widely today.

CONSTITUTION

As mentioned above, the corrosion resistance or "stainlessness" of the stainless steels is primarily a function of their chromium content. Therefore, in order to understand the structures, heat treatments, and properties of the present commercial steels, a working knowledge of the iron-chromium, the iron-chromium-nickel, and iron-chromium-carbon diagrams is needed.

Iron-Chromium System—At the present time, the iron-chromium diagram is known only on a semi-quantitative basis. The diagram illustrated by Figure 47—1 is a compromise diagram based on the work of many investigators.^(2,3) The difficulties of establishing a precise equilibrium diagram are due primarily to two causes:

1. The difficulty of preparing pure alloys of iron and chromium (nitrogen and carbon seem to be the chief impurities).
2. The sluggishness of the iron-chromium alloys to respond to heat treatment.

The first difficulty is relatively unimportant because melting practices have improved and purer alloys may be expected. However, the second difficulty often may be overlooked and thus lead to false conclusions.

The high-temperature portion of the diagram is based on the data of Adcock reported in 1931.⁽⁴⁾ Adcock's data were accepted because of the high purity of his alloys and the techniques he employed.

The existence of the gamma loop was discovered in 1926 by Bain,⁽⁵⁾ who also showed the effect of higher carbon contents on enlarging the austenite field. The intermetallic compound, sigma phase, was discovered in 1927 by Bain and Griffiths.⁽⁶⁾

These two regions were extensively studied by other investigators and their data differed widely. This difference was especially marked for the sigma region. The most careful investigation, that of Adcock, who used the purest alloys of all, failed to detect the phase and Adcock came to the conclusion that the phase did not exist.

However, the evidence of other investigators was overwhelmingly in favor of the existence of sigma phase. In 1936, Jette and Foote,⁽⁷⁾ using alloys similar in purity to those of Adcock, were able to produce and identify sigma phase. Surprisingly enough, when they used treatments similar to those of Adcock, no sigma phase was formed. They concluded that Adcock's alloys were too pure and too well annealed for transformation to take place in the time allowed. Finally, the entire matter was conclusively settled in 1943 by Cook and Jones⁽⁸⁾ who, using Adcock's original alloys and longer transformation times, reported the sigma limit as shown. The boundary lines as shown by Cook and Jones are based

† Columbium is also called niobium.

FIG. 47—1. The iron-chromium equilibrium diagram. (Adapted from American Society for Metals Handbook, 1948 Edition.)

on X-ray data but may still be questioned because equilibrium may not have been attained and longer annealing times may widen the ferrite + sigma region. An excellent bibliography pertaining to more recent studies of sigma phase in stainless steels has been published by Smith.⁽⁴⁰⁾

The diagram itself shows that as the chromium content increases, the austenite region is decreased until, above 12.5 per cent chromium, austenite no longer exists. After normal heat treatment, alloys above this chromium content consist entirely of a single phase—alpha, but as shown, sigma phase is stable and will form after long times at temperatures as low as 900° F (480° C) and below the upper limit.

Very little is known quantitatively about the effect of impurities upon this diagram. Bain⁽⁴¹⁾ has reported on the effect of carbon on the austenite region. Andersen and Jette⁽⁴²⁾ reported that silicon increases the sigma region. Bain and Aborn⁽⁴³⁾ reported that nickel also increases the sigma region. Aluminum, molybdenum, ti-

tanium, and columbium (niobium) probably increase it.

Iron-Chromium-Nickel System—Like the iron-chromium system, the iron-chromium-nickel system is known only semi-quantitatively but the existing diagrams are useful for interpretation of what otherwise would be mysterious behavior. The investigation of this system also has been hampered by slow reaction rates.

The first investigation of the iron-chromium-nickel system was conducted in 1909-1912 by Strauss⁽⁴⁴⁾ who studied the iron-rich corner. He found that the alloy having 20 per cent chromium and 7 per cent nickel contained free carbide which could be dissolved at 2280° F (1250° C) and retained in solution at room temperature by rapid cooling. He also noted a grain boundary precipitation at 1290° F (700° C).

The first comprehensive study was the heretofore mentioned investigation of Bain and Griffiths.⁽⁴⁵⁾ These investigators were the first to report sigma phase and they noted that nickel raised the upper temperature limit of this phase.

FIG. 47—2. The iron-chromium-nickel diagram at constant chromium contents.⁽¹⁰⁾ The symbols "A" and "F" stand for austenite and ferrite, respectively.

FIG. 47—3. The iron-chromium-nickel diagram. Isothermal section at 1200° F.⁽¹¹⁾ α , γ and σ represent alpha (ferrite), gamma (austenite), and sigma phases, respectively.

FIG. 47-4. (Above) The iron-chromium-nickel diagram. Section at 8 per cent nickel.^{as} α , γ and σ represent alpha (ferrite), gamma (austenite), and sigma phases, respectively. L signifies liquid.

FIG. 47-5. (Below) The iron chromium-carbon diagram. Section at 0.10 per cent carbon.^{as} α , γ and σ represent alpha (ferrite), gamma (austenite), and sigma phases, respectively. $C_1 = (Fe, Cr)_C$, $C_2 = (Cr, Fe)_C$, $C_3 = (Cr, Fe)_C$.

Bain and Aborn⁹⁹ made a comprehensive review of the iron-chromium-nickel system, which is summarized in Figure 47-2.

The work of the British in this field has been very extensive. Figure 47-3 shows an isothermal section at 1202° F (650° C) based on the data of Rees, Burns and Cook.¹⁰¹

Figure 47-4 shows a diagram at constant nickel content.

Iron-Chromium-Carbon System—The most complete information on the iron-chromium-carbon system has been supplied by Tofaute and his co-workers.^{102, 103} Figure 47-5¹⁰³ shows a section through the iron-chromium-carbon diagram at 0.10 per cent carbon and, as may be seen, the diagram is quite complex. The three carbide phases shown in this diagram are:

1. (Fe, Cr)₃C—iron carbide (cementite) capable of dissolving up to 15 per cent chromium.
2. (Cr, Fe)₇C₃—chromium carbide capable of dissolving up to 50 per cent iron.
3. (Cr, Fe)₂₃C₆—chromium carbide capable of dissolving up to 25 per cent iron.

An excellent discussion of the various investigations which have been made on the iron-chromium-carbon alloys is given by Kinzel and Crafts.¹⁰⁴

MANUFACTURE AND FABRICATION

For the purpose of general discussion, the stainless steels are grouped into three classes:

1. **Martensitic**—Those iron-chromium alloys that lie within the gamma loop and thus are hardenable by heat treatment. Include Types 403, 410, 414, 416, 420, 431, 440A, 440B, 440C, 501 and 502.
2. **Ferritic**—Those iron-chromium alloys that are largely ferritic and not hardenable by heat treatment (ignoring the 885° F embrittlement). Include Types 405, 430, 430F and 446.
3. **Austenitic**—The iron-chromium-nickel alloys not hardenable by heat treatment and predominantly austenitic as commercially heat treated. Include Types 301, 302, 302B, 303, 304, 305, 308, 309, 310, 314, 316, 317, 321 and 347.

Melting—All of the stainless steels are melted in either the electric-arc or high-frequency induction furnace, the largest tonnages by far being melted in electric-arc furnaces. A description of arc-furnace melting practice is contained in earlier chapters.

Hot Working—General—Before discussing the details of any particular process used for the production of stainless steel, a few general remarks will be made concerning the hot- and cold-working characteristics of these materials. These general remarks, describing the salient differences in behavior between the carbon steels and the stainless steels, will apply to any hot- or cold-working operation to which the stainless steels may be subjected.

Unlike the performance characteristic of carbon steels, ruptures in the stainless steels do not "heal" easily, if at all, and more conditioning is necessary; in fact, after many of the hot-working operations, the surfaces of the resultant product are completely conditioned. All of the stainless steels have lower thermal conductivity than the carbon and low-alloy steels and, accordingly, precautions must be taken when heating, or surface burning will result. Also, for most of the stainless grades, the temperature ranges for optimum hot-working char-

acteristics are narrower than those for the carbon steels and, hence, closer temperature control is necessary when hot working the stainless steels.

For all grades of stainless steel, optimum hot workability is obtained when the structure of the steel at the hot-working temperature consists essentially of a single phase. Small amounts of ferrite in the structure of the austenitic and martensitic steels and small amounts of austenite in the structure of the ferritic steels can be tolerated, but must be kept within proper limits either by proper adjustment of the chemical composition of the steel or by adjustment of the hot-working temperature.

The martensitic stainless steels can be forged, pierced and rolled. However, because these steels are air hardening, they must be annealed after rolling before any subsequent operation such as conditioning or cold working. Their "as-rolled" hardness also makes for brittleness which must be taken into account when handling the hot-rolled product.

The ferritic stainless steels also can be forged, pierced and rolled. These steels are very soft when hot, thus they are easily marked by guides or rolls, and spread considerably during hot rolling. Over-heating these grades causes excessive grain growth, which makes the material susceptible to tears and cracks. Additions of nitrogen have helped somewhat in preventing grain growth. To refine the grain size, finishing temperatures are kept as low as possible. Annealing is necessary for those steels which are susceptible to the 885° F (475° C) embrittlement.

The austenitic stainless steels are generally stronger than ferritic steels at rolling temperature and, consequently, require more power for deformation. Like the ferritic steels, the austenitic steels are susceptible to grain growth and overheating should be avoided. Low finishing temperatures are not practicable because of the power required. During the heating of these nickel-bearing austenitic steels, special precautions are taken to keep the sulphur content of the furnace or soaking pit atmospheres at a minimum because these steels, after being heated in atmospheres containing sulphur, tend to tear and crack during rolling. Apparently, the sulphur in the atmosphere combines with the nickel in the steel to form nickel sulphide. This reaction usually occurs at the grain boundaries of the metal and, because the nickel sulphide is liquid at the rolling temperatures, the steels so attacked are weak and easily break apart during rolling. The steels which are completely austenitic after cooling from the rolling temperature to room temperature can be rolled without difficulty. The usual precautions, such as slow heating, must be observed. On the other hand, those steels such as 18-8 Mo (Type 316), 18-8 Cb (Type 347), 18-8 Ti (Type 321), and 25-12 (Type 309), show poor hot-working characteristics which are blamed on the presence of delta ferrite. The explanation for the poor working characteristics is that the difference in plasticity between the soft ferrite and the tough austenite causes ruptures.

Table 47-II lists the forging and annealing temperature ranges commonly used for the standard stainless steels, based on the 1950 AISI Steel Products Manual.

Cold Working—General—With the exception of the high-carbon hardenable steels, all of the stainless steels can be cold worked. However, certain precautions must be taken.

The ferritic stainless steels, especially those containing over 20 per cent chromium, are extremely notch sensitive at room temperature and care must be taken to avoid notches, otherwise considerable breakage will result. However, between 400° F (205° C) and 600° F

Table 47—II. Forging and Annealing Temperatures for Stainless Steels* From AISI Steel Products Manual, Section 24 (1950).

Type of Steel	Initial Forging Temperature Range (° F)	Annealing Temperature Range (° F)	Rate of Cool from Annealing Temperature

*Preheating time about twice that required for carbon steel.

(315° C) the steels are tough, and difficult cold-working operations are successfully accomplished by working the material in this temperature range.

Cold work causes some austenitic stainless steels to transform partially to a low-carbon martensite. This transformation, plus the effect of the strain hardening caused by the cold work itself, causes such austenitic steels to have a high rate of work hardening. More power is required to work these steels. Figure 47—6 shows flow

diagrams illustrating the various steps involved in the manufacture of stainless-steel products.

The Rolling of Stainless-Steel Ingots to Blooms and Slabs—The equipment used for the heating and rolling of stainless-steel ingots is the same as that used for carbon-steel ingots. However, as previously mentioned, close temperature control and avoidance of sulphur contamination are precautions which should be followed when heating the stainless steels. Also, the stainless steels require more conditioning than the carbon steels. The bloom and slab products are completely conditioned.

Rolling of Billets—The blooms used for the production of billets are also completely conditioned prior to heating for rolling. As was true for the rolling of ingots, the rolling of stainless-steel blooms to billets is performed on the same equipment used for carbon steels and the usual precautions of close temperature control and avoidance of sulphur contamination are taken.

After rolling, the air-hardenable martensitic grades must be cooled slowly in order to soften the material. This practice prevents thermal cracking during subsequent conditioning.

Rolling of Stainless-Steel Plates—The equipment used for the heating and rolling of stainless-steel plates is the same as that used for the heating and rolling of carbon-steel plates. However, because the austenitic stainless steels are very stiff at elevated temperatures, they require more power for rolling. Consequently, the amount of reduction per pass is smaller for the austenitic grades. Also, these steels spread less than do the ordinary steels and due allowances are made for this lack of spread in order that the resulting plate widths will satisfy dimensional requirements.

After rolling, the stainless-steel plates are annealed and pickled. As might be expected, the annealing temperatures employed depend upon the composition of the material, and the specific annealing temperatures used for the standard AISI grades are listed in Table 47—II. The pickling procedure used for stainless steel varies from plant to plant. One installation consists of a 10 per cent sulphuric acid bath operated at 140° to 160° F (60° to 70° C) and a 10 per cent nitric acid, 4 per cent hydrofluoric acid bath operated at 130° to 150° F (50° to 70° C). The first bath softens and loosens the scale but will not remove it completely; the second solution will remove the scale loosened by the first solution.

Most recent of the developments in the pickling of stainless steels is the use of molten salts consisting of sodium hydroxide to which is added some agent such as sodium hydride. These molten-salt descaling processes are rapid and efficient and have replaced many acid pickling installations.

After annealing and pickling, the stainless plates have what is called a No. 1 (hot-rolled, annealed, and pickled) finish and, in this condition, the plates are sheared to size, and are then suitable for shipment.

Rolling of Stainless-Steel Bars—The billets used for the rolling of stainless-steel bars are conditioned as the surface requires it. Martensitic steels must not exceed 275 Brinell hardness prior to conditioning, and if this hardness is exceeded, the billet must be annealed before swing grinding in order to prevent thermal cracking which might occur during the grinding operation or during heating for rolling. Prior to heating for rolling, the ends of the billets are pointed by a scarfing torch to prevent the splitting of the ends of the bar and also to decrease slippage when entering the mill.

During the rolling of the ferritic grades, spread control is important and is accomplished by providing a billet size slightly less in cross-section than that which

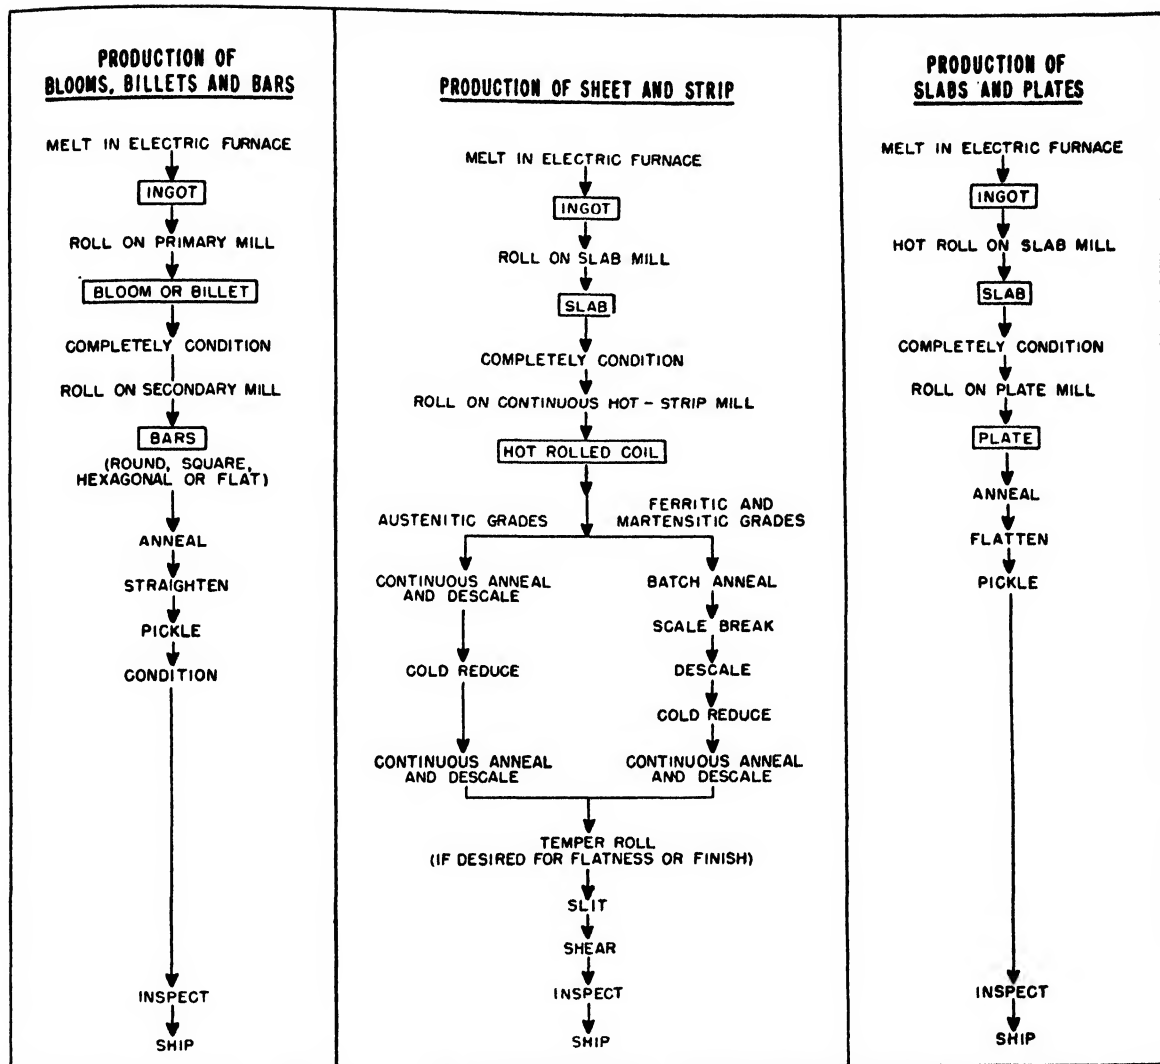

FIG. 47—6. Flow sheets indicating general principal steps in the production of stainless-steel products.

would be used for carbon or alloy steels. This smaller size permits lighter initial drafting.

On delivery from the rolling mill, the austenitic and ferritic stainless-steel bars are rapidly (air) cooled, while cooling of the martensitic stainless-steel bars is deliberately retarded. Sections of the latter two inches and over are cooled slowly in covered pits, while those under two inches have cooling retarded by packing on the hot bed.

After annealing and pickling, stainless-steel bars are straightened on standard equipment and may be shipped in this condition or finished by centerless grinding or cold drawing.

Rolling of Stainless-Steel Sheet and Strip—In this section, the discussion of the rolling of stainless-steel sheet and strip will be confined to the continuous method by which the largest tonnage of stainless steels is produced. However, recognition should be given to hand-mill methods which, although being gradually replaced by the continuous method, find importance for the production of those grades of stainless steel that are difficult to roll and also for the production of small lots not conveniently produced by the continuous method.

Figure 47—6 presents a flow chart indicating typical steps in the processing of stainless-steel sheet and strip.

The slab or billet used for the production of stainless-steel sheet or strip is completely conditioned, although some progress is being made toward the practice of conditioning only those areas containing defects ("spot conditioning"). As is true for the other products, stainless-steel sheet and strip is rolled on the same equipment as that used for carbon-steel sheet and strip.

After rolling and annealing, all of the stainless steels are descaled, usually by pickling in acids. For the plain-chromium grades of stainless steel containing up to 18 per cent chromium, the hot-rolled sheet or strip, in coil form, is batch annealed at sub-critical temperatures. On the other hand, the plain-chromium grades containing over 18 per cent chromium, and the austenitic grades, are annealed on a continuous unit and quenched from the annealing temperature. Often, for the austenitic steels, this annealing is performed in an oxidizing atmosphere which, by producing a heavy scale, "burns off" the defects and thus reduces the amount of conditioning necessary at some later stage. The quenching practice used depends upon the thickness of the material. For

FIG. 47-7. Stainless-steel strip entering a continuous pickling line.

thick materials, high-pressure water sprays are used, but for thin materials, cooling in still air is sufficient. All of the stainless steels are descaled on continuous units, usually arranged in tandem with a continuous annealing unit.

A typical continuous descaling or pickling installation (see Figure 47-7) consists of two 35-foot long tanks containing approximately 15 per cent hydrochloric acid (HCl) at 160°F followed by a tank of similar size containing about 4 per cent hydrofluoric acid (HF) and 10 per cent nitric acid (HNO_3) at 150°F to 170°F . In some installations, electrolytic-pickling facilities using either cold sulphuric acid (H_2SO_4) or nitric acid (HNO_3) are substituted for the first two tanks.

Molten-salt descaling processes are now being used commercially. Normally a light acid pickle, usually hot nitric acid, follows the descaling treatment. These processes provide scale removal on all grades of stainless steel without metal loss and result in a smoother surface than is obtainable from acid pickling. The method requires more heat input than pickling, and care must be taken to prevent the introduction of any water.

After annealing and pickling, the material is inspected and the defects removed by grinding or by reannealing and repickling. At this stage, the material has what is known as a No. 1 or a hot-rolled, annealed and pickled finish and, after shearing to the required lengths and widths, may be shipped as hot-rolled, annealed and pickled sheets. However, in order to obtain lighter gages and improvements in surface, grain size and mechanical properties, the material is cold rolled in coil form.

Usually, the cold rolling of stainless-steel sheet and strip is performed on a reversing mill, although a tandem mill may be used. Depending upon the final thickness desired, an intermediate anneal may or may not be used. This intermediate anneal and pickle, as well as the final anneal and pickle, is performed on a continuous unit (see Figures 47-8 and 47-9).

After annealing and pickling, the surface of the cold-rolled material has what is called a No. 2-D (dull, cold-rolled) finish for sheet or a No. 1 cold-rolled finish for strip. In this condition, the material either may be sheared to desired lengths and shipped, or may remain

FIG. 47-8. General view of stainless-steel strip annealing and pickling lines.

FIG. 47-9. Close-up view of stainless-steel strip emerging from one of the continuous furnaces shown in Figure 47-8.

in coil form and be subjected to further processing. If a brighter finish is desired, the material is rolled on a temper mill; the finish resulting from this process is called a No. 2-B (bright, cold-rolled) finish for sheet or a No. 2 cold-rolled finish for strip. Higher finishes are obtained by mechanical polishing. Flattening, or leveling, is accomplished on standard units used for this purpose.

Of special interest is the work-hardening characteristic of the austenitic stainless steels which permits these grades to be produced to tensile strengths as high as 200,000 pounds per square inch. The composition best suited for the production of these high strengths is AISI Type 301 (17 per cent chromium, 7 per cent nickel). Usually, this grade is supplied to four standard minimum tensile strength levels of 125,000, 150,000, 175,000 and 185,000 pounds per square inch. Materials having these respective tensile strengths are designated commercially as having $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and full-hard temper. The amount of cold reduction necessary to produce these strengths depends upon the composition of the material. Generally, 10 per cent cold reduction is needed for producing $\frac{1}{4}$ hard, 22 per cent for $\frac{1}{2}$ hard, 32 per cent for $\frac{3}{4}$ hard, and 37 per cent for full-hard material.

HEAT TREATMENT

Heat Treatment of Iron-Chromium Stainless Steels—Knowing the phase diagrams of the stainless steels, an understanding of the philosophy of the commercial heat treatments employed for the various grades becomes possible.

From 5 per cent chromium to 12 per cent chromium, using 0.15 per cent carbon as a base, the steels are hardenable by the austenite-to-martensite transformation. As would be expected from the high chromium contents, the hardenability of these steels is good and increases with increasing chromium and carbon.

However, most of the applications for the 5 to 9 per cent chromium steels require the metal to be in the most ductile condition, and the "softening" practice employed consists of normalizing and tempering or one

of the various annealing cycles. Ductility is required because these steels, before they are placed into service, are subjected to various cold-fabrication practices. Because these steels are air hardening, welding must be performed with the necessary precautions such as preheating and post-heating. Often in field welding, these precautions cannot be taken and, when this situation is anticipated, stabilization with titanium or columbium (niobium) may be employed. Titanium and columbium form stable carbides and the material behaves like a low-carbon stainless steel and has lower hardness than material without stabilizing elements. Improvements in melting practices have led to the development of extremely-low-carbon grades which, theoretically, should not harden after welding.

Depending upon the intended application, the 12 per cent chromium steels are used in the fully-hardened and tempered as well as the annealed condition. These materials may be either air-cooled or oil-quenched from the hardening temperature. Oil quenching produces slightly higher hardnesses but air cooling is employed in order to minimize the danger of cracking or warping. Figure 47-10 shows the effect of tempering temperature on the hardness and tensile properties of hardened Type 410 (12 per cent chromium, 0.10 per cent carbon). The impact strength decreases in the temperature range 750° to 950° F; also maximum corrosion resistance is not obtained in the range 1000° to 1200° F, hence, the range 750° to 1200° F is to be avoided. Heating this type of steel below 750° F is commonly called "stress relieving" while heating above 1200° F is called "tempering." Annealing is usually accomplished by heating above the lower critical temperature and slow cooling, but also may be accomplished by sub-critical annealing. As is true for the lower chromium steels, the 12 per cent chromium steels must be welded with caution because of air-hardening. Unlike the lower chromium steels, the hardenability of the 12 per cent chromium steels is lowered by small additions of aluminum. These small amounts of aluminum (0.3 per cent) are sufficient to minimize austenite formation and make the steel

FIG. 47-10. The effect of tempering for one hour on the hardness and tensile properties of hardened Type 410 (12% Cr-0.10% C) stainless steel.

ferritic at all temperatures so that no phase transformation, and consequently no hardening, occurs.

The higher chromium steels (17 per cent chromium, high carbon excepted) are completely ferritic. Annealing would then seem to be a simple process of heating at a recommended temperature for a reasonable time and slow cooling. However, two difficulties arise. First, the alloys are single phase except for carbide, hence, no grain refinement by a phase transformation is possible. A large grain size once formed by improper heating procedure will be retained on cooling to room temperature. Only by cold work and recrystallization can the grain size be reduced. The fact that the high-chromium steels are inherently notch sensitive makes the effect

of grain coarsening even worse. Additions of nitrogen have been used to obtain a finer grain size. The nitrogen forms small pools of austenite which inhibit grain growth.

The second difficulty is that embrittlement occurs when the steels are heated in or slowly cooled through the temperature range of 800° to 1400° F. The embrittlement, which is actually an age-hardening phenomenon, is caused by the precipitation of a body-centered cubic phase of iron and chromium containing 70 to 80 per cent chromium.⁽⁵⁰⁾

Keeping in mind grain growth and embrittlement, the high-chromium steels are annealed by heating in the temperature range 1400° to 1700° F and cooling rapidly.

FIG. 47-11. The effect of carbon on the constitution of stainless steels containing 18 per cent chromium and 8 per cent nickel.⁽¹⁰⁾

Iron-Chromium-Nickel Stainless Steels—The austenitic stainless steels also are considered to be single phase although this belief is erroneous for two reasons.

First, in ordinary 18-8, austenite is not thermodynamically stable at room temperature. By the means of plastic deformation at or below room temperature, meta-stable austenite can be transformed, at least partially, to martensite. Furthermore, additions of aluminum and titanium in sufficient quantities cause the 18-8 steel to transform to a low-carbon martensite without benefit of cold work. This effect has been used advantageously in developing Stainless W, an age-hardening ferritic 17 per cent chromium, 7 per cent nickel steel.⁽¹⁴⁾

Second, the carbide phase, unfortunately, cannot be ignored. In Figure 47-11⁽¹⁰⁾ it will be noted that the carbide solubility changes abruptly with temperature. Therefore, during slow cooling a carbide precipitation occurs and these carbides, rich in chromium, precipitate at the grain boundaries. At the temperature where the precipitation occurs, chromium diffusion from the matrix is not rapid enough to replenish the chromium taken out of the immediate vicinity of the carbide and, consequently, this region is low in chromium. Because chromium is the element largely responsible for the excellent corrosion resistance, the region adjacent to the carbide becomes lower in corrosion resistance and the material is susceptible to intergranular corrosion.

The austenitic steels are, therefore, heat treated by an anneal at a temperature high enough to effect carbide solution but low enough to minimize grain growth, and then cooled to room temperature rapidly enough to keep the carbides in solution.

Such a treatment is not always possible, especially where these steels are welded in the field, and modifications of the austenitic grades have been developed. These modified steels contain titanium or columbium (niobium) which combine with the carbon and eliminate intergranular carbide precipitation and susceptibility to intergranular corrosion. Titanium in amounts of five times the carbon and columbium in amounts of ten times the carbon are considered to be sufficient, although the actual amounts necessarily depend upon the grain size and composition (other than carbon content) of the material (see also "Intergranular Corrosion").

The relationship of these variables to the amount of titanium required has been quantitatively evaluated, and a suitable formula developed.⁽¹⁴⁾

The titanium or columbium grades are sometimes given a stabilizing treatment at 1600° F to insure complete chemical combination of carbon with titanium or columbium.

CORROSION RESISTANCE

As was mentioned previously, the corrosion resistance of the stainless steels generally increases with increasing chromium content. There has been some speculation as to why chromium should impart stainlessness to steel. The popular concept is that when sufficient chromium is present, a thin, tight, chromium oxide is formed on the surface and this oxide prevents any further oxidation or corrosion. Environments which are oxidizing in nature strengthen this film while reducing environments tend to break down the film and cause the steel to corrode.

This theory of passivation by an oxide film now has considerable experimental support. Films were first stripped by Evans⁽¹⁷⁾ and his co-workers. More recently, Rhodin⁽¹⁸⁾ and his associates have isolated films to determine their structure and chemical composition. Rhodin's results show the films to be "jell-like" substances having no well-defined crystalline structure. A chemical composition corresponding to the approximate formula is:

where:

$$12\text{M} = 7 \text{ Fe} + 2 \text{ Ni} + 3 \text{ Cr}, n \text{ is approximately } 9.$$

Voluminous data have been published on the corrosion resistance of specific grades of stainless steel in specific environments. The data in the literature represent both controlled laboratory tests and actual service records. To discuss these corrosion data, the subject of corrosion is divided into four separate parts: atmospheric, elevated-temperature, intergranular, and pitting corrosion.

Atmospheric Corrosion—The most common type of corrosion encountered in steel is ordinary rusting. Recent investigations of the atmospheric corrosion of stainless steels have disclosed that ferritic steels above 12 per cent chromium are partially resistant, and above 18 per cent chromium are fully resistant to rusting.

Fig. 47-12. The influence of chromium on the atmospheric corrosion of low-carbon steel.⁽¹⁰⁾

Figure 47-12⁽¹⁰⁾ shows graphically the effect of chromium content on the atmospheric corrosion of stainless steels. Noteworthy are the breaks in the curve at 3 per cent and 12 per cent chromium. Some variations from this behavior may be expected in different atmospheres and when the metal is in different conditions of heat treatment.

The austenitic steels also are very resistant to atmospheric corrosion. The results of a series of tests lasting over several years were reported in the 1946 Symposium sponsored by the American Society for Testing Materials. These results indicated that installations of 18-8 should be cleaned periodically especially in marine atmospheres where salt deposits might cause pitting. Of course, if the installation is fully exposed to the atmosphere, automatic cleaning occurs during rainfall, but installations which are fully or partially sheltered may be subject to pitting. An 18-8 stainless steel containing molybdenum was shown to have the best resistance to all conditions of corrosion.

The effect of surface was also studied and it was reported that the smoother the surface, the better the corrosion resistance.

The amount of work which has been done on the corrosion of stainless steels in various reagents is voluminous but, unfortunately, the data never have been properly organized. The effect of chromium on the resistance of steel to corrosion by these various reagents is similar to its effect on the resistance to atmospheric corrosion, although nickel and molybdenum enhance the resistance to corrosion by certain chemicals.

Elevated-Temperature Corrosion—Corrosion at elevated temperatures is usually one of three types: oxidation, carburization, and sulphidation.

As was true for atmospheric corrosion, the resistance of the stainless steels to oxidation is primarily a function of the chromium content. This effect of chromium on oxidation resistance is discussed in Chapter 48, entitled "Steels for Elevated-Temperature Service."

The chromium content also determines the rate of carburization. In general, ferritic steels are more resistant to carburization than austenitic steels. Addition of 2 per cent silicon improves resistance of 18-8 and 25-20 to carburization, but the effect of titanium, columbium (niobium) and molybdenum is negligible.

Usually, carburization rates are not appreciable below

1500° F in steels containing 18 per cent or more chromium. However, under special conditions, especially cyclic oxidation and carburization, 18-8 has been known to carburize at 1400° F.

The austenitic stainless steels, because of their nickel content, are susceptible to attack by reducing sulphurous gases, notably hydrogen sulphide. The ferritic stainless steels are more resistant.

Oxidizing sulphurous gases slightly increase the corrosion of the austenitic and the ferritic stainless steels.

These three types of elevated-temperature attack are very important but too often neglected when recommending materials. In many installations, elevated-temperature corrosion by oxygen, carbon, or sulphur causes more failures than stresses. Consequently, many of the steels such as 18-8, although possessing adequate strength, will not meet service requirements because of excessive oxidizing, carburizing or sulphidizing conditions.

Intergranular Corrosion—Bain, Aborn, and Rutherford⁽¹¹⁾ have ascribed intergranular corrosion to chromium impoverishment at the grain boundaries, caused by the grain boundary precipitation of chromium-rich carbides. There are two possible remedies for this difficulty. First, the carbon may be immunized, either by precipitating the carbide at a temperature where chromium diffusion will be rapid enough to restore passivity to the grain-boundary area, or by forming a stable carbide of some element other than chromium. Second, the steel may be made with less than 0.03 per cent carbon.

Probably the first method to be used commercially was that of forming a stable carbide of some element other than chromium. Bain, Rutherford and Aborn suggested the addition of titanium in amounts of four to five times the carbon content. By heating the titanium-bearing 18-8 at 1600° F, they obtained the complete fixing of carbon by titanium to form titanium carbide, and the steel was said to be stabilized. Concurrent with this development, the Union Carbide and Carbon Corporation developed a columbium-bearing (niobium-bearing) steel having a columbium content of eight times the carbon content. The columbium, like titanium, formed a stable carbide and thus prevented the formation of chromium carbide at elevated temperatures.

During World War II, United States Steel Corporation developed a method for producing 18-8 and 18-8 containing molybdenum, both containing 0.03 per cent maximum carbon. These "new" steels are more resistant to carbide precipitation and the resultant susceptibility to intergranular corrosion than regular grades of these steels, because of their lower carbon contents. These new grades, designated as Types 304L and 316L have been accepted commercially as replacements for the columbium- and titanium-bearing grades for service at temperatures below about 800° F.

Pitting Corrosion—Pitting usually occurs during continuous exposure to relatively-weak corroding media, such as chlorides, to which the steels are otherwise substantially resistant. Very little is known about the cause of this type of corrosion except that it probably occurs in certain vulnerable spots where the passivity is continuously destroyed. Pitting manifests itself by small holes distributed at random over the surface of the steel, or it may develop at points where the steel is in contact with other materials, such as leather, glass, and grease. The formation of an electrolytic cell may be the cause. The mechanism probably involves a lack of oxygen on the surface of the metal that is corroded.

Pitting may be inhibited somewhat by treating the environments with some strong oxidizing agents such

as some chromates or phosphates. Molybdenum additions to 18-8 also inhibit pitting.

MECHANICAL PROPERTIES

Low-Temperature Properties—At extremely low temperatures, the ferritic and martensitic steels are quite brittle, having impact strengths on the order of one foot pound. However, the austenitic stainless steels have impact strengths above 15 foot pounds at minus 320° F and are the best materials for use at the extremely low temperatures.

Room-Temperature Properties—The range of room-temperature mechanical properties of each grade of stainless steel is given in the AISI Steel Products Manual.⁽¹⁾ Table 47—III shows typical properties of Type 301 (18-8), Type 410 (12 per cent chromium), and Type 430 (17 per cent chromium).

As was mentioned, the martensitic grades are hardenable, and by proper selection of composition and heat treatment, their tensile properties can be made similar to those of the low-alloy steels. Ductility values and impact strengths are somewhat inferior to those of the low-alloy steels.

The ferritic grades cannot be hardened to any extent by heat treatment, although the 885° F embrittlement involves hardening. Table 47—III shows typical properties of 17 per cent chromium, Type 430. These steels are extremely notch sensitive. The notch sensitivity, or rather the transition temperature from brittle to ductile behavior, increases with chromium content, the 27 per cent chromium steel having a Charpy impact strength of only two foot pounds at room temperature. This notch sensitivity is undesirable, and when fabricating these steels, special precautions must be taken. Because of the notch sensitivity, aggravated by large grain size and 885° F embrittlement, both of which may result from welding, the ferritic steels have not found as wide usage at room temperatures as have the austenitic steels. However, the ferritic steels have as good corrosion resistance as the austenitic steels, and, if it were not for the disadvantage in ductility, they would be used almost as much as the more expensive austenitic steels.

The austenitic steels are not hardenable by heat treatment but they can be hardened by cold work which for some grades transforms the austenite (metastable at room temperature) to a low-carbon martensite. This transformation hardening by cold work is additive to the

strain hardening and the result is that an extremely wide range of tensile properties may be produced. As an example, Table 47—III shows typical properties of Type 301 (17-7). As would be expected, the degree of hardening obtained by cold work is a function of the composition, and extensive investigations have been made on the effect of various elements on the work hardenability of 17-7.^(1a)

The disadvantage of the austenitic stainless steels is that the work hardening is confined to those shapes which can be rolled (cold worked). For example, an article such as a valve cannot be hardened economically by cold working. This disadvantage was overcome by the development of an age-hardening stainless steel designated as Stainless W.^(1a)

Stainless W is essentially a 17 per cent chromium, 7 per cent nickel steel containing titanium and aluminum. As would be expected, this is an "unbalanced" composition. At high temperature, its structure consists of austenite and delta ferrite. On cooling, the austenite transforms at about 200° F (93° C) to low-carbon martensite, so that the room-temperature structure of this alloy consists of martensite plus delta ferrite and some retained austenite. The age hardening occurs in the martensite and in the ferrite but not in the austenite. Aging is accomplished by heating in the temperature range 900° to 1050° F. Table 47—IV shows the typical properties of Stainless W in the annealed and aged conditions.

Elevated-Temperature Properties—In Figure 47—13 is shown the creep strength of many of the commercial stainless steels, compared with that of carbon steel. Note that the austenitic stainless steels have higher strength than the ferritic stainless steels and that additions of chromium and silicon have little effect on the creep strength. On the other hand, the effect of molybdenum, columbium (niobium), and tungsten are marked. This phase of the subject is discussed in detail in Chapter 48.

APPLICATIONS

Martensitic Grades—The most widely used of the martensitic grades is Type 410 containing under 0.15 per cent carbon and 11.50 to 13.50 per cent chromium. In the annealed condition, this grade may be drawn or formed. As it is an air-hardening steel, a wide range of mechanical properties may be obtained by heat treatment. In sheet or strip form, Type 410 is used extensively in the oil industry for bubble trays, bubble caps and liners.

3	No. 1 plus Aged at 1000° F, ½ hour, Air Cooled.	170-210	190-220	8-14	10-15	38-46
4	No. 1 plus Aged at 1050° F, ½ hour, Air Cooled.	150-185	170-210	8-15	10-16	35-43

* For thicknesses of plates and bars indicated.

FIG. 47-13. The creep strength of some stainless steels.

It is also used for furnace parts where the operating temperature is not over 1200° F and for blades and buckets in steam turbines. Type 420, with about 0.35 per cent carbon and resultant greater hardness, is used for cutlery. In bar form it is used for valves, valve stems, valve seats, and shafting where resistance to corrosion and wear are needed. Type 440 may be employed for such applications as surgical instruments, especially those requiring a durable cutting edge. The necessary hardness for different applications can be obtained by selecting Grade A, B, or C, which have increasingly greater carbon contents, in that order.

Types 410 and 420 are usually not used for welding applications because of their hardening characteristics. However, as mentioned previously, the addition of 0.1 to 0.3 per cent aluminum to Type 410 decreases its hardening tendency and makes it easier to weld.

Other martensitic grades are Types 501 and 502, the former having carbon over 0.10 per cent and the latter having under 0.10 per cent carbon, but both containing 4 to 6 per cent chromium. These grades are also air-hardening, but do not have the corrosion-resisting properties of the 12 per cent chromium grades. These grades have wide application in the oil industry for such uses

as hot-oil lines, bubble towers, valves, plates, and so on.

Ferritic Grades—The most common and widely used of the ferritic grades is Type 430 containing 0.12 per cent carbon or under and 14 to 18 per cent chromium. The higher chromium content of Type 430 makes its corrosion resistance superior to that of the martensitic grades and, in addition, this material may be drawn, formed and, with proper techniques, welded. It is widely used for automotive and architectural trim. Its resistance to nitric acid makes it useful in the manufacture and handling of this acid. Type 430 does not have a high creep strength, but it is suitable for some types of service up to 1500° F and thus finds application for such parts as combustion chambers for domestic heating furnaces.

The high chromium content of Type 446 (23 to 27 per cent chromium) gives this grade excellent heat-resistant characteristics although its elevated-temperature strength is only slightly better than that of carbon steel. Type 446 is used in sheet or strip form at temperatures up to 2100° F. This grade does not have the good drawing characteristics of Type 430, but it may be formed. Accordingly, it is used widely for furnace parts such as muffles, burner sleeves and annealing baskets. Its resistance to nitric and sulphuric acids makes it suitable for much chemical-processing equipment, and tubular products of Type 446 were widely used during World War II by the synthetic-rubber industry for the processing of butane.

Austenitic Grades—The basic and most widely used grade of the austenitic types is "18-8"—Type 302, with 0.15 per cent maximum carbon, 8 to 10 per cent nickel and 17 to 19 per cent chromium. It has excellent corrosion resistance and, because of its austenitic structure, possesses very good ductility. It may be deep drawn and can be very severely formed. It can be welded readily, but, as described in the general section on iron-chromium-nickel alloys, the heat of welding may cause carbides to precipitate in the weld and in the metal adjacent to the weld if a sufficiently rapid rate of cooling is not obtained, thus rendering these zones susceptible to intergranular corrosion. This may be corrected by annealing the welded part above 1900° F to redissolve the carbides, followed by rapid cooling to retain them in solution. Where such a treatment is not feasible, Types 321, 347, or 18-8 with 0.03 per cent maximum carbon may be used.

The applications of Type 302 are wide and varied, including kitchen equipment and utensils; dairy installations; transportation equipment; oil-, chemical-, paper- and food-processing machinery.

Type 301 contains a maximum of 0.15 per cent carbon, 6 to 8 per cent nickel and 16 to 18 per cent chromium. Its lower nickel content causes it to work harden more rapidly than Type 302 (18-8) because of reduced austenite stability. Accordingly, it does not have quite as good drawing properties as Type 302, but for the same reason, this grade (Type 301) can be cold rolled to very high strength levels for use in applications where a high strength-to-weight ratio is desired.

Type 304 is a companion grade to Types 301 and 302. Its carbon content is somewhat lower, 0.08 per cent maximum, and it has a slightly higher chromium content, 18 to 20 per cent. Because of its lower carbon content it is not so prone to give trouble after welding due to carbide precipitation and resultant corrosion. In addition, the somewhat higher chromium content makes it slightly more resistant to general corrosion. It is well suited for those applications which require resistance to severe forms of corrosion such as are encountered in the paper and chemical industries. The austenitic grades have good elevated-temperature strength and these

grades are widely used for elevated-temperature service.

Types 321 and 347, with carbide-forming additions of titanium and columbium (niobium), respectively, are widely used in those applications involving welding and where high-temperature service under corrosive conditions is required. Type 304L, the 0.03 per cent maximum carbon grade, may be used as an alternative for Types 321 and 347 in those applications involving welding and stress relieving for service below about 800° F.

The addition of 2 to 4 per cent molybdenum to the basic 18-8 composition produces Types 316 and 317 which have improved corrosion resistance. These grades are used in applications in the textile, paper and chemical industries where strong sulphates, chlorides and phosphates and such reducing acids as sulphuric, sulphurous, acetic and hydrochloric acids are used in such concentrations as to make the use of a more highly corrosion-resistant alloy mandatory. Types 316 and 317 have the highest creep and rupture strengths of the commercial stainless steels.

The austenitic stainless grades most resistant to oxidation are Types 309 (22 to 24 per cent chromium, 12 to 15 per cent nickel) and Type 310 (24 to 26 per cent chromium, 19 to 22 per cent nickel). Because of their high nickel and chromium contents these steels resist scaling at temperatures up to 2000 and 2100° F and, consequently, are ideal for furnace parts and heat exchangers. They are somewhat harder and not as ductile as the 18-8 types, but they may be drawn and formed. They can be readily welded and are finding increasing use in the manufacture of jet-propulsion motors and industrial-furnace equipment.

For applications requiring good machinability, Type 303 containing sulphur or selenium may be used.

SUMMARY

The stainless steels are alloys of iron and chromium or iron, chromium, and nickel, although occasionally small amounts of certain other elements are added in order to enhance corrosion resistance and mechanical properties or to immunize the steels to the action of certain harmful impurities. The inherently slow reaction rates of the stainless steels have hampered the establishment of precise equilibrium diagrams; however, the diagrams now in existence permit at least qualitative conclusions to be drawn regarding the structure of these steels. In regard to corrosion resistance, the chromium content seems to be the controlling variable and the effect of chromium may be enhanced by additions of molybdenum, nickel, and other elements. The mechanical properties of the stainless steels, like those of the plain carbon and lower alloy steels, are functions of the structure and composition of the material. Thus, the austenitic steels possess the best impact properties at low temperatures and the best strength at elevated temperatures while the martensitic steels possess the highest hardness at room temperature. Therefore, the stainless steels, by being available in a variety of structures, exhibit a range of mechanical properties which, combined with their excellent corrosion resistance, makes these steels highly versatile from the standpoint of design.

Chapter 48

STEELS FOR ELEVATED-TEMPERATURE SERVICE

SECTION 1

CLASSES OF STEEL

The designation "elevated-temperature service" is an inclusive one, involving many operations and industries. Examples of equipment operated at high temperatures are steam and mercury boilers and turbines, gas turbines, stills for cracking petroleum, tar stills, vessels for hydrogenating oils, heat-treating furnaces, and fittings for Diesel and internal-combustion engines. Jet-propelled planes and guided missiles powered by gas turbines or rocket motors are introducing new requirements for metals with even greater strength at elevated temperature, and are increasing the complexity of problems in high-temperature design, both in the motors and in the fuselage. Valve steels, hot-working die steels, and high-speed tool steels are also used at elevated temperature, but these form special categories and are discussed elsewhere in this book.

The steels under consideration in this section are those in commercial use in large tonnages for construction of equipment to operate under stress at elevated temperature, where creep is involved. (Creep and creep testing are discussed in detail in the section on "Creep and

Rupture Testing" in Chapter 49.) In spite of the fact that plain carbon steel has the lowest strength, it is widely used for elevated-temperature applications up to 1000° F, where scaling commences and a chromium-bearing steel must be employed. Low-alloy steels, containing small amounts of chromium and molybdenum, have higher creep strength than carbon steel and are employed where material with higher strength is needed. Above 1000° F, the amount of chromium required for scaling resistance increases rapidly. The 5 per cent chromium steels, with added molybdenum, are useful up to 1150° F, and steels containing 10 to 14 per cent chromium may be employed up to 1250° F. Above this temperature, the austenitic 18 per cent chromium, 8 per cent nickel stainless steels are used customarily, and their scaling resistance is considered adequate up to 1600° F. For service in the temperature range between 1600° and 2000° F, steels containing 25 per cent chromium and 12 per cent nickel, 25 per cent chromium and 20 per cent nickel, or 27 per cent chromium are used.

SECTION 2

FACTORS AFFECTING HIGH-TEMPERATURE PROPERTIES

Composition and Temperature—The creep strength of plain carbon steel can be greatly improved by the addition of alloying elements. It has been found that creep strength may be increased by use of those elements such as molybdenum which increase the recrystallization temperature and form stable carbides or intermetallic compounds. The effect of molybdenum is shown in Figure 48—1 and the effect of chromium is shown in Figure 48—2. Small additions of chromium do not appear to improve the creep strength of plain molybdenum steels and higher additions actually decrease the strength. However, above 1000° F, chromium is needed for surface protection.

Carbon itself is beneficial in amounts to about 0.15 or 0.20 per cent; above this amount, increase of the carbon content results in decrease of creep strength. Tungsten and vanadium act in a manner similar to molybdenum and are quite useful in improving high-temperature strength although they are not as widely used in this country. Titanium and columbium (niobium) are moderately beneficial and a slight increase in phosphorus has been found desirable. The influence of manganese, nickel, copper and silicon is mild, and aluminum decreases creep strength. It has been found that the face-centered cubic structure of austenite is more creep resistant than the body-centered cubic structure of ferrite, and the austenitic chromium-nickel steels have excellent creep strength; i.e., when used as a means of changing

the lattice structure, nickel is very beneficial, and nitrogen may act in a similar manner.

The effect of the alloying additions on creep strength is summarized in Figure 48—3, which shows the decrease of strength with increase of temperature. For the sake of simplicity and comparison, this chart is based on average properties, but actually the strength of any particular steel at a given temperature comprises a range rather than a single value. The spread of the data is due partly to the fact that all steels are purchased under specifications which permit some latitude in composition, and partly to the other causes such as variation of heat treatment and manufacturing practice to be discussed in detail below.

Heat Treatment (Microstructure)—The strength of steel at elevated temperatures is profoundly affected by its microstructure, and hence by the heat treatment employed for the material. Carbon and molybdenum steels are used in the as-rolled, normalized, or annealed condition, while the air-hardening chromium-molybdenum steels are normalized and tempered or annealed. Steels for bolts are quenched and tempered. Stainless steels are annealed or annealed and stabilized. Steels are purchased to specifications having room-temperature mechanical strength and hardness requirements. Since these properties may be produced by several of the above heat treatments, few of the various types of steel are used in only one condition of heat treatment, ac-

FIG. 48-1. Effect of molybdenum content on creep strength (stress per creep rate of 1 per cent per 10,000 hours) of molybdenum steel at 1000° F.

counting for much of the spread in the high-temperature data. It should be borne in mind that specifications do not contain requirements concerning the properties of the steels at elevated temperature.

The effect of heat treatment on the creep strength of molybdenum steel was clearly shown by Weaver. In creep tests at 1000° F, he found that the stress to produce a creep rate of 1 per cent per 10,000 hours varied from 20,000 to 4,500 lb. per sq. in., depending upon whether the structure was pearlitic or spheroidized.

The temperature at which the steel is used in service may serve as a heat-treating temperature and bring about internal changes in the material which will cause a change of its properties. Sometimes the strength and hardness are found to increase, at least temporarily, but more often the lack of structural stability causes a progressive loss of strength. There are several forms in which structural instability makes itself manifest, such as spheroidization, graphitization, precipitation hardening or aging embrittlement, and carbide precipitation. These will be discussed in the section entitled "Behavior of Steels at Elevated Temperature."

Grain Size—It has been found that the creep strength is increased somewhat by a coarsening of the grain size. It is not possible to coarsen the grains unduly without injuring other properties such as impact strength, but a grain size of 2-5 instead of the customary 6-8 has been found to be beneficial.

Cold Working—The long-time creep strength of cold-worked material will generally be lower than that of annealed material free from strain hardening. However, for short time periods of a few hours up to several hundred hours at moderately elevated temperatures, the strengthening effect of cold working may persist long enough to be useful in certain short-time applications.

Manufacturing Practice—The creep behavior of a material is a very sensitive index of its strength and is strongly affected by differences in chemical composition and microstructure. However, even for materials of similar composition and microstructure, the creep strength is not always the same, but is affected by the method by which the steel is manufactured. For example, pearlitic carbon steel under a stress of 15,000 lb. per sq. in. at 850° F shows a thousandfold difference in creep rate de-

FIG. 48-2. Effect of chromium content on creep strength (stress for creep rate of 1 per cent per 10,000 hours) in chromium-molybdenum steel at 1000° F.

FIG. 48-3. Creep strength (stress for creep rate of 1 per cent per 10,000 hours) of various steels at temperatures between 800° and 1400° F.

FIG. 48-4. Creep strength (stress for creep rate of 1 per cent per 10,000 hours) of carbon steel at temperatures between 800° and 1300° F.

pending upon the manner in which it was manufactured.

The variation of the available data on the creep strength of carbon steel is shown in Figure 48—4. At 1000° F, for example, the creep strength varies from 2,000 to 7,000 lb. per sq. in., and at 800° F from about 12,000 to 27,000 lb. per sq. in. Part of this variation in strength is, of course, due to variation in grain size and microstructure. However, the method of deoxidation has been found to have an important effect on the creep strength. For example, molybdenum steels deoxidized with ½ lb. and 1½ lbs. of aluminum per ton were tested

for creep strength at 850° and 1000° F. The steels were heat treated to produce identical grain size and microstructures, eliminating these variables. It was found that at 1000° F, the low-aluminum steel was more creep resistant than the high-aluminum steel, indicating that the aluminum content itself affected the behavior of these materials. The same behavior has been noted in carbon steels.

Electric-furnace steels have been reported to have a higher creep strength than open-hearth steels of the same type.

SECTION 3

BEHAVIOR OF STEELS AT ELEVATED TEMPERATURE

A. INTERNAL STABILITY

Carbide Instability—Steels in service at elevated temperature do not usually show any significant change of grain size or shape, but both visible and invisible changes may occur within the grains. Visible changes within the grains may be classified as formation of new phases, spheroidization and migration of carbides and nitrides, and graphitization.

In carbon and molybdenum steels, spheroidization occurs at temperatures above 1000° F; as shown in Figure 48—5, graphitization, particularly in fine-grained aluminum-killed steel, may also occur. The addition of chromium tends to stabilize the carbides, thus lessening or eliminating graphitization and delaying spheroidization. The relative stability of 24 steels at 900°, 1000°, and 1100° F, is shown in Table 48—I.

A form of carbide instability occurs in the austenitic chromium-nickel steels in the temperature range between 800° and 1600° F. In this temperature range, chromium carbides form and precipitate at the grain boundaries, depleting these regions in chromium and hence lowering the resistance of the grain boundaries to corrosion. This form of carbide precipitation has not been found to lower the tensile, creep or impact strength of the material, which has been successfully used for oil-cracking still tubes in this temperature range. Elimination of the carbide precipitation is accomplished by lowering the carbon content below 0.02 per cent or

alloying with such carbide stabilizers as titanium or columbium (niobium).

Aging—Aging or precipitation hardening as a heat-treating process may be utilized to increase the strength of metals at elevated temperature providing that the material is used below the temperature at which over-aging would occur during life of the part. For example, in age-hardened Stainless W, an alloy containing 17 per cent chromium, 7 per cent nickel with added titanium, relaxation measurements show that, while some softening occurs in about a week at 800° F, very little softening occurs in the same length of time at 600° F. Below this temperature, therefore, it should be possible to utilize the strengthening produced by the precipitation hardening.

Aging can, of course, occur during service and may result in embrittlement of the material. In carbon steels, it has been found that aging occurring at temperatures between 400° and 600° F is more pronounced in Bessemer steels than in those made in the open hearth, and that it is greater the less thorough the deoxidation or killing of the material. The aging tendency is lessened by addition of titanium and aluminum. If this aging or precipitation hardening resulted only in an increase of strength, no harm would result. However, as the strength increases, the ductility decreases, particularly as measured by the notched-bar impact test after straining. The sensitivity to strain-aging is lessened by normalizing and by thorough deoxidation of the steel.

*It may be assumed that steels showing a change of microstructure at 1000° F would do so at a higher temperature, and that steels which remained unchanged at 1000 or 1100° F would do likewise at a lower temperature.

**AC = Air Cool FC = Furnace Cool WQ = Water Quench
†0 —no change. II —moderate change.
I —slight change. III—marked change.

Temper Brittleness—Steels with even moderate amounts of chromium or manganese, and such steels plus nickel, are likely to become brittle if cooled slowly from the tempering operation after quenching—hence the name, “temper brittleness.” Steels with 1 to 2 per cent manganese, and even plain 3 to 5 per cent nickel steels, may show it. The addition of 0.30 to 0.50 per cent Mo lessens or prevents the embrittlement. The higher the nickel and chromium content, the greater the amount of molybdenum required to increase freedom from embrittlement, and an increase in the nickel content decreases the resistance to embrittlement of steels containing chromium and molybdenum. The brittleness resulting from heating at about 840° F can be eliminated by heating to between 930° and 1110° F. Embrittlement can occur under no load, but stress has been found to accelerate the embrittlement.

Temper brittleness is found in bolts, studs, and other quenched and tempered parts used in high-temperature steam lines at temperatures in the vicinity of 800° to 900° F. The embrittled material may retain its full original toughness at the service temperature, and yet be brittle to a notch test at room temperature. The fundamental cause of the embrittlement is not known, but is thought to be due to some form of precipitation hardening. There is no measurable difference between the tough and the embrittled forms of the steel observable in tensile, bend or fatigue tests, provided that the test pieces are not notched. Vanadium has also been found to minimize the effect of this embrittlement, and chromium-molybdenum or chromium-manganese-vanadium steels have been widely adopted for heat-treated fastener applications.

Embrittlement of Ferritic Chromium Steels—Plain chromium steels containing more than 12 to 15 per cent chromium have been found to become embrittled during prolonged heating in the vicinity of 900° F. This embrittlement is due to the formation or precipitation of a body-centered-cubic iron-chromium compound containing 70 to 80 per cent chromium. The embrittlement during heating at higher temperatures (1120° to 1470° F) is due to the precipitation of the sigma phase, an iron-chromium compound, FeCr. The ductility and impact properties of alloys containing over 20 per cent chromium may be seriously impaired even by slow cooling in the range 1100° to 700° F.

B. EXTERNAL OR SURFACE STABILITY

Scaling and Corrosion Resistance—The property of surface stability or corrosion resistance is considered to be of primary importance, since the metal must not deteriorate excessively during service at elevated temperature. One of the simplest forms of corrosion, and one frequently encountered, is oxidation or scaling of the metal. Scaling occurs by a process of diffusion of oxygen inward and of alloying elements outward through the scale layer already formed. In plain carbon steel, the amount of scaling in air is negligible below 1000° F. Above this temperature, the rate of scaling of carbon steel increases rapidly. For a given period of exposure, the amount of scaling varies exponentially with respect to the reciprocal of the absolute temperatures.

The most important element for increasing the scaling resistance of carbon steel above 1000° F is chromium. This element appears to oxidize preferentially to iron, and to form a tightly adherent layer of chromium-rich iron oxide on the surface of the metal, retarding the inward diffusion of oxygen and inhibiting further oxidation. Other elements such as silicon and aluminum also increase the scaling resistance, particularly when added to a steel containing chromium. These elements have

FIG. 48-6. Oxidation of plain carbon and 5 per cent chromium—0.5 per cent molybdenum steel at 1100° F.

a greater affinity for oxygen than does iron, and are also preferentially oxidized.

The rate of scaling decreases as the scale becomes thicker and additional protective layers are formed. The nature of the progress of scaling with time at 1100° F is shown in Figure 48-6 for carbon steel and 5 per cent chromium steel containing molybdenum. At the start, the rate of scaling of the alloy steel is as rapid as that of the carbon steel or perhaps more so, but the rate of scaling of the alloy steel soon decreases while that of the carbon steel continues at a rapid rate. The results of oxidation tests are shown in Figure 48-7. In these tests, the amount of scaling (oxidation) was measured by the gain in weight in 1000 hours. Several interesting points immediately become apparent. As the temperature is increased above 1000° F, the amount of scaling

in the plain carbon and molybdenum steels increases rapidly, and increase of chromium to 2.25 per cent or of silicon to 0.75 per cent does not improve the scaling resistance significantly. The 5 per cent chromium steels are somewhat better, but their scaling resistance decreases rapidly above 1200° F. Additions of 9 per cent or 12 per cent chromium considerably improves the scaling resistance, these materials showing little scaling in 1000 hours below 1400° F. The increase in scaling resistance in going from 5 per cent to 9 per cent chromium is noticeable. The very large increase in scaling resistance produced in 3 per cent chromium or 5 per cent chromium steel by addition of 1.5 per cent silicon is also striking.

A survey of the available data indicates that the chromium content for freedom from scaling is roughly

FIG. 48-7. Amount of oxidation (scaling) of carbon, low-alloy, and stainless steels in 1000 hours in air at temperatures from 1100° to 1700° F.

Fig. 48-8. Maximum amount of chromium necessary for freedom from scaling at temperatures from 1000° to 2000°F.

proportional to the temperature, as shown in Figure 48-8. While this diagram indicates the maximum chromium content for freedom from scaling, it should be noted that addition of 1.25 to 1.50 per cent silicon greatly improves scaling resistance, decreasing the amount of chromium needed for protection at a given temperature.

Effect of Various Atmospheres—The corrosion of steels at elevated temperatures in air is not necessarily indicative of their performance in other atmospheres. However, it is generally true that the corrosion resistance of steel increases with its chromium content. The precise behavior must, however, be established under the conditions in which the material will be used in service. Based on service experience in various atmospheres, as well as on laboratory tests, the American Society for Testing Materials has listed the maximum temperature which various stainless steels can withstand without excessive scaling (Table 48-II).

In 3000 and 7000 hour tests in steam at 1100° F, Van Duzer and McCutchan found that the silicon content of

the chromium-molybdenum steels did not increase their resistance to steam corrosion, as had been expected from laboratory scaling tests in air. They also found that the corrosion of the plain carbon steels proceeded at a constant rate, but that as little as 1 to 2 per cent chromium lessened materially the amount of scaling. In the 12 per cent chromium stainless steels, the high-sulphur free-machining steel was as good as the standard grades, but addition of 2 per cent manganese lowered the corrosion resistance.

Rohrig, Van Duzer and Fellows tested various carbon and alloy steels in steam at 925° and 1100° F. In periods up to 15,000 hours at 925° F, the steels formed a thin, dense, tightly adherent layer of scale. The amount of scaling was very light and there was little difference between the various types of steels. At 1100° F, scaling of the carbon steels was continuous, but that of the alloy steels decreased after a period of time. In general, the same trends are shown by these tests in steam as by the scaling tests in air.

Scaling tests in carbon dioxide show about the same results as scaling tests in air.

In flue gases, Oertel and Landt found that the amount of scaling in 10 per cent chromium steels at temperatures between 1300° and 2000° F was three times as rapid as in air. Gases that are chemically reducing in nature increase the scaling rate over that obtained in air.

Chromium is particularly effective in increasing the resistance of steel to corrosion by sulphur compounds at elevated temperature, a condition frequently encountered in oil refining. Service experience with oil-cracking still tubes and evaporators has shown that under these conditions small additions of chromium are effective; 2 per cent chromium was found to reduce the amount of corrosion to $\frac{1}{3}$ that encountered in plain carbon steel.

In ammonia synthesis, Schiffer and Berlecken showed that the conditions at high temperatures and pressures lead to reactions between the hydrogen of the gas and the carbon of the steel to form methane (CH_4) and other hydrocarbons. At 390° and 750° F, at 50 and 75 atmospheres pressure, respectively, carbon steel and 1 per cent chromium steel with molybdenum showed loss of impact strength after service, while 5 per cent chromium steel with molybdenum was unaffected. The improvement of the resistance of steels to hydrogen must be accomplished by using lower carbon content, minimizing inclusions, and alloying with chromium, prefer-

FIG. 48-9. Thermal conductivity of various steels at temperatures between room temperature and 1500° F.

FIG. 48-10. Influence of temperature on linear thermal expansion. The diagram shows the change of length, in inches per foot, occurring in carbon, low-alloy, and stainless steels as they are heated from room temperature to any temperature between 400° and 1200° F. For the ferritic steels, the thermal expansion decreases with increasing chromium content, following the order of the steels as listed on the diagram. In the austenitic steels the thermal expansion is larger than in the carbon steel.

ably above 3 per cent, in connection with such carbide stabilizers as tungsten, molybdenum, titanium, vanadium, tantalum, and columbium. The elements that resist hydrogen are good nitride formers, so failure can occur by formation of a brittle nitride layer. All high-chromium and chromium-nickel steels show excellent resistance to hydrogen. Chromium steels are resistant to hydrogen sulphide (H_2S) and sulphur dioxide (SO_2) gases, while nickel steels are sensitive to these gases. A chromium-silicon-aluminum steel was found to be useful where gases containing H_2S had to be handled at $1830^\circ F$.

Caustic Embrittlement of Boiler Plates—Caustic embrittlement or "caustic cracking" of boiler plates sometimes occurs when alkalis are present in the boiler feedwater. The caustic cracking is intergranular and results from a combination of stress, exposure to alkaline solutions at temperatures of $212^\circ F$ or above, and the opportunity for concentration of the solution in capillary spaces. Both hydrogen (H_2) and the deposit of iron oxide (FeO) formed by the reaction enter into the process, but the full explanation of the process is lacking. Common methods of protection when using alkaline water are to maintain a ratio of sulphate to alkali above a certain value which depends on the working pressure, or to distill the water.

Thermal Conductivity—Another property of importance at elevated temperature is the thermal conductivity of the material, shown in Figure 48—9. It will be noted that the addition of alloys decreases the thermal conductivity of carbon steel, and that the difference between the thermal conductivities of the various steels decreases with increasing temperature. The thermal conductivities of the austenitic 18 per cent chromium, 8 per cent nickel and of the 25 per cent chromium, 20 per cent nickel steels are the two lowest on the chart.

Thermal Expansion—In designing apparatus for use at elevated temperature, allowance must be made for the thermal coefficient of expansion of the component materials.

The linear thermal expansion (increase in length), in inches per foot in going from room temperature to any elevated temperature up to $1200^\circ F$, is shown in Figure 48—10.

The steels are listed in the order in which they occur on these bands. It is seen that the austenitic stainless steels have a higher coefficient of expansion than the ferritic steels, in which the thermal expansion is decreased by the addition of alloying elements.

Modulus of Elasticity—Elastic moduli are often needed for design for service at elevated temperatures. The temperature dependence of Young's modulus (tensile modulus, E) for a number of ferrous materials that might be used in service at elevated temperatures is shown in Figure 48—11. The relatively low spread in values which encompasses all the ferritic or austenitic steels should be noted, since it indicates that this prop-

FIG. 48—11. Young's modulus, E , of various ferrous materials, as affected by temperature.

erty is relatively independent of composition and micro-structure.

Chapter 49

MECHANICAL TESTING

SECTION 1

INTRODUCTION

The manner in which metals react to applied forces is important in almost all practical applications. Steels, for example, are used in a multitude of applications involving their ability to withstand service loadings without permanently deforming or rupturing. Of equal importance, on the other hand, is the ability of steel to undergo large permanent deformations, thus permitting the formation of useful shapes under the application of the proper forces. Even though the final service application of a metal part may not in any way involve load-carrying ability, it is almost certain that at some stage in fabrication the manner of reaction of the metal to applied forces has come into play. Mechanical properties are the characteristic response of a material to applied forces; the methods of measurement of these properties and of evaluating their significance form the subject matter of this chapter.

It is both logical and useful to think of mechanical properties as falling into two broad categories: strength and ductility. Strength properties are related to the ability of the material to resist applied forces, while ductility is a measure of the ability to undergo permanent changes of shape without rupturing. Many mechanical characteristics or behaviors depend on both strength and ductility, frequently in a complex manner, as illustrated so well by that characteristic of materials known as toughness, or the ability to absorb energy. Even such complex behavior can be better understood, however, by considering it in terms of the separate contributions of strength and ductility.

The mechanical reactions of metals to applied forces are extremely diversified, depending upon the exact nature of the forces and the conditions under which they are applied. It is essential that cognizance be taken of this fact in attempting to devise or select tests which will permit a prediction of service performance. The final answer to the question of suitability for service can, in general, only be found in an actual service test. In most cases, however, actual service tests are impractical and simpler tests must be found, especially where frequent inspection of material is essential. In devising simpler tests, it is important that the type of forces involved in the particular service application of interest be known, i.e., whether the loading is tension, compression, bending, twisting, shear, etc. It is also important to know whether the loading is static or dynamic, and if dynamic, it is important to know the nature of the rate of application and variation of the loading. The temperature at which the loading is applied also may be of critical importance. If these features of the service conditions are known, one can be guided in the selection of tests most likely to provide a reliable evaluation of the suitability of a material for a particular application. One criterion of test validity with respect to service would be,

then, the extent to which the test simulates the actual application. For example, suppose that a large structural member is required to carry a certain compressive load at a temperature of 500° F. A test of the actual member is out of question because of the large size. An alternate course of action is to select from the material in question a small specimen suited to available testing equipment and to make a compression test at 500° F. The type of loading and the service temperature are thereby duplicated, and it is likely that the test results will be a reliable guide in selecting a material suitable for the application.

Another criterion by which a test may be selected depends on whether or not the test measures the same ultimate fundamental property on which successful performance in service depends. For example, in bending, the minimum bend radius obtainable with a particular material depends on the ability of the material to elongate over very short gage lengths on the tension fibers of the bend. Since the reduction of area in the tension test may be interpreted also as a measure of ability to elongate over very short gage lengths, it has been possible in some instances to relate minimum bend radii to reduction of area. The test is thus measuring a property which is directly responsible for the behavior in the application.

There exist a great many applications of metals, however, which are characterized by such complex conditions of loading that a directly applicable test may not be readily found. Because of this circumstance, the selection of mechanical tests for a particular instance is based primarily on experience. It may be known that, over a period of years, many lots of a certain grade of steel having properties falling within a certain range have performed satisfactorily in service. It can be expected, then, that new lots of this grade of steel having the same mechanical properties will perform satisfactorily in the same application.

A good example of a test selected on the basis of experience is offered by the extensive use of hardness testing in the inspection of deep-drawing sheets. It is known from experience that, in order for a sheet to be formed satisfactorily into a particular part, its hardness must lie within a certain range. Although hardness in itself can hardly be considered the property which controls the performance, it reflects the critical properties to a degree which makes it extremely useful as a control test, particularly in view of the ease with which hardness tests can be made. Testing on this basis, however, should only be considered as a means of increasing the probability of selecting satisfactory material. Unless the actual characteristics which determine the performance are known and are actually being tested for, an arbitrary test, even though backed by considerable experience, may at some

time fail to discriminate between good and poor material.

In the field of the mechanical behavior of metals, there is a strong trend away from arbitrary tests and toward a more exact evaluation of the fundamental properties which are actually called upon in particular service applications. The new methods of experimental stress analysis, particularly the wire-resistance strain-gage techniques, have permitted great advances to be made in more thorough evaluation of service requirements. Once the mechanics of an application have been analyzed and the critical fundamental material characteristics have been ascertained, the task of selecting a suitable test is greatly simplified.

Many steel products are sold to mechanical-property specifications and much of the testing carried out by the steel producer is for the purpose of ascertaining whether or not a given specification is being met. If the product is a widely used one, a standard specification may be set up by a body such as the American Society for Testing Materials in order to assist the user in specifying material for a certain application. Such specifications may provide fundamental design figures for the engineer, or in many cases may be based on previous experience which indicates that, if a material has certain properties, it will serve a particular purpose satisfactorily.

As already indicated, mechanical testing may be carried out as a means of quality control, even though the product may not be sold to a mechanical-property specification. In such instances, the experience of the producer dictates the test most suitable for the purpose.

The particular test chosen may depend to a great extent upon the ease with which it can be made if frequent inspection or extensive sampling is needed.

Another important function of mechanical testing is to determine the causes for failure in service. If the material is shown to be at fault, a substitution of another material or the elimination of the deficiency of the first material can be guided by judicious mechanical tests. If no fault can be found with the material, a change in design may be indicated.

Still another function of mechanical testing results from its great usefulness in the development of new and improved products. Even in applications so complex in nature that a final test in service may be required, it is usually possible, by judicious mechanical tests, to establish trends and select the materials most likely to perform satisfactorily.

In the subsequent sections of this chapter, the mechanical tests most generally applied to steel will be discussed. Attention will be focused primarily upon the tension test, the hardness test, the notched-bar impact test, the fatigue test, and the creep and rupture tests. In addition, certain miscellaneous tests sometimes made on steel will be briefly described. Emphasis will be placed on the significance of the various mechanical properties to be discussed, as well as on the precautions necessary to obtain reliable test results. Test procedures approved and recommended by the American Society for Testing Materials will be indicated for those tests for which standards or tentative standards have been established.

SECTION 2

THE TENSION TEST

Because of the large amount of information which can be derived from it, the tension test is undoubtedly the most generally useful of all the mechanical tests applied to steel. The versatility of the tension test lies in the fact that it permits both strength and ductility properties to be measured. The strength properties measured in the tension test are directly useful in design, whereas the ductility properties provide some indication of the extent to which changes in shape can be brought about by plastic forming, or an indication as to whether sufficient ductility is present for the intended service. Since the tension test is used quite extensively in the steel industry, a rather complete description of the test and of the properties measured will be presented.

Testing Machines—The machines employed in tension testing consist essentially of a load-producing mechanism and a load-measuring mechanism. The most elementary method of producing a tensile load simply involves the suspension of dead weights from the specimen to be loaded. This procedure is in general not practicable, however, because of the inconvenience of handling the large weights which would be required. Dead-weight loading, sometimes with the force multiplied by a lever, is used in certain instances, however, where it is desired to subject a specimen to a fixed load for a period of considerable duration. Creep and rupture testing, which is discussed in a later section, is perhaps the best example of the use of dead-weight loading for testing purposes.

The more commonly used testing machines employ either a mechanical system of loading actuated by screws or a hydraulic system in which the load is applied through a hydraulic ram. In both types of machines, there is a fixed crosshead and a moving crosshead through which the tensile force is applied. The moving crosshead in the screw machine is motivated either by

threaded columns (screws) rotating in stationary nuts or by rotating nuts, depending upon the design of the machine. Various speeds of crosshead movement are available through changes of the gear combination in the drive. In the hydraulic testing machine, the moving crosshead is powered by a hydraulic ram. The hydraulic machine has the advantage of a continuous variation in rate of crosshead movement which is controlled by a simple valve system. A complete range of rates of loading from very slow up to the limit set by the capacity of the testing machine pump can be obtained. The popularity of the hydraulic machine has been increasing in recent years.

The mechanical or screw type of testing machine is characterized by the load-measuring mechanism generally employed. In this mechanism, the load is transmitted through a system of levers acting on fulcrums of hardened steel to a beam carrying a movable weight or poise. The lever system is arranged so that the force exerted by the poise on the beam has a great mechanical advantage and can balance the force being applied to the tensile specimen. The poise can be moved outward along the beam, thereby increasing its lever arm and providing by its position a means of load indication. The movement of the poise is effected by manually rotating a screw during the test so that the beam is kept in balance. Because of the characteristic load-measuring mechanism, this type of machine is generally referred to as a "beam-and-poise" or "lever" machine. A typical machine is shown in Figure 49-1. One of the greatest objections to the lever machine lies in the manual operation of the weighing mechanism and the attendant human factor introduced into the test. An attempt has been made in one development to circumvent this objection by permitting the end of the beam to actuate a pendulum, the

FIG. 49—1. Beam-and-poise testing machine. (Courtesy, Riehle Testing Machines Division, American Machine and Metals, Inc.)

movement of which provides a continuous and automatic indication of load.

Most of the recent developments in the field of tensile testing machines have centered around the hydraulic machine. Hydraulic testing machines are of two main types: the lapped-ram type and the packed-ram type. In the lapped-ram type, the piston and cylinder are lapped to an extremely close fit so that an almost frictionless movement is possible. Because of the extremely low friction, the oil pressure in the cylinder can be used directly as a measure of load on the machine. One load-measuring device used rather widely is the pendulum weighing mechanism. A small piston is acted upon by the same hydraulic pressure acting on the main ram, thus producing a force proportional to that acting on the main ram. The small piston is arranged in such a way as to displace a pendulum, the magnitude of the displacement providing an indication of the test load. Another method employs electronic indication methods for the direct measurement of the oil pressure.

In the packed-ram type of hydraulic testing machine, the piston and cylinder are not fitted as closely as in the lapped-ram type, and a packing is necessary to prevent leakage of oil from the system. Since friction between the packing and the ram is variable, depending upon the applied hydraulic pressure, the possibility of a direct pressure measurement being used to provide an accurate indication of load is precluded. One device used to circumvent this difficulty is the so-called Tate-Emery load indicator, which utilizes a hydraulic capsule. The load on the machine acts on the capsule which is part of a closed hydraulic system. The capsule is a very rigid assembly containing an oil layer of only about 0.030-inch thickness. As the load is applied, a pressure is developed in the capsule and transmitted to a Bourdon tube. The actual load indication is provided by a measurement of the force which is necessary to hold the tip of the

Bourdon tube in its equilibrium position. This force is measured by the displacement of the free end of a helical spring attached to the tip of the Bourdon tube. The spring is made from an alloy of the Elinvar type, so that the spring constant is unaffected by minor temperature fluctuations. Since the tip of the Bourdon tube is not required to move more than a very small amount, the usual objections to a Bourdon tube, such as hysteresis effects, are eliminated, and the weighing system is practically free of inertia. A modern hydraulic testing machine provided with a weighing system of the type just described is shown in Figure 49—2.

Generally, a number of load-measuring ranges are provided so that the most sensitive and accurate range can be chosen for a particular test, that is, the range having its top limit just above the maximum load expected in the test. It is important to know the accuracy of the load-measuring mechanism, and frequent calibration should be carried out to insure that the accuracy remains within the desired limits. With modern load-measuring mechanisms, accuracies of one-half of one per cent of the indicated load over all but the lowest portion of the range may be guaranteed. For most purposes, one per cent accuracy is considered satisfactory, but even at this level of accuracy, frequent calibration is desirable. If the errors are found to exceed the desired limits, the load-measuring mechanism should be adjusted until further calibration indicates the accuracy to be within the desired range.

Electronic devices are employed for load measurement in some machines of recent design. Wire resistance strain gages are used to measure the changes in dimensions of an elastic member through which the load is applied. The system is calibrated so that the changes in resistance of the strain gages provide an indication of the load. Different load ranges can be obtained by appropriate selection of the dimensions of the elastic member.

FIG. 49-2. Modern capsule weighing testing machine (Courtesy, The Baldwin-Lima-Hamilton Corp.)

In the ASTM Standards, three methods for the verification of testing machines are described. These include: (a) verification by standard weights (only applicable in the case of machines weighing a downward force), (b) verification by standardized proving levers, and (c) verification by elastic calibration devices. The first two of these methods make use of standard weights, in one case applying the weights directly to the machine, and in the other case making use of levers to multiply the forces that can be applied by the standard weights. Although both methods are quite accurate, they are obviously very inconvenient, and the feasible range of load capacities which can be covered does not encompass the larger machines.

The most widely used method of calibration makes use of elastic calibration devices. The most frequently employed device of this type is the so-called proving ring, shown in Figure 49-3. Such a ring is subjected to a series of loads in the machine to be calibrated, and the deflection of the ring is measured by a micrometer which is an integral part of the proving ring. Proving rings are available in a variety of ranges up to 300,000 lb. and are calibrated and certified by the National Bureau of Standards.

Extensometers—Certain aspects of tensile testing require the use of some device for the measurement of the

extension of the specimen; such a device is called an extensometer. There are a very large number of types of extensometers available and no attempt will be made here to describe the features and specific applications of all the various types. The characteristics of a few of the more widely used types will be discussed briefly in order to illustrate the general nature of commercially available extensometers.

Extensometers can be considered to fall into two main groups, depending on the range of extensions which can be covered. On the one hand, there are the very accurate, high-sensitivity extensometers used for the measurement of minute extensions. These extensometers are characterized by very small ranges; i.e., the total extension which can be measured is quite small. On the other hand, there are the long-range extensometers designed to measure extensions up to the instant of rupture of the specimen. It is evident that, if long range is desired, sensitivity must be sacrificed; while it is equally true that sensitivity can be gained only at the expense of range.

The optical types of extensometers provide a high degree of sensitivity and accuracy for extremely small extensions. Such extensometers are used in elastic-strain measurements and for very precise indications of the beginning of plastic yielding. Perhaps the most con-

FIG. 49-3. Morehouse proving ring, compression type. (Courtesy, Morehouse Machine Company.)

venient and frequently used optical type is the Tucker-man extensometer. This extensometer is attached to the specimen so that a fixed knife edge and a movable knife edge are in contact with the specimen. The movable knife edge consists of a lozenge, one face of which is polished to a mirror finish. A light beam is focused on the lozenge, and as the lozenge rotates as a result of extension of the specimen, the reflected beam is displaced relative to the incident beam. A specially calibrated collimator provides the light source and measures the deflection of the reflected beam. Extensions as small as two millionths (0.000002) of an inch per inch can be measured on a gage length of two inches.

Generally, the great sensitivity of the optical extensometers is not required and other more convenient types of low-range extensometers are employed. Extensometers can be either of the direct-reading (indicating) or recording type. The indicating extensometers make use of a dial gage to measure the movement of some element of the extensometer. A great many combinations of range and sensitivity can be obtained in dial-gage extensometers, the choice depending on the strain range over which observations are to be made.

Bonded wire resistance strain gages are sometimes

used in the determination of stress-strain curves, although their main application is in experimental stress analysis. Essentially, this type of gage consists of a grid of fine wire which is suitably bonded to the specimen, usually by cementing. As the specimen is strained, the wires of the grid undergo similar strains which produce a change in the cross-section of the wire. This change in cross-section results in a change in electrical resistance that is proportional to the amount of strain and can be readily measured. The range of strain of most wire resistance gages is about one per cent, but special gages having considerably higher ranges have recently become available. When suitable techniques are employed, the sensitivity and accuracy of wire resistance gages is at least as good as the best optical strain gages.

Recording extensometers are now in wide use and offer the advantage of an automatically plotted stress-strain curve from which determinations of various material characteristics can be made, as well as the advantage of a permanent record of the test. High-sensitivity short-range recording extensometers can be obtained with an accuracy of 0.00005 inch or one-half of one per cent of indicated strain, whichever is greater, and with a range of from 0.02 inch to 0.04 inch. Sensitivities up to

NOTE 1.—When necessary, it is permissible to use a narrower specimen but in such a case the reduced portion shall be not less than 1 in. in width.

NOTE 2.—The dimension "T" is the thickness of the test specimen as provided for in the applicable material specifications.

NOTE 3.—The reduced section shall be parallel within 0.010 in. and may have a gradual taper in width from the ends toward the center with the ends not more than 0.010 in. wider than the center.

NOTE 4.—The ends of the specimen shall be symmetrical with the center line of the reduced section within 0.10 in.

A.—STANDARD RECTANGULAR TENSION TEST SPECIMEN WITH 8-IN. GAGE LENGTH.

NOTE 1.—The dimension "T" is the thickness of the test specimen as provided for in the applicable material specifications.

NOTE 2.—The reduced section shall be parallel within 0.005 in. and may have a gradual taper in width from the ends toward the center, with the ends not more than 0.005 in. wider than the center.

NOTE 3.—The ends of the specimen shall be symmetrical with the center line of the reduced section within 0.05 in.

B.—STANDARD RECTANGULAR TENSION TEST SPECIMEN WITH 2-IN. GAGE LENGTH.

NOTE 1.—The gage length and fillets shall be as shown, but the ends may be of any shape to fit the holders of the testing machine in such a way that the load shall be axial.

NOTE 2.—The reduced section may have a gradual taper from the ends toward the center, with the ends not more than 0.005 in. larger in diameter than the center.

C.—STANDARD ROUND TENSION TEST SPECIMEN WITH 2-IN. GAGE LENGTH.

NOTE 1.—If desired, the length of the reduced section may be increased to accommodate an extensometer.

NOTE 2.—The gage length and fillets shall be as shown, but the ends may be of any shape to fit the holders of the testing machine in such a way that the load shall be axial.

NOTE 3.—The reduced section may have a gradual taper from the ends toward the center, with the ends not more than 0.003 in. larger in diameter than the center.

D.—EXAMPLE OF SMALL SIZE SPECIMENS PROPORTIONAL TO STANDARD 2-IN. GAGE SPECIMEN.

FIG. 49—4. Sketches of ASTM standard tension specimens. (From "ASTM Standards, 1955")

0.00002 inch can be obtained. This type of extensometer operates on a micrometer-screw principle. A small electric motor, known as a Selsyn motor, rotates a screw which makes electrical contact with an element of the extensometer actuated by the extension of the specimen. The movement of the screw results in a corresponding movement in the stress-strain recorder which can be calibrated to indicate the extension directly. By a different arrangement of the lever system in this type of recording extensometer, the range can be greatly extended, and such an extensometer, known as a total-elongation extensometer, is commercially available. The

magnification ranges of this extensometer vary from 5 to 20 as compared to 250 to 1000 for the more sensitive, short-range extensometer.

Another type of long-range recording extensometer which has seen considerable application is the wedge type. In this extensometer, a wedge of known taper is pulled through a slot in the extensometer which opens as the specimen elongates. The movement of the wedge is used to rotate the recorder drum and since the taper of the wedge is known, the strain can be calculated. The magnification obtainable with this extensometer depends upon the degree of the taper in the wedge.

Another type of recording extensometer operates on a magnetic principle. In this extensometer, the lever system is arranged in such a way that extension of the specimen results in a movement of an iron core in a small magnetic coil, thus changing the inductance of the coil. A similar magnetic coil is contained in the recorder, and is automatically kept in balance with the extensometer coil by a servomotor which also actuates the recorder. This extensometer provides a smoother motion of the recorder than the micrometer screw or Selsyn motor type of extensometer already described. The ranges and sensitivities available are comparable to those available in the micrometer-screw type.

For strain measurements in and just beyond the elastic range, it is desirable to use extensometers which incorporate an averaging mechanism. Unless extreme precautions are taken, axi-ality of loading will not be obtained and a non-uniform strain distribution will result. By averaging the extension along two opposite fibers of the specimen, a closer approximation to the extension which would have occurred had the loading been axial can be obtained.

Specimens—Certain standard tension specimens have been adopted and are recommended by the American Society for Testing Materials. The shapes and dimensions of the most frequently used tensile specimens are shown in Figure 49-4. Figure 49-4A shows the rectangular cross-section specimen with 8-inch gage length used for tests of plates and structural sections. The rectangular cross-section specimen with 2-inch gage length generally used in sheet-metal testing is shown in Figure 49-4B. The standard circular cross-section specimen with 2-inch gage length is shown in Figure 49-4C. The details of the ends of this type of specimen will vary widely, depending on the types of grips employed. If the section from which the specimen is to be taken is too small to permit the procurement of a full-size specimen, smaller specimens can be used if the dimensions are kept in geometric proportion. It is especially important that the gage length for measuring elongation be proportioned to the nominal diameter of the specimen. One-inch and 1.4-inch gage-length specimens are frequently used and have diameters of 0.252 inch and 0.357 inch respectively. The nominal diameters of 0.252, 0.357 and 0.505 inch for the specimens having gage lengths of 1 inch, 1.4 inches, and 2 inches, respectively, were selected to simplify calculation of loads in pounds per square inch from actual loads. These diameters provide specimens having respective cross-sectional areas of very nearly 0.05, 0.1, and 0.2 sq. in. Other specimens for special products can be found in the ASTM Standards. For certain types of products, such as small bars, tests may be made on the full section, in which case the only preparation necessary is the cutting of the specimen to length.

A number of general precautions should be observed in the procurement and preparation of tension-test specimens. It is important that heating and cold working of the specimen be kept to a minimum during procurement and preparation if reliable results are to be obtained. When specimen blanks are flame cut from plates, for example, allowance should be made for machining off all metal affected by the heat introduced during flame cutting. Cold shearing or punching of specimen blanks should be performed with care, since specimens improperly prepared in this manner may become cold worked and thus not be representative of the material being sampled. Care should also be taken to insure that the test specimen is straight and flat. An initial bow or curvature in a tension specimen will result in distortion of the elastic loading line and may affect the stress level at which initial plastic yielding occurs. In machining

tension-test specimens, precautions should be taken to insure that the various portions of the specimen are symmetrical with respect to the loading axis of the specimen. If such precautions are not observed, the specimen will be loaded eccentrically, and bending stresses will be set up. Such eccentric loading will affect the elastic loading line and may influence the initial yielding behavior.

Grips used in tension testing vary considerably, depending upon the type of specimen being used. For many tests, the so-called wedge grips, which are serrated and simply grip the specimen by a transverse pressure which builds up as the specimen is loaded, are satisfactory. However, if the specimen is rather short, eccentric loading may become serious, necessitating the use of machined specimen ends and of grips with spherical bearings, an arrangement which to some extent provides self-alignment. Eccentric loading of plate or sheet-type specimens may be caused by the method used in preparing the test specimen; for example, shear or punch drag, or beads of metal deposited on the edges of the grip ends when burning out the specimen. A sketch of typical spherical seated grips is shown in Figure 49-5.

FIG. 49-5. Sketch of self-aligning tension grips. (From "ASTM Standards, 1955.")

For extremely accurate work, adjustable grips may be used in which the load is transmitted through a small hardened-steel ball and which permit a shift of the specimen with respect to the load application points in order to obtain a very high degree of axi-ality.

The Tension Test and the Properties which are Determined—In conducting a tension test, the specimen is introduced into the machine in such a manner that a load can be applied along the specimen axis, and the applied

load is then gradually increased until the specimen breaks. An important factor which is generally controlled within certain predetermined limits in tension testing is the speed of testing. Some of the tensile properties are markedly affected by rate of straining, and it is important to specify and control the speed of testing within certain definite limits. These limits should be chosen in such a way as to prevent more than a certain percentage variation in the property being measured from arising as a result of variations in the speed of testing. Speed of testing may be specified in terms of rate of stressing the specimen, rate of crosshead movement, or rate of straining of the specimen. The most reliable of the three methods of specifying speed of testing is the rate of straining of the specimen, since any variations in properties as a result of variations of speed of testing arise directly from variations of strain rate in the specimen itself. In some instances the rate of crosshead movement may be closely enough related to rate of strain in the specimen that it can be used satisfactorily for control purposes.

Before considering the determination of specific properties in the tension test, it is necessary to define stress and strain, since these concepts are used in the definitions of the various tensile properties. The definitions of stress and strain proposed by the American Society for Testing Materials are as follows:

Stress—The intensity at a point in a body of the internal forces or components of force which act on a given plane through the point. Stress is measured in force per unit area (pounds per square inch, kilograms per square millimeter, etc.).

Strain—A measure of the change in size or shape of a body, due to force, referred to its original size or shape. Strain is a non-dimensional quantity, but it is sometimes expressed in inches per inch, etc.

In discussing the various properties which are determined in tension tests, these properties will be classified according to whether some aspect of strength or ductility is being measured. Further details of testing procedure will be mentioned as they apply to the measurement of specific properties.

A. STRENGTH PROPERTIES

Modulus of Elasticity (Young's Modulus)—When a metal is subjected to load, there is an initial range of loading in which no permanent deformation of the specimen occurs; i.e., if the load is removed at any value within this range, the specimen will return completely to its original dimensions. Furthermore, within this range of loading, which is designated as the **elastic range**, the strain produced is directly proportional to the applied stress; i.e., the strain produced by 20,000 lb. per sq. in. stress will be twice that produced by 10,000 lb. per sq. in. The law of proportionality between stress and strain in the elastic range is known as **Hooke's Law**. The modulus of elasticity is simply the proportionality constant between stress and strain and can be obtained from the slope of a plot of stress against strain within the elastic range. The modulus for ordinary steels is usually taken as about 30,000,000 lb. per sq. in. in design work. Since the modulus does not vary much from steel to steel, it is not determined except in special instances where a more accurate value may be needed, or for example, where the effect of temperature on the modulus must be ascertained. Very great accuracy of load measurement and strain measurement is necessary for reliable modulus determinations. Furthermore, special precautions must be exercised to procure specimens free from residual stress and to insure very accurate specimen alignment.

Elastic Limit—In practice, the elastic limit is determined by subjecting a specimen carrying a strain-measuring device (extensometer) to a series of loading steps in which the maximum load applied is gradually increased, the load being released completely at each step. A load will finally be reached upon release of which the specimen will fail to return to its original length: this load is the elastic limit. The size of the load increments used and the sensitivity of the extensometer used will, of course, affect the value obtained, and, consequently, this property is not frequently determined.

Proportional Limit—The proportional limit represents an aspect of elastic behavior similar to the elastic limit, the principal difference lying in the method of determination. The straight-line proportionality between stress and strain in the elastic range has already been discussed. It is the upper limit of the range of proportionality that defines the proportional limit. In other words, the proportional limit is the greatest stress which a material is capable of developing without a deviation from the law of proportionality (Hooke's Law).

In practice, the proportional limit is determined from a plot of stress against strain, being taken as the stress at the first visible departure from the straight line drawn through the points in the elastic range. Since the departure from linearity is in general quite gradual, the determined value will depend on the accuracy and sensitivity of the strain-measuring device employed in the test. The experimentally determined value for a given material will be found to decrease as the sensitivity of extensometer used is increased, that is, as the ability to detect smaller and smaller strain increments is increased. Because of these uncertainties, proportional limit is very seldom employed in specifications.

Yield Strength—As the tensile load on a specimen is increased through the elastic range, a stress will be reached at which the specimen will begin to deform in a plastic manner; i.e., it will undergo a permanent set which is not recoverable upon release of load. In the design of structural members to be subjected to static loads, it is generally necessary to design so that the service loads do not cause large deformations, since the usefulness of the structure would thereby be destroyed. It is for this reason that the portion of the tension test concerned with the onset of plastic yielding is of extreme importance. It has already been shown that in many materials the very first stages of plastic yielding are very difficult to detect, and that the stresses corresponding to the apparent beginning of yielding depend on the sensitivity of the strain measuring instrument used. It has become customary, therefore, to refer to the stress at which a material exhibits a specified limiting permanent set as the yield strength. The choice of the limiting amount of offset is to some extent arbitrary, but insofar as possible should be based on that amount of plastic yielding that would be considered damaging in a statically loaded member of a structure. Generally, yield strength is based on a 0.2 per cent permanent set.

Assuming that a 0.2 per cent permanent set has been chosen, the following example will illustrate the so-called offset method which is commonly used in determinations of yield strength. In Figure 49-6, the early portion of a stress-strain diagram extending up to about one per cent elongation is shown. Let the origin be designated as O and the elastic line and its extension as OA. Now, on the strain axis, lay off OB = 0.2 per cent, and construct BC parallel to OA. The stress corresponding to the point at which BC intersects the stress-strain curve represents the 0.2 per cent offset yield strength. The offset method is based on the observed fact that if the load is released at X, the specimen will recover

FIG. 49-6. Diagram illustrating offset method for determining yield strength.

along BX until at zero load, the permanent set OB remains. The procedure for any other amount of offset is identical with the exception that the offset OB will correspond to the new amount of permanent set chosen as the basis of the yield strength. The amount of offset used should always be reported with yield-strength values.

If a large number of tests, as for example in production control testing, are to be made on a material for which the stress-strain characteristics are known from experience, a shortened procedure for determination of yield strength may be used, which is known as the extension-under-load method. This method is based on the fact that the total extension, i.e., the sum of the elastic and plastic extensions, corresponding to the amount of permanent set chosen as a basis for the yield strength determination will be known within certain fairly narrow limits. Since for a given material the stress corresponding to the yield strength will not ordinarily vary more than a certain percentage, say 10 per cent, the elastic strain present at the offset on which the yield strength is based also will not vary more than 10 per cent. This 10 per cent variation in elastic strain will be a small fraction of the total strain at 0.2 per cent offset. For this reason, the yield strength can satisfactorily be determined at a total extension which is based on the permanent set chosen plus a mean expected value of elastic strain. An extensometer reading to 0.0001 in. per in. of gage length should be used for the total-strain method.

It should be pointed out that the elastic limit and the proportional limit can be considered as special cases of yield strength, the permanent set or offset corresponding to the least permanent strain detectable with the instruments used.

Yield Point—It is only for those materials that with increasing stress show a gradual departure from elastic behavior and thus exhibit a stress-strain curve such as shown in Figure 49-7 that it is necessary to define the onset of plastic yielding in terms of yield strength. Many steels exhibit a rather abrupt yielding and may show an initial increase of strain without any appreciable in-

crease of stress when yielding occurs. Such materials are said to exhibit a yield point, the yield point being defined as "the stress in a material at which there occurs a marked increase in strain without an increase in stress." This definition of yield point is that presented in the ASTM Standards and forms the basis for yield-point specifications. As will be pointed out, the definition does not provide a complete description of the yield-point behavior.

Since the yield-point phenomenon is complex, an understanding of its general features is essential for the proper planning and execution of yield-point determinations. The degree to which the yield point is manifested varies widely, depending upon the grade of steel being tested and upon the thermal and mechanical history of the steel. In some steels, the yield point may appear as little more than a "jog" in the stress-strain curve, while in low-carbon deep-drawing steel whose final treatment has been box annealing, the yield-point behavior may extend over elongations of several per cent.

The yield-point behavior can most easily be pictured by a description of the sequence of events during the yielding of a steel which shows a very pronounced yield point. If such a steel is stressed in tension, the load rises as the specimen is strained in the elastic region, and suddenly falls when the first yielding occurs. After this initial drop, with continuing elongation, the load fluctuates about some fairly constant value for a time and then begins to rise again. The maximum stress before the sudden drop is known as the upper yield point, and the average value of the relatively constant stress level that follows is known as the lower yield point. The amount of extension which occurs before the load begins to rise steadily again is called the yield-point elongation. The yielding process just described is very heterogeneous, different portions of the specimen successively undergoing yielding. After the first drop in load, locally depressed areas can be seen to form and to grow over the entire specimen as straining proceeds. These locally deformed areas are usually visible in the form of surface irregularities or strain markings which are referred to by a variety of terms including Lüders' lines, Hartmann lines, stretcher strains, "worms," and others. The formation of such strain markings has also been referred to as the Piobert effect, since the Frenchman Piobert was one of the first to observe the phenomenon. As the

FIG. 49-7. Stress-strain curve for box-annealed rimmed deep-drawing steel.

FIG. 49-8. Stress-strain curve for AISI 4340 steel, quenched and tempered at 900°F.

specimen is strained through the yield-point-elongation range, which may amount to about 10 per cent, the strain markings continue to grow and gradually merge until the entire specimen has yielded. From this point on, the specimen deforms in a homogeneous manner, as opposed to the highly localized mode of deformation occurring during the yield-point elongation. Aggregate features of the yielding behavior just described are well illustrated by the stress-strain curve shown in Figure 49-7 for an annealed-last, rimmed, deep-drawing steel. Generally, the heterogeneous yielding process will be much less pronounced as, for example, is illustrated by the stress-strain curve shown in Figure 49-8 for a quenched and tempered bar of AISI 4340 steel.

Heterogeneous yielding is associated with the presence of carbon and nitrogen in solid solution in ferrite. The carbon and nitrogen atoms are so situated that they exert an anchoring effect against the onset of plastic flow. When a sufficiently high stress is reached, the anchoring effect is suddenly overcome, and a yield point is observed.

One of the outstanding features of the yield-point behavior is the extreme sensitivity of the upper yield point to specimen preparation and testing conditions. Initial yielding can be greatly affected by nonaxial loading, sharp fillets in the specimen, cold working of the specimen during procurement or preparation, or the presence of residual stresses in the specimen. Any of these factors may be sufficiently effective to obscure the upper yield point entirely, and if the material being tested does not exhibit appreciable yield-point elongation, the influence of the aforementioned factors may eliminate all evidence of the yield point.

A number of methods of determining the yield point are recognized by the American Society for Testing Materials. These include the drop-of-beam or halt-in-gage

method, the dividers method, the total-strain method using an extensometer, and the autographic-diagram method. These methods are generally used only for materials exhibiting "sharp-kneed" curves for their stress-strain characteristics; for other materials a value equivalent to the yield point in its practical significance may be determined by methods outlined in "ASTM Standards, 1955," under Designation A370-54T (pages 359 and 360).

a. Drop-of-the-Beam Method—This method applies particularly to tests conducted on the beam and poise type of testing machine described in a preceding section of this chapter. As the specimen is loaded, the beam is kept in balance by running the poise outward along the beam. To quote the ASTM Standard A370-54T: "When the yield point of the material is reached, the increase of load stops, but the operator runs the poise a trifle beyond the balance position and the beam of the machine drops for a brief but appreciable interval of time." The load at this drop of the beam is recorded, and the corresponding stress is taken as the yield point. In view of the previous general discussion of the yield-point behavior, it seems evident that, if an especially pronounced yield point is present, an actual drop in the load carried by the specimen may occur at the upper yield point, which will result in a true drop of the beam not depending upon the operator. The main criticism of the drop-of-the-beam method lies in the fact that a drop of the beam can be obtained when a true yield point is not present in the specimen. When yielding occurs, even if no yield point is present, the rate of change of stress with strain undergoes a marked decrease. If the operator is running the poise out along the beam at a fast rate such as used in ordinary testing, he is apt to overshoot the load at which yielding occurs and observe a drop of the beam. Thus, it is possible to obtain a drop of the beam even though the stress-strain curve exhibits no region in which the strain increases with no increase in stress. For this reason, considerable skill and experience are required in the operation of the beam-and-poise machine, some indication of the presence of a true yield point being provided by the sharpness of the drop of the beam. It must be accepted, however, that the human factor is a serious variable in the drop-of-the-beam method of determining the yield point.

In testing machines provided with automatic load-indicating devices, a sudden halt or a drop of the load-indicating pointer will occur at the yield point. The load at the "halt in the gage" is recorded and the corresponding stress taken as the yield point.

b. Total-Strain Method Using Dividers, or Dividers Method—In this method, an observer with a pair of dividers set to correspond to the distance between two gage marks on the specimen places the divider points in the gage marks and watches for visible elongation as the specimen is loaded. When visible stretch has been observed, the load is noted, and the corresponding stress is taken as the yield point.

c. Total-Strain Method Using Extensometer—This method is similar to the dividers in principle but is more sensitive. An extensometer reading to 0.0001 inch per inch of gage length is attached to the specimen, which is loaded at a uniform rate. The yield point is based on the load at which the specimen is observed by the extensometer to exhibit a sudden increase of rate of elongation. Because of the greater sensitivity, this procedure may result in lower yield-

Fig. 49-9. Typical load-extension diagram.

point values than those obtained by the dividers method.

d. **Autographic-Diagram Method**—When a load-extension diagram has been obtained by an autographic recording device, the stress corresponding to the top of the knee or the point at which the curve drops is taken as the yield point. When a pronounced yield-point behavior is exhibited, both upper and lower yield points, as well as the amount of yield-point elongation are often reported. In this manner a more complete description of the behavior of the material is provided.

Tensile Strength—As the specimen is strained past the yield point, the load rises. For ductile materials, the load passes through a maximum and fracture eventually occurs, as shown in the schematic load-extension diagram of Figure 49-9. Some less-ductile materials may fracture while the load is still increasing, that is, without passing through a maximum. The tensile strength, according to the ASTM, "shall be calculated by dividing the maximum load carried by the specimen during a tension test by the original cross-sectional area of the specimen."

As already mentioned, speed of testing can affect the tension properties of a material. Considerable research has been conducted on the effects of speed of testing, and it has been generally concluded that the yield point is affected to a much greater extent than the tensile strength. It has been shown that a tenfold increase in rate of pulling increased the yield point of a 0.12 per cent carbon steel by about 7200 lb. per sq. in. in a two-inch gage length specimen. The effect on tensile strength in the range of speeds investigated was considered to be negligible. These observations have the practical significance that, in general, the control of the speed of testing is more critical in the region of the yield point than in the later stages of the test.

B. DUCTILITY PROPERTIES

Elongation—One aspect of the ductility of a material which is generally determined in the tension test is the elongation which the material is capable of undergoing before the occurrence of fracture. The elongation is

measured over some arbitrarily chosen gage length which is laid out on the specimen prior to the test. The gage length chosen depends upon the specimen being tested, but is usually two inches or eight inches. After the specimen is broken, the two fractured portions are fitted together and the new distance measured, usually to the nearest 0.01 inch. The percentage elongation is then calculated in the following manner:

$$\text{Per Cent Elongation} = \frac{\text{New length} - \text{Original length}}{\text{Original length}} \times 100$$

The original length refers to the initial gage length chosen and the new length refers to the length to which the initial gage length has been extended during the test.

The elongation at fracture of a ductile metal is not distributed uniformly along the length of the specimen. This nonuniform distribution is a consequence of necking down, the local elongation being greatest in the necked-down region of the specimen. This behavior is illustrated in Figure 49-10, which shows the distribu-

Fig. 49-10. Distribution of elongation along fractured tension specimen. (Original spacing between gage marks, ½ inch.) (From "The Mechanical Testing of Metals and Alloys," by P. Field Foster, page 76. Published by Sir Isaac Pitman & Sons, Ltd., London, 1948.)

tion of elongation over one-inch gage lengths along a fractured specimen. Up to the maximum load, the specimen elongates in a uniform manner; at maximum load, however, the strain becomes localized and the specimen necks down. The portions of the specimen sufficiently removed from the necking zone then cease to elongate. It can be seen, therefore, that the total elongation measured at fracture over some arbitrary gage length is a sum of two components: the elongation up to maximum

Fig. 49-11. Per cent elongation as function of gage length for fractured tension specimen. (From "The Mechanical Testing of Metals and Alloys," by P. Field Foster, page 77. Published by Sir Isaac Pitman & Sons, Ltd., London, 1948.)

load (uniform elongation) and the elongation after maximum load (local elongation). The elongation will obviously vary, therefore, with the gage length over which it is measured, being greater the smaller the gage length. This variation of elongation with initial gage length is illustrated in Figure 49-11 for the same specimen represented in Figure 49-10.

When comparing elongations obtained from different sizes of specimens, it is essential that geometric similarity be observed in the comparison. In other words, the ratio of gage length to cross-sectional dimensions must be held constant if comparable results are to be obtained. Barba's Law of Similarity states that for tension tests on different sizes of specimens from the same material, the same elongation values are to be expected only if the gage lengths are maintained in proportion to the square root of the cross-sectional area of the specimens.

Reduction of Area—The reduction of area provides a measure of the ultimate local ductility of a material up to the instant of rupture. In determining the reduction of area, the fractured tensile specimen is fitted together, and the dimensions at the minimum cross-section are measured. From the original and final areas, the percentage reduction of area is calculated in the following manner:

$$\text{Per Cent Reduction of Area} = \frac{\text{Original Area} - \text{Final Area}}{\text{Original Area}} \times 100$$

C. SIGNIFICANCE OF THE TENSION TEST

In addition to providing engineering design data, the tension test is used to a very great extent as an empirical test for evaluating the suitability of materials for particular mechanical applications. The test is interpreted in such instances on the basis of a wealth of practical experience, which permits an engineering opinion of the probable performance of a material to be drawn according to the tensile properties of materials known to have performed satisfactorily in the past. Many tensile-property specifications are drawn up in this manner and may not be used directly for actual design purposes.

Traditionally tensile strength has been used widely as a basis for design. At present, there is a marked trend to base the engineering design of structures to be subjected to static loads upon yield point or yield strength, with the application of safety factors based on engineering judgment. The use of the yield point or yield strength as a basis for design is, of course, based on the premise that any appreciable over-all yielding of the structure will destroy its usefulness. Tensile ductility specifications are almost universally based on practical experience as to what amount of ductility in the tension test has accompanied adequate ductility in service.

With regard to the use of the tensile yield strength or yield point in design, the question may well be raised as to how such a property, determined in a simple unidirectional tensile loading, can be used in the design of structures which are to be subjected to complex loads and complex states of stress. Any state of combined stresses can always be broken up into three so-called principal normal stresses which act in three mutually perpendicular directions. These three principal stresses can be designated as S_1 , S_2 , and S_3 , the subscripts indicating the order of algebraic magnitude; i.e., S_1 is the algebraically greatest principal stress. Some examples of simple stress combination are listed below and are illustrated in Figure 49-12. Tensile stresses are ordinarily designated as positive, while compressive stresses are designated as negative.

FIG. 49-12. Illustration of simple states of stress.

Simple tension:	S_1 positive; $S_2 = S_3 = 0$
Simple compression:	$S_1 = S_2 = 0$; S_3 negative
Balanced biaxial tension:	$S_1 = S_2$, both being positive; $S_3 = 0$
Balanced triaxial tension:	$S_1 = S_2 = S_3$, all positive
Torsion or twisting:	$S_1 = -S_3$, S_1 positive and S_3 negative; $S_2 = 0$

Two principal theories of initial yielding are used in predicting the strength under combined stresses: the critical shear stress theory and the critical shear strain energy theory. Shear stresses are those stresses which tend to cause one part of a body to slip over another part, as opposed to normal stresses which act in such a way as to tend to separate the body along a plane normal to the stress direction. It is recognized that shear stresses are the important stresses in controlling plastic flow. The maximum shear stress theory of yielding states that plastic action will begin when the maximum shear stress reaches some critical value characteristic of the material, the maximum shear stress being given by half the difference between the greatest and the least principal normal stresses. If the yield point in the tension test is designated as S_0 , the maximum shear stress yielding criterion can be stated as:

$$\text{Critical shear stress} = \frac{S_1 - S_3}{2} = \frac{S_0}{2}$$

As an example of the use of this relationship, the value of the greatest principal stress at yielding will be calculated for torsion, where the state of stress is: $S_1 = -S_3$; $S_2 = 0$. For purposes of illustration, it is assumed that the yield point in simple tension, S_0 , is 100,000 lb. per sq. in. It is then found that:

$$S_1 - S_3 = 100,000$$

$$S_1 - (-S_1) = 100,000$$

$$S_1 = 50,000$$

This solution indicates that a bar which is twisted will yield at half the value of the greatest principal stress, S_1 , at which a bar pulled in tension will yield.

The other important theory of yielding is the shear strain energy theory. As a body is loaded in the elastic range, elastic strain energy is stored up, just as when a spring is stretched. The total elastic energy stored in a body consists of two parts: that resulting from a change in volume of the body and that resulting from a change in shape of the body. The latter portion is known as the distortion energy or the shear strain energy. According to the shear strain energy criterion for initial yielding, yielding will occur when the shear strain energy reaches a critical value, which is dependent upon the material. This criterion can be expressed in terms of the three principal stresses as follows:

$$(S_1 - S_2)^2 + (S_2 - S_3)^2 + (S_3 - S_1)^2 = 2S_y^2$$

where S_y is again the yield point in simple tension. If the problem of the torsion of a bar of 100,000 lb. per sq. in. yield point material is again considered, it will be found that the value of S_1 at yielding is 57,700 lb. per sq. in. as compared to the value of 50,000 lb. per sq. in. predicted by the maximum shear stress theory, a difference amounting to 15.4 per cent. In actual experiments conducted to test the two theories, the predictions of the shear strain energy theory are generally found to be in better agreement with the experimental results. The maximum shear stress theory is sufficiently accurate for many purposes, the difference between the predictions of the two theories never amounting to more than the 15.4 per cent cited for the example of torsion.

Another direction in which the significance of the tension test has been extended is the development of the concept of the so-called true stress-strain curve. Ludwik, a German investigator who was one of the outstanding figures in the development of better understanding of the mechanical behavior of materials, pointed out around 1910 that the definitions of stress and strain, as commonly used in materials testing and in defining engineering properties, are in some respects lacking in fundamental significance. Only in relatively recent years, however, have the concepts of Ludwik come to be widely used in this country. The principal criticism of the customary treatment of tensile data lies in the definitions of stress and strain, these quantities generally being referred to the initial dimensions of the specimen throughout a test. Such a procedure is obviously in error and has no real physical significance except at the very beginning of the test.

As a tensile specimen is stretched, its cross-sectional area diminishes progressively. Only at the beginning of the test, therefore, can stress be based on the original area without introducing appreciable, and, indeed, serious error. True stress, then, is defined as the instantaneous stress acting on the specimen and is computed by dividing the instantaneous load by the actual cross-sectional area at the instant that particular load is acting.

Since the area will have changed a negligible amount at initial yielding, the usual definitions of yield point and yield strength are satisfactory. Since the change in cross-sectional area at the maximum load is considerable, however, it must be concluded that the tensile strength is not a real stress and has no fundamental physical significance. Its principal use is for relative comparison purposes and in testing for uniformity of product.

The usual definition of strain, in which strain is referred to initial dimensions, is likewise in error. The inaccuracy of referring elongation increments to an original gage length can be visualized in the following

manner. If a bar ten inches long is stretched one inch, the elongation expressed as a percentage is 10 per cent. Now suppose that the bar, initially ten inches long, has been stretched to a length of 100 inches and is then stretched one inch further. The last inch of stretch referred to the original length would represent an elongation of 10 per cent. If, however, we base the elongation produced by the last one inch increment of stretch on the length of the specimen just prior to that increment, the elongation would be considered to be 1 per cent. Obviously, the latter procedure provides a truer physical description of the stretching process than referring the strains to the initial dimensions. "True strain" has been defined, therefore, in the following manner:

$$\text{True strain} = \int_{l_0}^l \frac{dl}{l} \\ = \log_e \frac{l}{l_0}$$

where l_0 is the original length between two gage marks, l is the instantaneous length between these marks as the specimen is stretched, and e is the base of Napierian or natural logarithms. \log_e is usually expressed simply as \ln , so that the above expression may be written: True strain = $\ln \frac{l}{l_0}$. According to this definition, true strain

is simply a summation of strain increments in which each increment is referred to the instantaneous specimen dimensions. A comparison of true strain with ordinary or nominal strain can be seen in Figure 49-13.

A stress-strain curve making use of true stresses and true strains provides a more fundamental description of the plastic behavior of a material than the ordinary nominal stress-strain curve and can, therefore, be expected to be of greater general significance. In practice, the method of determining true stress depends to some extent upon the shape of the specimen. For a cylindrical specimen, a convenient method is based on simultaneous measurements of load and minimum specimen diameter. The true strain can be calculated from area changes as well as from length changes, since the volume of the specimen does not change by a significant amount during plastic deformation. Therefore,

$$A_0 l_0 = A l \quad \text{and} \\ \frac{A_0}{A} = \frac{l}{l_0}$$

where A_0 and l_0 are the original cross-sectional area and length, A and l are the instantaneous area and length, respectively. Since true strain was defined as $\log_e \frac{l}{l_0}$,

it follows that $\log_e \frac{A_0}{A}$ also represents true strain. Pointed

micrometers should be used in the diameter measurements for the determination of true strain, especially after maximum load when the local constriction produced by necking down has become appreciable.

With thin sheet specimens, where area measurements are difficult to make, an extensometer can be used up to maximum load; i.e., during the period of uniform elongation, for obtaining length measurements to be used in calculating true strain. In order to obtain instantaneous area values for the calculation of true stress, the constancy of volume condition is used, thus permitting a computation of area changes from length changes. This procedure must not be used after maxi-

FIG. 49-13. Comparison of nominal and true strains.

FIG. 49-14. Typical true stress-strain curve.

mum load because of the nonuniformity of the elongation along the gage length which arises as a result of necking down.

An example of a true stress-strain curve is shown in Figure 49-14. It can be seen that the true stress rises continuously with increasing true strain. This is a consequence of strain hardening which is active during the entire test up to the instant of fracture. It is apparent that the ordinary load-extension diagram does not provide a clear-cut description of strain hardening. The strain-hardening characteristics of a material are of especial importance in sheet metal forming operations where the ability of the sheet to work harden and thereby pass the deformation along from element to element is critical. This is only one example of many problems where the true stress-strain curve, which is based on actual physically existent stresses and strains rather than fictitious ones, provides a more rational approach to the understanding of material behavior under loading.

The significance of the ductility properties determined in the tension test with respect to service is much more difficult to interpret. Gillette has presented a very capable discussion of this question in the American Society for Testing Materials "Symposium on The Significance of the Tension Test of Metals in Relation to Design." Tensile ductility values are rarely used in design, primarily because it is indeed seldom that the amount of ductility needed for a certain service application is known. Furthermore, even if such a value were known, it is doubtful if it could be translated into terms of ductility measured in a tension test. As already mentioned, ductility specifications are almost universally based on engineering judgment and experience. Because of the many uncertainties in interpretation with our present state of knowledge, however, it must be recognized that the significance of tensile ductility is somewhat limited.

Gillette mentions a number of categories of service which require that the materials used possess a certain amount of ductility. The first example is that of plastic forming, especially where operations such as bending or deep drawing are involved, and the deformations may be sufficiently large to substantially exhaust the capacity of the material to deform. In attempting to apply tension-test ductility data to analyses of formability, it is important that care be taken to interpret the ductility data in the proper manner. Many attempts have been made to correlate the percentage elongation in 2 inches in the tension test with formability, and the general lack of success is well known. The total elongation in the tension test can only be considered as a rough indication of relative ductility to be expected in actual drawing operations. One obvious reason for the failure of the total elongation in the tension test to correlate with drawability lies in the fact that, as already pointed out, the total elongation value includes both the uniform and the local or necking elongation. In a stretching type of sheet metal forming operation, it is more logical to expect a correlation of uniform elongation with performance. Once a pronounced necking down or localization of deformation occurs in a

forming operation, the useful limit of elongation has been reached, since the material at positions removed from the neck can no longer contribute to the overall deformation necessary to successfully form the part.

The problem of bending provides another example of the lack of fundamental significance of total elongation in the tension test. In bending, the local elongation at fracture is of critical importance, and there is some evidence that the reduction of area in the tension test, which is a measure of the ability to deform locally, correlates with the ability of a material to be bent. This correlation is based on the fact that the peak elongations at fracture in the tension fibers of a bend approach the values of the local elongation in the tension test for the same material, provided the comparison is made on a true strain basis.

The second example of service cited by Gillette, which involves ductility, is that in which the normal service calls for plastic extension. In many structural applications, a small amount of local plastic extension may be very important in relieving local stress concentrations, thereby possibly preventing rupture. Readjustment of local stresses by local plastic flow may also occur in cyclic loading applications. Although the availability of sufficient ductility to permit these readjustments is very important, it is extremely difficult to predict just what amount of ductility is adequate. Again, the engineer must call upon his past experience and best judgment.

Ductility is sometimes demanded as an "insurance factor," that is, extra protection in the event of accidents or overloads. The ability to deform and absorb such overloads without rupture may be desired, although again the necessary amount of ductility may be unpredictable. Actually, what is required in this class of applications is the ability to absorb energy, or toughness, an attribute which depends not only on ductility but on strength as well. Toughness will be discussed in more detail in a subsequent section dealing with impact testing and notch toughness.

In considering the significance of ductility, it is important to recognize that ductility in the tension test, especially as measured by reduction of area, is strongly dependent upon microstructure and is considered, therefore, to be a "structure sensitive" property. The tensile and yield strength, on the other hand, are less structure-sensitive. Tensile ductility, therefore, may provide a useful means of detecting the presence of undesired microstructures, particularly in heat-treated steels, which could result in inferior mechanical performance.

In summary, it can be said that the tension test, if properly conducted and interpreted, is a very informative and versatile test, providing information on both the strength and ductility properties of materials. In addition to the direct application of some of the tensile properties in design, the wealth of practical experience built up around the tension test makes it extremely useful in specifying materials for particular applications as well as in the control of the uniformity of material supplied for those applications. This practical experience also makes the tension test an extremely useful tool in the development of new and improved materials for applications on which previous experience is available.

SECTION 3

HARDNESS TESTING

Hardness is a material characteristic which can perhaps best be defined in terms of resistance to deformation. The degree of hardness of a material can be

manifested in a number of different ways depending upon the conditions to which the material is subjected. In metals, the most commonly used measure of hardness

depends upon the resistance to penetration by a much harder body. Hardness may also be manifested as a resistance to abrasion or wear, as a resistance to cutting, as a resistance to crushing, as a resistance to deformation as in tension or compression, as a manifestation of resilience, i.e., rebound hardness, and others. In this discussion, attention will be focused on the types of hardness tests which measure the resistance to penetration under certain specified conditions, since these are by far the most widely used.

The extremely wide use of hardness tests, especially in conjunction with the making, shaping, and treating of steel, can be attributed not only to the extreme simplicity of sample preparation and test procedure, but also to the close relationship between hardness and other mechanical properties. The best example of the correlation between hardness and other mechanical properties is provided by quenched and tempered steels, where a hardness measurement permits a good estimate of most of the other mechanical properties. Hardness tests are especially well adapted to checks of uniformity of product, because of the great ease with which they can be made. If a process or treatment passes out of control, the departure from uniformity can frequently be detected in hardness changes in the product. It is primarily because of this usefulness in control of uniformity that hardness testing is used so extensively in the steel industry.

The two hardness tests used most widely are the Brinell test and the Rockwell test, each of these tests having been standardized by the American Society for Testing Materials. Because of their universal usage, these two tests will be described in considerable detail. Other types of hardness tests which have certain specialized applications will also be discussed briefly.

THE BRINELL HARDNESS TEST

In the Brinell hardness test, which was proposed by Dr. J. A. Brinell of Sweden around 1900, a spherical ball, usually made of hardened steel, is forced into the specimen under a definite static load. The size of the resulting indentation provides a measurement of hardness as it is manifested under the particular conditions of the Brinell test.

A Brinell hardness tester consists of a device for applying a predetermined static load to the specimen through the indenter. One of the most commonly used types of Brinell machines is shown in Figure 49—15. In this machine, the load is applied hydraulically, and a weighted yoke is provided to prevent the maximum load desired from being exceeded. The yoke, which carries weights proportional to the desired load, acts on a small piston in the hydraulic system. As the pressure is increased by pumping, the load on the indenter and on the yoke piston will gradually increase until the yoke and weights float, indicating that the desired load has been attained. As long as the weights float, the load will remain constant. A Bourdon tube is usually provided for the purpose of giving an indication of the rate of loading and the approach to the desired testing load. If the parts of the hydraulic system are well made and the pistons accurately lapped, this type of machine will provide a very accurate load application and is much to be preferred to the use of a Bourdon gage alone.

The standard indenter for the Brinell test used in this country is a 10-millimeter spherical ball which is usually made of hardened steel. For tests on extremely hard materials, cemented carbide balls may be employed. According to the ASTM Standard for the

Brinell test (A370-54T), a ball must not exhibit a permanent change in diameter greater than 0.01 mm. (0.0004 in.) when pressed with a force of 3000 kg. against the test specimen.

Once an indentation has been made, either its depth or diameter must be measured in order to obtain the Brinell hardness number. Measurement of depth of indentation, however, has never been approved as a standard method. The diameter is usually determined by a special measuring microscope which is fitted with a glass scale graduated in tenths of a millimeter. The depth of the indentation can be measured by a special device attached to the indenter. Although measurements of indentation depth can be made very rapidly, it has been found that, in general, hardness values determined on the basis of depth measurements are less reliable than those determined from diameter measurements. Unless great speed is desired, therefore, the diameter of the indentation should be used in determining the Brinell hardness number.

FIG. 49—15. Brinell hardness testing machine. (Courtesy, Tinus Olsen Testing Machine Company.)

Brinell-Testing Technique—In selecting and preparing the specimen for use in the Brinell test, a number of precautions should be observed. First of all, the specimen must be thick enough that no anvil effect is encountered. After a test, the side of the specimen opposite the impression must show no effect from the loading such as a local bulging. In order to avoid such effects, which may lead to fictitious hardness values, the thickness of the specimen should never be less than ten times the depth of the impression. Care should also be

taken that an indentation is not made too near the edge of the specimen. A distance from the specimen edge of not less than 2.5 times the diameter of the indentation should prove sufficient to eliminate edge effects. The specimen should be flat, and its surface should be sufficiently smooth that the periphery of the indentation appears sharply defined under the measuring microscope. Another precaution which should be observed is concerned with spacing of multiple indentations. A spacing of at least two indentation diameters should be used in order to avoid testing metal which has been disturbed by a previous indentation.

In the United States, the load for the Brinell test on iron and steel has been standardized as 3000 kilograms; for softer materials, a load of 500 kilograms may be used. In conducting the test, the prepared specimen is placed on the anvil, which is raised until the specimen is in contact with the penetrator ball, and the load applied as smoothly as possible. The load is held for at least 10 seconds in the case of ferrous materials and for at least 30 seconds for softer metals. In order to be acceptable by ASTM standards, the load-measuring device should indicate actual loads within 3 per cent tolerance.

In measuring the diameter of the indentation, most satisfactory results may be obtained by measuring in at least two directions and using the average in determining the hardness number. If the indentation is not circular, a directional variation in hardness may be present in the material being tested. On the other hand, out of roundness of the indentation may also indicate deformation of the indenting ball. The ASTM Standard requires that if a ball is used in testing a specimen of greater than 500 Brinell hardness number, it should be checked for permanent set after each indentation.

The Brinell hardness number is given by the quotient of the applied load and the surface area of the indentation, i.e.,

$$\text{Brinell Hardness Number (BHN)} = \frac{P}{A},$$

where P is the applied load in kilograms, and A is the area of the surface of the indentation expressed in square millimeters. It is important to note that the area referred to is the actual surface area and not the projected area of the indentation. If " D " is the diameter of the ball indenter, and " d " is the diameter of the indentation as measured with the Brinell microscope, the Brinell hardness number will be given by the relationship

$$\text{BHN} = \frac{\pi D}{2} \left(D - \sqrt{D^2 - d^2} \right)$$

where " P " is expressed in kilograms and " D " and " d " are expressed in millimeters. Tables have been calculated from this equation for the standard test conditions of 500-kilogram and 3000-kilogram loads and the 10-millimeter ball. Hardness numbers are tabulated for a wide range of impression diameters, so that it is merely necessary to locate in the table the diameter measured in the test and to read the corresponding number.

It may sometimes be desirable to obtain Brinell hardness values on very small specimens or thin specimens in which the standard loads and indenter would be too large to obtain a satisfactory test from the point of view of anvil or edge effects. In such instances, it is possible to obtain an approximate Brinell hardness number by reducing the size of the ball indenter, and at the same time reducing the applied load in proportion to the

square of the reduction in diameter of the ball. In other words, comparable test results should be obtained with different sizes of indenting balls, provided the applied loads are in the same ratios as the squares of the diameters of the indenting balls. For iron and steel, where the standard conditions call for a 3000-kilogram load and a 10-millimeter ball, the load " P " which should be used for a ball diameter " D " will be given by the equation:

$$\frac{P}{3000} = \frac{D^2}{10^2}$$

or

$$P = 30 D^2$$

A test carried out under other than the standard conditions is not considered as standard by the ASTM, but is merely recommended as an alternate if the specimen size prohibits a standard test. From Table 49—I, however, it can be seen that it is possible to obtain consistent results under a wide range of test conditions.

Table 49—I. Results of Brinell Hardness Determinations Using Various Loads and Sizes of Indenters

Diameter of Ball, mm.	Load, kg.	Diameter of Impression, mm.	Brinell Hardness Number
10.00	3,000.0	6.300	85
7.00	1,470.0	4.400	85
5.00	750.0	3.130	87
1.19	42.5	0.748	86

In considering the Brinell test, it should be remembered that the deformation of the indenter under load, in addition to a certain amount of recovery of the indented metal, prevents a perfectly spherical surface from being formed. When the indenting ball is pressed into the specimen, it tends to flatten to an extent which depends on the magnitude of the applied load, and thus creates a larger diameter of indentation than would have resulted had no deformation of the indenter occurred. This circumstance, of course, causes some error in the hardness tables, particularly at higher hardness levels. One of the principal reasons for standardizing on the size and characteristics of the indenting ball and on the magnitude of the applied load has been to circumvent this difficulty; in reality, an attempt has been made to standardize the error. In the "Hardness Conversion Table for Steel" presented in the ASTM Standards for Ferrous Metals, the effect of varying amounts of indenter deformation can be seen. Brinell hardness numbers are shown for standard steel balls, Hultgren balls (a cold-worked steel ball), and carbide balls for a 3000-kilogram load. Up to 433 Brinell hardness, the values agree for all three balls. Above 433 BHN, the carbide ball deforms least and indicates the greatest hardness of any of the indenters. When the indicated hardness with the carbide ball is 517, it is only 505 with a standard steel ball. Above 505 BHN no hardness values are given for the standard steel ball since in tests on harder materials it no longer conforms to the requirements for permanent set. However, a comparison of the Hultgren ball with the carbide ball is given at a considerably higher hardness level. When the carbide ball indicates 656 BHN, the Hultgren ball results in a value of only 615. Undoubtedly, if a material such as diamond were used as an indenter, a still higher hardness would have been indicated. In attempting to compare results of tests above 433 BHN, therefore, it is important to take into account the characteristics of the balls used in making the indentations. The type of ball used in tests at

THE MAKING, SHAPING AND TREATING OF STEEL

high hardness levels should always be designated in reporting test results.

THE ROCKWELL HARDNESS TEST

The Rockwell hardness test, like the Brinell test, measures that aspect of hardness which manifests itself as a resistance to penetration. Because of its simplicity, accuracy, and extreme versatility, the Rockwell test is more widely used today than any other type of hardness test. A wide variety of testing conditions is available, which permits testing over a wide range of hardnesses and also permits testing of very thin materials. In the Rockwell test, in contrast to the Brinell test, the hardness numbers do not bear a mathematical relation to diameter of indentation but are dial divisions, which indicate the depth of impression. Much of the inaccuracy associated with a measurement of total indentation depth is eliminated by the use of a differential depth measurement. The indenter is first seated by a minor load, after which a standardized major load is applied. It is the increment in indentation depth produced by the major load over that produced by the minor load which provides the basis of the Rockwell hardness. In this manner, the effects of small surface irregularities and surface disturbances caused by the indentation itself are eliminated and a very reproducible measurement is made possible.

The Rockwell hardness machine which is shown in Figure 49—16 is a precision-built apparatus which per-

FIG. 49—16. Rockwell hardness testing machine. (Courtesy, Wilson Mechanical Instrument Div., American Chain and Cable Co., Inc.)

mits the application of accurate, predetermined loads to standardized indenters, as well as a device for measuring the depth indentation produced. The load is applied through a system of weights and levers, and the rate of loading is controlled by a dashpot mechanism which provides a smooth, steady application of load. A dial gage which indicates depth directly during the test is provided for measurement of indentation depth, thus eliminating a separate operation such as required in the Brinell test. On the normal Rockwell machine, one dial division is equivalent to 0.002 millimeter penetration.

The penetrators which are most frequently used are

the spheroconical diamond penetrator and the $\frac{1}{16}$ -inch spherical steel ball, which are designated as the C-scale and B-scale penetrators respectively. The C-scale penetrator consists of a conical portion with a spherical tip lapped tangent to the cone. The angle of the cone is 120 degrees, and the radius of the spherical tip is 0.200 millimeter.

Specimen preparation for the Rockwell test is somewhat more critical than for the Brinell test, since the size of the indentation is much smaller. The surface of the specimen should be smooth, clean, and dry, and if a high degree of accuracy is desired, polishing through 2/0 or 3/0 metallographic paper is advisable. The surface to be tested should be free of scale and other foreign particles. The bottom surface should be reasonably flat, parallel to the test surface, and should also be free of scale or other matter which would tend to crush under the applied load. Pitted surfaces should be avoided. The presence of oil on the test surface will also tend to cause a low reading. The thickness of the specimen should be sufficient to prevent any anvil effect. It is desirable that no effect of the indentation be evident on the back side of the specimen, although if any such effect is not too pronounced, the hardness reading may not be greatly affected. It has been found in tests on specimens of commercially pure iron of Rockwell hardness B-35 that the readings were not affected by thickness down to a thickness of 0.040 inch, although the impressions showed through the specimen at 0.060-inch thickness. Although no definite procedure is specified by the ASTM, it is recommended that caution be exercised with respect to "anvil effect."

When the specimen has been prepared, it is placed on the anvil of the machine ready for testing. The anvil is raised slowly until the indenter is contacted, and continued to be raised until the minor load is applied. The small pointer on the machine dial shown in Figure 49—17 indicates the application of the minor load. When

FIG. 49—17. Indicating dial on Rockwell hardness testing machine. (Courtesy, Wilson Mechanical Instrument Div., American Chain and Cable Co., Inc.)

the minor load has been applied, the hardness dial is set to zero on the scale being used, and the major load is applied. The rate of application of major load, which can be controlled by adjustment of the dashpot mecha-

FIG. 49—18. Sketches illustrating principle of operation of Rockwell hardness testing machine. (Courtesy, Wilson Mechanical Instrument Div., American Chain and Cable Co., Inc.)

nism, is very important and should be checked periodically. The ASTM recommends that the travel of the operating handle of the machine be completed in four to five seconds, with a major load of 100 kilograms and with no specimen in the machine. The duration of major load application is also important, and should be controlled according to the procedures described in ASTM Specification E 18-55T.

When the major load is removed, and with the minor load still on, the hardness is read directly from the dial which is an integral part of the Rockwell machine. The scale of this dial is calibrated to read Rockwell hardness number directly, as already indicated. The dial is divided into 100 equal divisions on each of two scales, the "B" and "C" scales. In order to avoid confusion, the B-scale is printed in red, while the C-scale is printed in black. The B-scale also differs in that the zero is shifted counterclockwise 30 hardness points so that the marking for hardness of B-30 corresponds to that of C-0. In using other Rockwell scales on the standard machine, the red scale is always used with a ball penetrator and the black scale with the C-scale penetrator. The scale of the dial is numbered in such a way that low numbers correspond to deep impressions and relatively soft material, whereas a high hardness is indicated for a shallow indentation in harder material. The dial scale can be rotated manually and can always be set exactly on zero just prior to application of the major load. This arrangement permits a direct reading of the increment of penetration produced by the application of the major load over that produced by the minor load.

The principle of operation of the Rockwell testing machine can be seen from the series of sketches shown in Figure 49—18, which indicates the sequence of steps in a test in which the B-scale is employed. The operation is identical for other scales, with the exception of variations in major load and indenter.

Table 49—II. Rockwell Hardness Scales

Scale Symbol	Penetrator	Major Load, kg.	Dial Figures
Group One			
B	$\frac{1}{16}$ -in. ball	100	Red
C	Sphero-conical diamond	150	Black
Group Two			
A	Sphero-conical diamond	60	Black
D	Sphero-conical diamond	100	Black
E	$\frac{1}{8}$ -in. ball	100	Red
F	$\frac{1}{16}$ -in. ball	60	Red
G	$\frac{1}{16}$ -in. ball	150	Red
H	$\frac{1}{8}$ -in. ball	60	Red
K	$\frac{1}{16}$ -in. ball	150	Red
Group Three			
L	$\frac{1}{4}$ -in. ball	60	Red
M	$\frac{1}{4}$ -in. ball	100	Red
P	$\frac{1}{4}$ -in. ball	150	Red
R	$\frac{1}{2}$ -in. ball	60	Red
S	$\frac{1}{2}$ -in. ball	100	Red
V	$\frac{1}{2}$ -in. ball	150	Red

In Table 49—II, the various standard Rockwell scales are listed. As already indicated, the "B" and "C" scales are most widely used. The B-scale is used in what might be considered a medium hardness range, and is especially useful in testing low-carbon and medium-carbon steels in the annealed condition. The $\frac{1}{16}$ -inch diameter hardened steel ball, used as the penetrator in the B-scale test, is carried in a special chuck which permits rapid change of balls. The ball must not differ by over ± 0.0001 inch from its nominal diameter, and must not show a variation of over ± 0.00002 inch in diameter within itself.

The C-scale is the scale used most frequently for hardness above C-20. There is some overlapping in a number of the Rockwell scales, and for the sake of accuracy, it is desirable to select a scale such that the test value will fall in the middle of the scale range. In making B-scale tests, the steel ball tends to flatten at hardnesses of 100 and above, while at very low hardness near B-0, the impression is so deep that the cap holding the ball may contact the specimen surface and affect the reading. Likewise, in using the C-scale indenter at hardnesses below C-20, the impression is so deep that inaccuracies which may exist in the upper portion of the cone may affect the readings.

Rockwell Superficial Hardness Tests—It is frequently necessary to obtain a hardness value under conditions which prohibit the use of other than an extremely shallow indentation. The Rockwell superficial hardness tester has been developed for such applications. This test operates on the same principle as the regular Rockwell test, but utilizes much lighter loads and a more sensitive dial gage. The superficial test is particularly useful in hardness determinations on very thin strip, on nitrided or lightly carburized surfaces, and on very small parts or parts shaped in such a manner that they would collapse under the heavy load used in the standard test. The small indentation is also frequently useful in obtaining hardness readings very close to the edge of an object where an edge effect would affect the reading in a regular test.

Two types of indenters are used in superficial hardness testing. One indenter is the same $\frac{1}{16}$ -inch diameter ball used in the standard test, and is used in superficial tests on the softer metals, such as brasses, bronzes, and unhardened steel. The superficial hardness scales using this indenter are designated by "T." In superficial tests on harder materials, a diamond penetrator having the same configuration as the standard C-scale penetrator is used, the only difference being a more accurate finishing to final dimensions. This penetrator is designated as the "N diamond," and the corresponding hardness scales are referred to as "N" scales. Table 49—III shows the various superficial hardness scales, with the indenters and major loads used in each. It will be noted that major loads of 15, 30, and 45 kilograms are used. The minor load in every instance is 3 kilograms. Each scale division

on the hardness dial represents 0.001 millimeter penetration, as compared to 0.002 mm. on the regular dial.

Specimen preparation for the superficial test is very critical, and polished surfaces are advisable. Specimens should be flat and free from dirt and foreign matter on both upper and lower surfaces. Test blocks are available for standardization as for the regular Rockwell test.

Superficial hardness numbers are prefixed by a number indicating the major load used and a letter designating the indenter. For example, if a reading of 42 were obtained in a test using the N-diamond and a 30-kilogram major load, the hardness would be designated by Rockwell 30N-42. If the $\frac{1}{16}$ -inch ball had been used, on the other hand, the hardness would be indicated as Rockwell 30T-42.

THE VICKERS OR DIAMOND PYRAMID HARDNESS TEST

The Vickers hardness test is another of the class of tests which measures resistance to penetration. It is similar in principle to the Brinell test, but utilizes a different indenter and different magnitudes of loads. The indenter used in the Vickers test is a square-based diamond pyramid, and the hardness value obtained when using this penetrator is frequently referred to as the diamond pyramid hardness. The angle between opposite faces of the pyramid is 136 degrees, which was chosen so that the Vickers hardness scale would correspond approximately to the Brinell scale. This choice is based on the fact that it is recommended that loads be used in the Brinell test which result in indentations having diameters in the range of 0.25 to 0.50 times the ball diameter. The average of this range is 0.375 times the ball diameter, and if tangents are constructed to an impression of this size at the specimen surface, it will be found that the angle between the tangents is 136 degrees.

In making the Vickers test, the indenter is forced into the specimen and the diagonals of the square impression measured and averaged. From the known geometry of the indenter, the surface area of the indentation can be calculated once the diagonals have been measured. The diagonals are measured rather than the sides of the impression in order to obtain greater accuracy. The diamond pyramid hardness number is then calculated as the ratio of the applied load to the surface area of the impression. For the 136-degree square-based pyramid, the hardness can be calculated from the formula:

$$\text{Diamond pyramid hardness} = 1.854 \frac{D}{P}$$

where "P" is the load in kilograms applied in making the indentation, and "D" is the average of the measured diagonals of the indentation expressed as millimeters.

The principal advantage of the diamond pyramid type of test is that geometrically similar indentations are always obtained regardless of the load applied. This useful characteristic of the impression geometry is not obtained with the spherical indenter, since the ratio of impression diameter to depth varies with the actual depth of the impression. In the discussion of the Brinell test, it was shown that, in order to make tests on thin material, it is not possible merely to decrease the load, but that it is also necessary to decrease the diameter of the indenter in proportion to the square root of the change in load in order to obtain a comparable hardness value. Since geometrically similar indentations are always obtained with the pyramidal indenter, decrease in load permits a satisfactory test on thin material, thus permitting the test to be applied over a wide range of thicknesses and over a wide range of hardnesses.

Table 49—III. Rockwell Superficial Hardness Scales

Major Load, kg.	Prefix Symbols				
	N or Diamond Scale	T Scale, $\frac{1}{16}$ -in. Ball	W Scale, $\frac{1}{16}$ -in. Ball	X Scale, $\frac{1}{16}$ -in. Ball	Y Scale, $\frac{1}{16}$ -in. Ball
15	15 N	15 T	15 W	15 X	15 Y
30	30 N	30 T	30 W	30 X	30 Y
45	45 N	45 T	45 W	45 X	45 Y

Specimen surface preparation is very important for the Vickers test, and for very light loads should approach a metallographic polish. It is also recommended that the thickness of the specimen be at least 1.5 times the diagonal of the indentation. The Vickers test is especially useful at high hardness levels because the diamond indenter deforms very little as compared to the balls used in the Brinell test. Up to about 300 Brinell hardness, Vickers numbers and Brinell numbers are practically identical. Above 300, the Vickers number becomes appreciably higher, partially because of the deformation of the Brinell ball and partially because of the shallowness of the Brinell impressions, which causes the 136-degree conical impression to be no longer comparable to the spherical impression.

For certain types of research work where especially reliable hardness values are desired, the Vickers test has seen considerable use. For general utility, as in rapid production testing, however, the Rockwell test is more commonly used.

MISCELLANEOUS HARDNESS TESTS

When a property is difficult to define and arbitrary tests must be devised to measure it, almost certainly a multitude of tests will be proposed. Hardness is no exception, and a great deal has been written about the various hardness tests which have been devised. Each of these tests attempts to measure some particular aspect of hardness which the proponent of the test considered to be of importance. A few of the more important miscellaneous methods of measuring hardness will be mentioned briefly primarily for purposes of identification.

a. **The Shore Scleroscope Test**—This test, which operates on the rebound principle, was introduced commercially about 1907, shortly after the advent of the Brinell test. It was used to a considerable extent for many years as a supplement to the Brinell test. The advantages claimed for the scleroscope are its portability and the small size of indentation made. The portability feature permitted the testing of massive objects which otherwise could not be readily tested. A small smooth spot was prepared, the scleroscope placed over it and a reading taken. The small impression made by the tester also made it suitable for testing finished articles on which a large indentation would have been undesirable.

The scleroscope itself consists of a small diamond-tipped hammer enclosed in a glass tube which is provided with a suction bulb whereby the hammer may be raised to the top of the tube and dropped from a fixed and predetermined height. When the hammer is dropped on the object being tested, it rebounds to a height which is considered as a measure of hardness. If the impact were perfectly elastic, the hammer would rebound to its original height. A slight amount of energy will be dissipated in deforming the specimen, however, and this energy is not available for the rebound. A scale is provided on the instrument for measuring the height of the rebound, the units of the scale being obtained by dividing the average rebound from quenched high carbon steel into one hundred equal parts. In one model the height of rebound is determined by careful observation, while another model is equipped with an indicating dial.

In making the test, precautions must be taken that the specimen is solidly supported, the sound of the impact providing some indication of the solidity. The specimen surface must, of course, be smooth and flat. The tube of the scleroscope must be vertical and the surface being tested must be horizontal so that true vertical impact and rebound can be obtained.

The scleroscope is not used as much as in the past

because the advantages once held over the Brinell test do not hold over newer types of tests. Furthermore, the nature of rebound hardness is not as well understood as indentation hardness. Perhaps the principal use of the scleroscope test has been in testing the surface hardness of rolls for rolling mills. Most other testing machines have the disadvantage that the throat is not sufficiently large to accommodate a large roll, whereas the scleroscope can be placed directly on the roll surface.

It is of interest to note that the rebound principle has also been utilized in establishing a go-no go gage for the hardness of steel balls. Balls are allowed to fall from an incline onto a hardened steel anvil. The balls rebound into two bins, one placed above the other, so that hard balls rebound into the top bin and softer balls rebound into the lower bin.

b. **The Penetrascope**—This instrument is a portable hardness tester which is similar in principle to the Vickers test in that a square-based 136-degree pyramidal diamond is utilized as an indenter. The operation of the Penetrascope consists of application of a load on the specimen through the indenter and the measurement of the diagonal of the resulting square indentation. The load is applied by a hydraulic thrust unit and can be varied through a range up to 40 kilograms. The measurement of the diagonal is made using a microscope with an adjustable opening consisting of movable knife edges. The adjustment of the knife edge opening operates a micrometer counter so that the diagonal can be measured to an accuracy of 0.001 mm. The diamond pyramid hardness number is obtained from the length of the diagonal by reference to a table.

The indenter is mounted on a turret along with the microscope for alignment of either component over the test area. The diamond indenter may be interchanged with one and two mm. diameter ball-type indenters.

The instrument is attached to the work with a chain clamp, "C" clamp or an electromagnetic base. With these clamping devices the instrument can be adapted for testing various dimensions and shapes.

The usefulness of the Penetrascope lies in the fact that with it a tool is available in the shop having the reliability and simplicity of the Vickers test plus the adaptability of securing diamond pyramid hardness results directly from the product. These features are particularly advantageous in inspection of those products having special requirements of relatively high surface hardness, such as the working surface of cold-reduction rolls or teeth in hardened gears. Since the instrument provides a means of measuring hardness directly on the surface of the product it also furnishes a means of not only maintaining process control but also of improving the effectiveness of the control of variables that influence surface hardness.

c. **File Hardness**—Hardness testing with a file is an old and crude method of measuring relative hardness, but one which can be useful in the hands of an experienced operator. A standard file is rubbed against the surface to be tested. If the file does not bite, the piece is designated as file hard. The test is, of course, greatly dependent upon the human factor and can only be considered useful where relatively large differences in hardness are of interest.

d. **The Monotron Hardness Test**—In this test, the load required to produce an indentation of fixed depth is measured. The standard penetrator is a hemispherical diamond of 0.75-millimeter diameter which is forced into the specimen to a depth of 0.045 millimeter. The hardness is read in Brinell units directly from a dial on the machine while the load is on the specimen. The test can be made on a surface which has had no special prepara-

tion by using a preloading arrangement which seats the indenter. The basic principle of the Monotron test is that the same size of indentation is always obtained so that the strain distribution in the specimen is always the same. The contribution of work hardening to the measured hardness is thereby controlled to some degree.

e. The Cloudburst Tester—The principal use of the cloudburst tester is in determining the uniformity of hardness over a relatively large area of surface. Essentially, the cloudburst process is simply a shot-peening process in which the intensity of peening can be adjusted. The surface of the object being tested is subjected to a rain of small balls $\frac{1}{8}$ inch in diameter. The force of impact is adjusted to a point so the impact just fails to indent material of the desired hardness. Softer areas will then be delineated by peening marks. The original cloudburst machine was also used as a shot peener for the purpose of surface hardening.

f. The Telebrineller (or Brinell Meter)—This instrument is a portable hardness tester consisting of a rubber anvil containing a 10-mm. Brinell ball that protrudes through the base of the anvil, and a $\frac{1}{2}$ -inch square steel bar, of known hardness, that is inserted into the anvil to back up the Brinell ball. To obtain a hardness number the tester is held in such a way that the ball is between the bar of known hardness and the specimen. The anvil is struck a sharp blow with a hammer and the diameters of the indentations made in the bar and the specimen are measured.

The Brinell hardness number of the specimen is then determined by multiplying the ratio of the diameter of impression in the test bar to the diameter of the impression in the specimen by the Brinell hardness number of the test bar. This calculation is done on a hardness calculator furnished with the instrument.

The instrument is used in determining the hardness of large castings, railroad rails, pipe, etc.

g. Microhardness Tests—Although the applications of microhardness testing are highly specialized, more and more applications are being found, and many special problems can be studied with this type of test. One of the primary uses of a microhardness tester is in fundamental studies of the hardness of various phases in the microstructure of a metal. By the use of very light loads, extremely small indentations can be placed in different phases in the microstructure and their differences in hardness determined. Extremely small scale variations in hardness such as variations across the diameter of very fine wire or across the thickness of very thin sheet can also be measured.

Several microhardness testers are on the market, but perhaps the most widely used of these is the Tukon tester. The indenter provided with this machine is

known as the Knoop indenter, a pyramidal type of indenter which was developed by the National Bureau of Standards. The indentation produced is a long, narrow, diamond-shaped impression. It is claimed that the advantage of this indenter lies in the fact that elastic recovery along the long axis of the indentation is very small, thus reducing variation from this source, which could be especially troublesome at very low loads. Hardness numbers are based on the long dimension of the indentation and are calculated as the ratio of the indenting load to the projected area of the indentation. An application of the Knoop indenter to a study of the variation of hardness in the various layers of a galvanized steel sheet is shown in Figure 49—19. The Tukon tester can also be fitted with the Vickers type of diamond pyramid, so that ordinary diamond pyramid hardness numbers can be obtained.

Another principle of microhardness measurement is utilized in the **microcharacter**. The microcharacter is a small, cubically pointed diamond mounted under a very light load. A scratch is produced on a polished specimen by drawing the specimen under the diamond, and the width of the scratch is measured under a microscope. Variations in scratch width indicate variations in hardness, the narrower the scratch the higher the hardness.

Hardness Conversion Tables—It is evident from the descriptions of the various methods of hardness testing, that each test possesses certain inherent advantages. The choice of test for a particular hardness determination will depend on a number of factors, including the size of specimen and the hardness level. Frequently it may be desirable to convert a hardness reading obtained on one scale, say Rockwell "C," to some other scale, say Brinell hardness, for purposes of comparison with other data. Hardness conversion tables have been prepared for this purpose. The Society of Automotive Engineers, American Society for Metals, and American Society for Testing Materials have jointly prepared a set of conversion data for steels harder than 220 BHN, which is presented in Table 49—IV. Considerable discretion must be exercised in making hardness conversions, and particular care must be taken with regard to testing details if reliable conversions are to be made. Hardness conversion tables for other metals, including austenitic stainless steels, can be found in the ASM Handbook.

Significance and General Utility of Hardness Tests—It has been seen that the most widely used hardness tests measure resistance to penetration under certain arbitrarily chosen conditions. In forcing a penetrator into a metal specimen, the metal in the vicinity of the penetration is plastically deformed, in order that the penetrator can be accommodated. The factors controlling the amount and distribution of this plastic deformation are very complex and no exact quantitative analysis of the penetration of a metal by any shape of indenter has been developed. Qualitatively, however, it can be seen that resistance to penetration is a measure of resistance to plastic flow and should be related in some manner to the stress-strain curve of the material being tested, i.e., to the strength and strain-hardening properties of the material. In general for steels, a good correlation has been found to exist between hardness and tensile strength. A particularly close correlation exists in quenched and tempered steels where, in addition, yield strength and ductility can also be predicted reasonably well from hardness measurements. For this reason, the hardness test is of particular value in the field of heat-treatable steels.

In the making, shaping, and treating of steel products, the most extensive use of the hardness test is for inspection and control of uniformity. A good example of

*For the 10-mm standard steel ball, no values of Brinell hardness are given higher than 500 Bhn. This is in conformance with the limitations established by the Standard Method of Test for Brinell Hardness of Metallic Materials (ASTM Designation E 10).

"Brinell" is the trade name for the C-scale spheroidal diamond penetrator. The Superficial Brinell penetrator has the same configuration but is finished to closer tolerances. The values of scleroscope hardness number and approximate tensile strength are from the 1955 SAE Handbook. All other values are from ASTM Standard E 48-47.

such use is provided by the extensive use of hardness tests in the production of deep-drawing sheets. It is usually known from experience that the hardness must be within a certain range if the sheet is to successfully form a certain part. Because of the great ease of making

hardness tests on sheet products, very frequent tests can be made to assure that all the product is within the desired hardness range. Most uses of hardness tests are of a similar nature, depending upon a combination of ease of testing and correlation with other properties.

SECTION 4

NOTCHED-BAR IMPACT TESTS

The notched-bar impact test is, as the name implies, a test in which a bar containing a notch is supported as a beam and subjected to the impact from a moving mass having sufficient kinetic energy to break the bar. The energy absorbed by the specimen is measured by the loss in kinetic energy of the moving mass. Notched-bar impact tests were originally conceived with the idea of providing an indication of the ability of a material to absorb punishment under very severe service conditions. Notches or stress concentrations of one kind or another are present in most structures and, generally, are the origin of structural failures. It was suggested that the capacity of a material to absorb energy in the notched-bar impact test should indicate the ability of the material to absorb energy in the event of overloading in a structural member and the ability to resist failure at local stress concentrations. In recent years, the notched-bar impact test has taken on a more general significance, in that attention has come to be focused on the variation of energy absorption with temperature, rather than on the absolute level of energy absorption at a single testing

temperature. Many steels exhibit a rapid drop-off in the level of energy absorption in some critical temperature interval as the testing temperature is lowered. As will be discussed in more detail in a subsequent section, the temperature range in which this abrupt decrease in energy absorption occurs provides much more information about the notch-toughness characteristics of a steel than the energy absorption at a single temperature.

Impact-Testing Methods—The details of impact testing procedures are described in a tentative ASTM specification designated as E 23-47T. The most generally used impact testing machines are of the pendulum type such as shown in Figure 49-20. In this type of machine, the impact energy is furnished by the swing of a weighted pendulum. The available energy depends, therefore, on the effective mass of the pendulum and its velocity at impact. The point of impact is usually situated at the bottom of the swing, at which point the pendulum has attained its maximum velocity. The available kinetic energy at this point is equivalent to the potential energy just before the start of the swing. If the pendulum were allowed to swing through its arc freely without striking a specimen, it would rise to the height from which it had been released, neglecting the effects of friction and air resistance. If a specimen is struck, the pendulum loses the amount of energy required to break the specimen and will not swing to the full height from which released. The amount by which the pendulum fails to reach its original height provides an easy method for the measurement of the energy absorbed by the specimen.

The two principal types of notched-bar or notched-beam impact tests are the simple beam test and the cantilever beam test, the former being generally referred to as the Charpy type and the latter as the Izod type. The methods of supporting and striking the specimen in each type of test are shown in Figure 49-21. Actually, the simple beam, or Charpy type of test, is used more extensively because of its greater convenience for other than room-temperature tests. The Izod type of test is impractical for controlled-temperature tests. In the Charpy type of test, it is a simple matter to transfer the specimen from a controlled-temperature bath to the anvil support and to break it in a sufficiently short time that no appreciable temperature change occurs. The Izod test has the added disadvantage that even in room-temperature tests, each individual specimen must be clamped and unclamped in the support, causing a considerable loss of time.

The types of specimens which are used in the simple beam type of notched-bar impact test are shown in Figure 49-22. The keyhole-notch specimen is a very widely used impact specimen and that upon which most impact specifications have been based in the past. The V-notch specimen is coming into wider usage, however, and its use is now required in many impact specifications. The details of impact-test specimen preparation are of considerable importance in that, in some temperature regions of testing, the degree of scatter of test results may be increased by improper attention to specimen preparation. The most critical part of the impact

CHARPY

IZOD

FIG. 49—21. Method of striking and supporting Charpy and

specimen is the root of the notch, and it is especially important that the finish of the notch surface be free of pronounced machining marks and excessive cold work from the machining operation. The base of the notch should be accurately parallel to the back face of the specimen, and the specimen should be square, so that fracture will not start at a corner of the notch surface. In notching the keyhole specimen, a hole is drilled at the proper location and a slot sawed or milled to the hole. Special care should be exercised that the saw or cutter does not accidentally bite the bottom of the notch, since the notch contour will be drastically altered. In the V and U notches shown in Figure 49—22, special attention should also be given to machining marks, since such marks will be disposed parallel to the notch axis and thus are more effective as stress raisers.

In an actual impact test, the pendulum is raised to its release position, the specimen placed on the anvil, the pendulum released, and the energy absorption noted. Details of machine calibration and precautions to be exercised in the use of pendulum impact machines can be found in the ASTM Specification E 23-47T already mentioned.

Since a great deal of impact testing is conducted at low temperatures, it is important to consider some of the methods employed in obtaining controlled testing temperatures. As already mentioned, the simple beam type of specimen is best adapted to low-temperature tests, since it can be cooled in a bath of the desired tempera-

ture and readily transferred to the impact machine and broken in a very short time. Temperatures between 212° F and 32° F can be obtained by water baths properly heated or cooled. The volume of the bath should be relatively large compared to the volume of specimens introduced, in order to make the bath temperature more stable. The bath temperature is also stabilized by efficient insulation of the bath container. Stirring of the bath is recommended in order to minimize temperature gradients.

Temperatures from 32° F down to about -110° F can be obtained conveniently by the use of dry ice as a refrigerant. Acetone is frequently used as a bath with dry ice. The dry ice can be introduced directly into the acetone bath, the resulting bubbling action providing rapid temperature equalization. Below -110° F, it is customary to use liquid nitrogen as a refrigerant. The container carrying the specimen bath may be immersed in liquid nitrogen until the bath temperature is lowered to the desired point; an alternative procedure involves passing liquid nitrogen through a copper coil immersed in the bath to be cooled. If testing is being carried out in a well ventilated room, inflammable liquids may be used for the bath, provided proper fire precautions are taken. Iso-pentane is frequently used as a cooling bath, permitting temperatures down to about -255° F to be reached. It is important to point out that the use of liquid air in conjunction with inflammable liquids is extremely dangerous, and very severe explosions have occurred under these conditions. For optimum safety conditions when using either liquid air or liquid nitrogen, it is recommended that some non-inflammable bath be used for the lower temperature ranges of testing.

A series of commercial refrigerants marketed under the trade name of Freon possesses a number of excellent characteristics for low-temperature testing. Freon is non-inflammable, non-toxic, and non-corrosive. The particular Freon compound (CCl_2F_2) designated as Freon 11 has a freezing point of -168° F and a boiling point of about 75° F. Freon 12 (CCl_2F_2) has a freezing point of -252° F and a boiling point of -22° F. The principal disadvantage of this material is its low boiling point, which necessitates considerable special handling equipment. Freon 13 (CCl_2F_2) freezes at -296° F, thus permitting testing in the interval between the freezing point of Freon 12 and the boiling point of liquid nitrogen. Boiling liquid nitrogen is frequently used as a bath giving a testing temperature in the neighborhood of -315° F, and in a few instances boiling liquid hydrogen has been used for tests at -423° F.

For low-temperature tests, the bath should be located near the testing machine and arranged so as to permit the most rapid transfer of specimens from bath to machine. It is desirable to use tongs that are of the bath temperature to avoid conducting heat into the specimen.

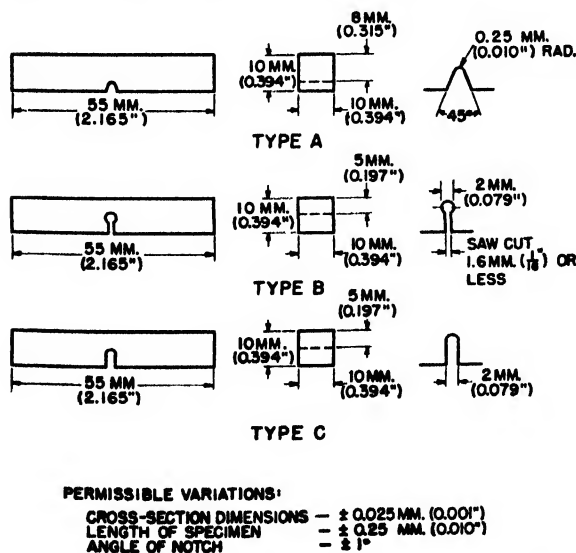

FIG. 49—22. Types of specimens for Charpy impact tests. (From "ASTM Standards, 1955.")

It should be possible to complete the test in from three to five seconds from the time of removal of the specimen from the bath, in which time the specimen temperature will have changed only very slightly. In tests at liquid nitrogen temperatures, the evaporation of the liquid on the specimen carried out of the bath may actually lower the surface temperature of the specimen to a slight extent.

Significance and Interpretation of Notched-Bar Impact Test Results—Before attempting to evaluate the significance of any notched-bar test, it is of the utmost importance to recognize that the behavior of a metal in such a test is strongly dependent on the geometry of test piece, rate of loading, and temperature of testing chosen as the basis of the test. Because of the extremely complex interrelationships among these variables, results obtained in some particular test cannot be translated directly, at least in our present state of knowledge, to a service application in which the conditions of loading are altogether different. Even if the energy-absorbing capacity needed in structures for safe performance could be estimated, which is rarely the case, the energy absorption in a notched-bar impact test could not be used directly as a design figure because of the lack of similarity of geometry and loading conditions. Impact specifications are, therefore, usually based on experience or engineering estimates, as has been seen to be the case in so many other mechanical-property specifications. Most impact-strength specifications are written in such a way as to specify the minimum energy absorption required, as, for example, 15 foot-pounds in the Charpy keyhole-notch test, at the minimum service temperature to be encountered. Although a steel passing such a specifica-

tion would probably perform better in service than one which did not pass, it must be recognized that passing does not necessarily assure the desired service performance. This uncertainty arises directly from the different geometry and loading conditions encountered in service, which are likely to be more severe than those in the small test piece used in the customary notched-bar impact tests.

The need for deriving a more general significance from notched-bar impact tests is obvious in view of such uncertainties as to the meaning of the results. The concept of the "transition temperature" does much to provide this more general basis of interpretation, not only for notched-bar impact tests, but for all other notch toughness tests. If a series of notched-bar impact tests is made on a ferritic steel at successively lower temperatures, it will be found that a temperature or temperature range will be reached where a very rapid decrease in energy absorption occurs. This is called the **transition temperature** or **transition temperature range**. Below this range, the energy absorption is very low, and the behavior is said to be brittle. Above the transition range, the energy absorption is relatively high, and the behavior is said to be tough. It is this transition from tough to brittle behavior that is now considered the crux of all notched-bar testing. The transition temperature provides the least uncertain basis for the comparison of the notch toughness characteristics of different steels. Two steels which would be considered alike in room temperature tests might be found to be markedly different, if compared on the basis of transition temperature, as can be seen in Figure 49—23. If tests are made at any single temperature above or below the transition range of both

FIG. 49—23. Schematic transition curves for two steels having same energy absorption at room temperature.

steels, it can only be concluded that the two steels are alike.

What, then, is the significance of the transition temperature with respect to service behavior? In structures such as welded ship hulls or welded pressure vessels, where a high degree of continuity exists in the strength members, rapidly propagating brittle-type fractures have in a number of instances resulted in complete structural failures. Presumably, if the construction materials had possessed greater toughness or energy-absorbing capacity under the design and loading conditions existing at the time of failure, the initiation of the fracture would have been prevented. It can be said that for the particular conditions existing at the time of brittle failure, the material which failed was below its transition temperature. In practically all of the brittle types of structural failures, the material involved exhibited entirely normal properties in the ordinary tension test, including a large amount of ductility. In spite of this fact, very little evidence of ductility could be found in the structural failures.

As already indicated, the temperature range of transition from tough to brittle behavior is markedly dependent upon the degree of restraint or state of stress imposed on the material. Sharper notches tend to raise the transition temperature; i.e., brittle behavior can be expected to occur at higher temperatures. Since extremely sharp notches and high degrees of restraint exist in most structures, particularly in welded structures having a high degree of continuity, the range of transition from tough to brittle behavior for most service conditions lies at higher temperatures than in the Charpy keyhole-notch test. This fact is extremely important, since it immediately follows that tough behavior at a certain temperature in a Charpy keyhole-notch impact test does not necessarily insure tough behavior at the same temperature in service. Because of the greater notch severity, the Charpy V-notch impact test shows a higher transition-temperature range, and would, therefore, be expected to correlate more closely with actual service. This indeed appears to be the case, as evidenced by many tests on steels of known service performance. The Charpy V-notch test is coming to be used more widely, and may well replace the keyhole-notch test in many specifications.

In attempts to correlate notch tests with service as well as with one another, it is essential that two types of transition behavior be recognized. In notched test specimens, a change in fracture appearance from a fibrous (shear mode) to a granular (cleavage mode) fracture occurs over a certain temperature range as the testing temperature is lowered. The temperature at some arbitrary point within this temperature range has been called the fracture-transition temperature. A drop in total energy absorption also occurs over the fracture transition range, but in many types of test specimens the energy absorbed at the temperature at which predominantly granular fracture is obtained is still appreciable. In this event, as the temperature is lowered still further, the energy absorbed continues to decrease. For some specimens and for some steels, a point is reached at which the energy absorbed drops suddenly to an extremely low value. This latter drop in energy, when it occurs, may be called the transition to brittle behavior, or, for simplicity, the ductility transition.

A performance curve showing both a fracture transition and a ductility transition might look like the solid curve sketched in Figure 49-24. The drop in energy at T_1 is associated with the change in fracture appearance which occurs at this temperature. The drop at T_2 represents the transition to brittle behavior. The dotted curve

FIG. 49-24. Types of transition curves.

of Figure 49-24 represents an instance in which no sharp ductility transition is obtained as for V-notched Charpy specimens. In this case, the evaluation of performance would have to be based upon some arbitrary low level of energy.

The cleavage mode of fracture is characterized by the separation of two portions of a crystal normal to some definite plane in the crystal. The separation of layers of mica or the cleavage of ordinary rock salt are examples of this type of fracture. A cleavage fracture in a ferritic steel exhibits a shiny, crystalline appearance because the fracture occurs essentially along a single plane in each ferrite grain, thus exposing a series of bright crystalline facets. The shear type of fracture, on the other hand, occurs by a sliding action; i.e., two portions of the grain separate by sliding over one another. The shear fracture is generally associated with greater amounts of plastic deformation than the cleavage fracture, especially during the propagation of the fracture. This results in a dull, fibrous appearance in the shear fracture. In general, therefore, the fibrous fracture can be interpreted as denoting a high energy absorption during crack propagation, whereas, the granular or crystalline fracture is associated with a very low energy absorption during crack propagation. It is for this reason that the latter type of fracture can be propagated at extremely high velocities and over great distances in a structure before the applied loads can be relieved.

The fracture transition, then, is regarded as being related to the ability of the material to resist rapid crack propagation. The ductility transition, on the other hand,

FIG. 49-25. Typical transition curve for Charpy keyhole-notch impact tests on a mild steel. (After R. W. Vanderbeck and M. Gensamer; "The Welding Journal Research Supplement," January, 1930.)

is related to the ability of the material to resist the initiation of a brittle fracture.

Since the transition from tough to brittle behavior in the impact test occurs over a range of temperature and the test results characteristically show considerable scatter in this range, some arbitrary method of defining the transition temperature or the transition-temperature range is necessary. A typical set of Charpy keyhole-notch impact data is shown in Figure 49-25. A procedure which is sometimes used to determine the ductility-transition temperature involves drawing an envelope about the results, as shown in Figure 49-25, and selecting a temperature near the middle of the envelope. Another procedure sometimes followed involves plotting the average energy absorption at each testing temperature and selecting the temperature at which the average curve crosses a selected energy level. It should be noted that the width of the scatter band will depend on the number of tests and the intervals between testing temperatures, but that the position of the middle of the scatter band will be less sensitive to these effects. Care should, of course, be taken that sufficient tests are made in the transition range that the middle of the range can be established within some predetermined number of degrees.

The results of Charpy V-notch impact tests are somewhat different in character, in that the transition from high to low energy absorption occurs over a wider temperature interval than observed for the keyhole specimen, as shown in Figure 49-26. The ductility-transition temperature is usually selected as the temperature at which a curve drawn through the average energy-absorption values reaches some selected low-energy level. The energy level selected is based on service experience or correlation with other tests. For rimmed and semikilled medium-carbon steels, a level of 10 to 15 ft. lbs. appears to give the best correlation with service performance. Other levels may be required, however, for other steels.

The fracture-transition temperature is usually based on some predetermined percentage of cleavage fracture. In some tests, where the fracture and ductility transi-

FIG. 49-26. Typical transition curve for V-notch Charpy impact tests on carbon steel.

tions are clearly separated, the fracture transition is also delineated by the change in energy absorption associated with the change in mode of fracture.

In conclusion, it can be said that the importance of the notched-bar impact test lies in its ability to discriminate between steels of varying susceptibility to brittle fracture, providing the results are interpreted on the basis of the temperature range of transition from tough to brittle behavior. The test is an extremely useful tool in the development of new and improved products with greater notch toughness, because of the possibility of detecting differences in materials which are not manifested in other tests, such as the tension test. Of particular value is the ability of the test to reflect differences in notch toughness caused by differences in steelmaking practices, as, for example, differences in deoxidation practice. Furthermore, on the basis of empirical correlations of Charpy V-notch impact-test results with service performance, it is now possible to evaluate with considerable reliability the suitability of steels for service in which a brittle-fracture hazard exists.

SECTION 5

FATIGUE TESTING

In a great many types of service applications, steel parts are required to withstand repeated or cyclic stressing; moving parts of machinery such as shafts, connecting rods, gears, etc., are examples of such applications. It has long been recognized that failures can occur in a machine part under repeated stress application at stresses well below those which the part is capable of withstanding under static load application. The failures which occur under repeated or cyclic stressing are referred to as **fatigue failures**. The importance of fatigue failures is well attested by the large percentage of failures in machine elements which are attributable to fatigue. It has been estimated that over 80 per cent of the failures in machines are a direct result of fatigue action.

Fatigue failures are progressive in nature, in that a crack is formed at some local spot or nucleus on the surface of the part after a certain number of load reversals, and is gradually propagated across the part. Finally, the remaining section becomes so small that it can no longer carry the applied load and complete failure ensues. A fatigue fracture generally appears brittle, even in metal which would be considered quite ductile in an ordinary tension test; the bright facets of the fracture led to the

erroneous concept that the metal had "crystallized." The extremely localized nature of the fatigue failure is one of its most distinguishing characteristics and one which must be constantly kept in mind in considering the danger of fatigue.

Fatigue failures can almost always be traced to a nucleus which is situated at some surface irregularity, such as a notch, a scratch, a flaw, or an abrupt change in section. It is evident, therefore, that the specific details of design and loading are of paramount importance in establishing the fatigue life of a particular part. The environment of the part is another aspect of the service conditions which is of great importance in establishing fatigue life in service. If the environment is at all corrosive, the fatigue resistance can be greatly impaired. It is obvious that the fatigue problem provides an excellent example of the importance of evaluating the actual service conditions to which a material is to be subjected, as discussed in the introduction to this chapter. Considerable data have now been accumulated which indicate that, if the actual loading conditions in the critical area of a part are accurately determined, the fatigue life of a particular material in that part can be

FIG. 49—27. R. R. Moore fatigue-testing machine. (Courtesy, The Baldwin-Lima-Hamilton Corp.)

predicted from simple laboratory tests. This conclusion has been reached on the basis of a comparison of results of both full-scale fatigue tests on actual parts, and service performance, with results on simple laboratory specimens.

The types of fatigue tests which are to be discussed here are those small-scale laboratory tests which are employed primarily to study materials, as opposed to tests of actual parts. Applicability of the results to service performance will be subject to the considerations of the relationship between test and service conditions mentioned above. It will be assumed that the tests to be discussed are at least capable of rating the relative fatigue properties of materials, and that, by properly taking into account particular service conditions, they may in many cases be directly applicable for design

purposes. Since so many of the applications to which steels are subjected involve repetitive loads, fatigue testing is considered of great importance since it is the only reliable method for evaluating the suitability of steels for this type of service.

Types of Fatigue Tests—The most commonly used type of fatigue test is the rotating-beam test, in which the specimen is subjected to a bending moment while being rotated. Any given fibre of the specimen is thus subjected alternately to compression and tension stresses of equal magnitude. One widely used machine of this type is the R. R. Moore machine shown in Figure 49—27. A schematic diagram of the loading arrangement is shown in Figure 49—28A, from which it is evident that a uniform bending moment is applied over the length of the specimen. Another type of rotating bending test utilizes a cantilever loading arrangement shown schematically in Figure 49—28B.

Another important type of fatigue test is the repeated bending or direct flexure test, in which the specimen is bent back and forth but not rotated. This type of test is particularly useful in the testing of specimens of flat rolled products. The direct flexure test has the further advantage that surface preparation of the specimen is not necessary, thus permitting the test to be made on specimens having the actual surface to be exposed in service. The mechanical type of machine shown in Figure 49—29 introduces the load into the specimen, which is fixed at one end, through an adjustable crank.

Direct flexure tests may also be of the resonant frequency type, in which the specimen is vibrated at its fundamental frequency by some oscillating applied force. Because of the characteristics of resonant vibrations, very small forces applied at or near the resonance frequency of the specimen are capable of producing large amplitudes of vibration and correspondingly high stresses. Some resonant frequency machines make use of an oscillating magnetic field tunable to the resonant frequency of the specimen. The specimen is supported at the nodes and vibrates as a free-free beam. By taking advantage of resonance vibration in this manner, specimens of relatively large cross-section can be tested

FIG. 49—28. Schematic loading arrangements for: (A) R. R. Moore and (B) cantilever-type of fatigue-testing machines. "S" indicates specimen and "P" indicates load, in both cases. (From "Manual on Fatigue Testing," published by American Society for Testing Materials, 1949.)

which would require very large machines if direct mechanical loading were employed. Other resonant frequency machines make use of mechanical rather than magnetic oscillators.

For certain types of fatigue, it may be desirable to conduct tests under direct, or axial loading conditions, i.e., the load is applied directly along the axis of the specimen. One of the major considerations in the design of axial-load fatigue machines is the provision of a loading arrangement which will insure the application of a truly axial load. Eccentricity of loading introduces

Table 49—V. Effect of Surface Condition on Endurance Limit

Moore & Kommers, rotating beam	
0.49% C quenched and drawn, 197 Brinell steel

Coarse file	33,000–34,000

bending moments in the specimen and may have a very pronounced effect on the observed fatigue properties. Most axial-load machines are designed so that tests can be conducted in which the mean stress is not zero, i.e., in which the stress is not completely reversed. In many service applications, a part may not be subjected to alternate compressive and tensile stresses of equal magnitude, as is the case in the rotating beam type of test. For example, the stress may vary from zero to a maximum of 10,000 lb. per sq. in. tensile stress, in which case the fatigue properties are quite different than if the loading produced a range of stresses from 10,000 lb. per sq. in. in compression to 10,000 lb. per sq. in. in tension. It should be pointed out that the direct flexure test also affords some possibility of variation in mean stress. In some types of direct-flexure machines, it is possible to bend the specimen back and forth about an average position different from its equilibrium position, thus arriving at an average stress other than zero.

As already indicated, the environment to which a part is subjected can exert a profound influence on the observed fatigue behavior. If corrosive conditions are involved in a cyclic loading application, it is necessary to conduct the fatigue test under the same corrosive conditions. Usually, the standard types of machines and specimens are used in corrosion-fatigue testing, it merely being necessary to provide a jacket about the specimen suitable for carrying the corrosive medium.

In the planning of corrosion fatigue tests, it is important to consider the relationship of testing frequency and rate of corrosion and to maintain a similar relationship to that existing in service.

Fatigue-Testing Specimen Preparation—The most critical aspect of fatigue testing is the preparation of the test specimen. As already pointed out, fatigue behavior is very sensitive to surface conditions, and unless extreme care is taken in surface preparation, large scatter and unreliable results can be expected. Table 49—V gives some indication of the effect of surface finish on observed endurance limit for a steel. In the preparation of cylindrical specimens for use in rotating bending tests, the specimen is first rough machined, great care being taken to obtain a concentric test section in order that the stresses can be calculated accurately. Following the rough machining operation, a finish machining cut is taken. This finishing operation should be made with a

FIG. 49-30. Sketch illustrating rotating-beam fatigue specimen (R. R. Moore type). (From "Manual on Fatigue Testing," published by American Society for Testing Materials, 1949.)

sharp tool and a light feed in order to prevent bending, overheating, or excessive cold working of the specimen. For steels harder than about Rockwell C-40, grinding should be used for the finishing operation. The finishing cut should allow about 0.003 inch to 0.005 inch on the diameter for polishing, which is the next step in the specimen preparation. In order to carry out this operation successfully, it is important to recognize that this polishing is actually a cutting and not a buffing operation. Buffing may cold work the surface layers of the specimen sufficiently to affect the test results. A wide variety of polishing procedures are employed in different laboratories, but, in general, fatigue specimens are polished by a series of alternate circumferential and longitudinal polishing operations in which successively finer abrasives are employed. In each stage, the scratches from the previous operation are completely removed, the final polishing being carried out in the longitudinal direction of the specimen, since longitudinal scratches are less harmful than those in the circumferential direction. The specimen is generally rotated slowly in a lathe during polishing, about five stages being used in the polishing operation. One criterion of satisfactory polish,

recommended by some laboratories, is that the surface produced should be satisfactory for metallographic examination at 100 magnifications. One of the types of specimens commonly used in rotating-beam tests are shown in Figure 49-30. In fatigue tests on notched specimens, great precautions must be taken in preparation of the root of the notch. The root of the notch should be very carefully lapped with a rotating, abrasive-bearing wire of the same radius as the notch root. Lapping should be continued until all circumferential scratches left by the machining operation have been removed.

In testing specimens of flat-rolled products, it is generally desired to include the actual surface of the manufactured product in the test, especially if this is the surface to be exposed in service. If such is the case, no extensive surface preparation is needed. It is desirable, however, to remove burrs from the edges of the specimen and to produce a very slight chamfer or radius of about 0.005 inch on the corners. Such a procedure will usually eliminate spurious edge effects which could affect the final results.

Presentation of Fatigue-Test Data—Data on the fatigue strength of metals are generally presented in the form of so-called "S-N" diagrams, in which fatigue life is plotted as a function of the applied stress. Such a diagram is shown in Figure 49-31. Test results are shown as open circles. It is convenient to use a logarithmic scale in plotting the number of cycles, since the duration of tests at low stress levels may extend to hundreds of millions of cycles. Most steels exhibit what is known as a fatigue limit or an endurance limit, i.e., a limiting stress below which an infinite number of stress cycles can be endured. The value of the endurance limit is the fatigue characteristic most frequently reported for steels. In some applications, such as aircraft parts, however, steels may be used at stresses above their

FIG. 49-31. Typical S-N diagram for a steel having a definite endurance limit.

endurance limit in order to permit savings in weight. Such parts are removed from service after some period of use based on some selected number of stress cycles. It is important to know, therefore, the highest value of stress which the material can withstand without failure for a given number of cycles. This value of stress is known as the **fatigue strength**, and is used not only for steels above the endurance limit but also in describing the fatigue characteristics of materials which do not show a true fatigue limit, such as austenitic stainless steels. Another fatigue characteristic sometimes reported is the fatigue life at some given stress level. For example, a part may be required to operate at a certain stress level. It then becomes necessary to select a material which can endure this stress for the greatest number of cycles.

In experimental determination of the endurance limit, it is customary to make the first test at a stress level well above the endurance limit, and to gradually lower the stress level in subsequent tests until the endurance limit is reached. If the approximate value of the endurance limit is not known beforehand, a tension test can be made, and the first fatigue test made at a stress level corresponding to about two-thirds of the tensile strength. It is obviously important to make the first tests

at high stress levels, since initial tests at stresses below the endurance limit are of very little value, because the proximity of a selected stress to the value of the endurance limit cannot be ascertained.

The S-N diagram for steels consists of a sloping portion and a horizontal portion corresponding to the endurance limit. For steels in a medium range of hardness, the knee of the curve will generally occur somewhere between one million and ten million cycles, so that an endurance limit value based on ten million cycles is usually satisfactory. Fifty million cycles may be somewhat more reliable, however, and judgment based on experience with the shapes of S-N diagrams for various materials should be used in selecting the maximum number of cycles for the series of tests to determine the endurance limit.

Significance of Small-Scale Fatigue Tests—There has been much discussion in recent years of the applicability of fatigue data derived from tests on small, highly polished bars to the prediction of fatigue life in service. One extreme point of view has been that such data are practically worthless and may even rate materials in the wrong order with respect to their service performance. This appears to be an unduly pessimistic attitude, especially in view of certain recent researches which in-

FIG. 49-32. Endurance limit as a function of tensile strength for polished, notched and corroding specimens. (From "Prevention of Fatigue of Metals," by the staff of Battelle Memorial Institute. Published by John Wiley & Sons, Inc., New York, 1941.)

dicating that if the service conditions are properly analyzed and if the state of stress at the critical point of a part is known, the endurance limit of the part can be related to that determined in a simple polished-bar test. Fatigue tests on full-sized automobile parts have provided the basis for this conclusion. It should not be inferred from these remarks, however, that results of polished-bar tests should be applied indiscriminately to predictions of service behavior. Frequently, the service conditions will be so complex as to preclude the possibility of accurate analysis. In this event, the only alternative is a simulated service test.

In general, the endurance limits of structural steels vary in a fairly regular way with tensile strength. An outstanding exception is provided by certain steels such as Bessemer steel or some of the high-strength low-alloy, phosphorus-bearing steels, in which the ratio of yield strength to tensile strength is higher than that normally found in most steels. In these steels, the endurance limit is relatively high for a given tensile strength, which may indicate that endurance limit is more closely related to the yield point than to tensile strength. The endurance ratio is defined as the ratio of the endurance limit to the static tensile strength and is in the neighborhood of 0.50 for most steels. Figure 49-32 is a schematic diagram for ordinary steels indicating the general relationship between endurance limit and tensile strength for polished specimens, severely notched specimens, and corroding specimens.

In considering the effect of notches on fatigue, it is customary to use as a measure of the notch effect the fatigue strength reduction factor, which is usually designated as K_t , and is defined as the ratio of the fatigue strength of a member or specimen with no stress con-

centration to the fatigue strength in the presence of stress concentration. It is obvious that the strength reduction factor has no meaning except in terms of a specific notch geometry. A concept of notch sensitivity originated by Peterson relates the strength reduction factor K_t to the theoretical stress concentration factor K_i resulting from the notch. K_i is the ratio of the maximum stress in a notched section to the nominal or average stress across the entire section computed from mathematical analyses or determined experimentally. Peterson defines notch sensitivity by a "q" factor which depends on the relative values of K_t and K_i in the following way:

$$q = \frac{K_t - 1}{K_i - 1}$$

Notch sensitivity according to this definition varies from zero (where $K_t = 1$) to unity (where $K_t = K_i$). This concept is useful in describing the reaction of a material to notches of varying degrees of severity. Since most actual parts subjected to cyclic loading actually contain stress concentrations of some type, it is important that the effect of notches on fatigue properties be considered.

In summary, it can be said that small-scale tests are very useful in comparing the behavior of different materials under repeated stress and can be used in studies of the effects of metallurgical variables on fatigue characteristics. Such tests not only form a useful guide in the development of new materials of improved fatigue strength, but also permit the evaluation of various surface treatments such as carburizing, nitriding, shot peening, cold rolling, etc. The effect of different environments on fatigue behavior also can be studied conveniently in laboratory tests.

SECTION 6

HIGH-TEMPERATURE TENSION, CREEP, RUPTURE AND HARDNESS TESTING

The design of load-bearing structures for service at atmospheric temperature is generally based on the yield strength—or for some applications, on the tensile strength—determined in the ordinary room-temperature tension test. In service at ordinary temperature with a design stress determined in such a way, the metal behaves essentially in an elastic manner, that is, the structure undergoes an elastic deformation immediately upon load application and no further deformation occurs with time; when the load is removed the structure returns to its original dimensions.

At elevated temperature the behavior is different. A structure designed according to the principles employed for atmospheric temperature service continues to deform with time after load application, even though the design data may have been based on tension tests at the temperature of interest. This deformation with time is called creep, since at the design stresses at which it was first recognized it occurred at a relatively slow rate. A somewhat similar, though not exactly analogous, phenomenon is the flow of tar under its own weight on a warm day. A detailed discussion of the subject of creep has been presented by Smith.

When creep was originally encountered—the subject first received experimental attention only several decades ago—it was logical to decrease the stress to a sufficiently low value that creep would not occur. Much of the early work was devoted to such an effort. It was discovered, however, that such a limiting creep stress was lower the greater the sensitivity of the measuring apparatus and that quite low stresses would have to be

employed to preclude the occurrence of measurable creep. In fact, the required stresses were so low and the section size correspondingly so large that the application of metals to high-temperature service was appreciably retarded. Accordingly, a new and more rational technique of design was developed and is now employed. This recognizes the existence of creep and is concerned not with avoiding its occurrence, but with limiting it to tolerable values within the contemplated service life of the structural member.

The rate of creep depends, for a given material, upon the stress, temperature and history of the material. Accordingly, the function of the creep-testing laboratory is to determine the dependence of creep upon such variables.

The possibility that creep may continue until fracture occurs raises another limitation in addition to that of the allowable deformation. In the use of metals at elevated temperature, not only must the design stress be chosen so that the deformation shall not exceed a limiting amount for the contemplated service life, but also it must be such that fracture will not occur. This latter characteristic is empirically related to the former. The variation of time for fracture or, as it is more commonly called, rupture, is determined in the so-called rupture test.

THE HIGH-TEMPERATURE TENSION TEST

The most common method for measuring the strength of metals is the tension test, which provides useful

FIG. 49-33. Elevated-temperature tension-test equipment showing specimen ready for testing in hydraulic tension test machine. Temperature control equipment at left.

information up to the temperature at which creep is encountered. The special techniques involved in performing the tension test at elevated temperature are covered by ASTM Specification E 21-43. Elevated temperature tension tests are made in conventional tension testing machines. The specimen is heated by a furnace supported on one column of the machine, the furnace being free to swing into and out of axial position. Figure 49-33 shows a general view of the equipment, including temperature controls.

Tests may be made on either bar or thin flat stock. For bar tests a 0.505-inch diameter specimen with threaded ends is gripped within the furnace; for sheet tests a longer specimen having a reduced gage section at mid-length is gripped outside the furnace.

The extension is recorded autographically by an extensometer, designed for this specific purpose, used in conjunction with a standard autographic recorder of the Selsyn motor type. With such equipment, accurate determinations of high-temperature yield strength may be made up to about 1400° F. This is well above the maximum temperature at which short-time yield-strength data should be used for design purposes; for high-temperature applications more reliable design information is obtained from creep or creep-rupture tests. Measurement of tensile strength, omitting determination of yield strength, may be made up to 2400° F. While of no particular value for design purposes, information on tensile strength, elongation and reduction in area at these very high temperatures is often useful as a guide for hot-working operations or for studying structural changes within the material.

The results of a series of elevated temperature tension tests on carbon steel and a wide variety of alloy steels are summarized in Figure 49-34. The strength of metals usually decreases with increase of temperature, but it will be seen from Figure 49-34 that the strength of plain carbon steel actually increases as the temperature of test is raised from room temperature to about 500° F.

This increase of strength and the accompanying decrease of ductility in certain steels is called "blue brittleness," because in this temperature range, the oxide film which forms on the steel has a bluish tinge. With further in-

FIG. 49-34. Tensile strength of various steels as measured at temperatures between room temperature and 1500° F.

crease of temperature, the strength of the material decreases, until at about 700° F, the strength is approximately the same as that at room temperature, after which the strength continues to decrease with increasing temperature. The increase of strength at 400° to 600° F is believed to be due to a selective segregation of carbon and nitrogen atoms during the progress of the tension test, and is usually called "strain-aging." The segregation, which may result in a special type of precipitate, is so small in amount that it cannot be detected under the electron microscope. The chemical composition of the precipitate is unknown.

THE CREEP TEST

Since strain hardening by cold working is progressive in steel stressed at temperatures below 700° to 800° F, and since creep is small and occurs at a decreasing rate at these moderately elevated temperatures, the tension test suffices for determination of strength values for design purposes in a temperature range from room temperature up to about 700° F. Above this temperature, steel will flow continuously under the applied load and design cannot be based on the yield strength or proportional limit as measured by the tension test. The rate of flow or creep rate is related to the stress, and the purpose of the creep test is to determine the stress which will result in a given creep rate.

The method of measuring creep resistance is simple

enough in principle, but in practice it requires considerable laboratory apparatus, and great care and precision in its operation. Disregarding for the moment the exact type of apparatus, the following fundamental steps are almost universally employed. The specimen is held at a constant temperature in an electric furnace, and is subjected to a static tensile load. The load causes the specimen to elongate gradually, and the amount of elongation is measured periodically. The total elapsed time of each test may be a matter of hours, weeks or months. Some creep tests have been run for more than ten years. In this country, the customary testing time is from 1000 to 3000 hours. The general method for creep testing is covered by ASTM Specification E 22-41.

At the E. C. Bain Laboratory for Fundamental Research at the United States Steel Research Center, Monroeville, Pa., there are six stands for creep tests, twelve stands for rupture tests in air, and two stands for rupture tests under an inert atmosphere or vacuum. A general view of these facilities including some of the temperature-control equipment is shown in Figure 49-35. The specimen of steel to be subjected to creep testing is machined to the shape shown in Figure 49-36. Indicating arms are attached to the specimen to bring the amount of elongation taking place in the gage length to a common point for measurement with a micrometer microscope. The assembly is then screwed into cast alloy-steel pull rods, and the whole unit is slipped into a tubular electric resistance furnace. The specimen is

FIG. 49-35. General view of creep and rupture testing equipment in the E. C. Bain Laboratory for Fundamental Research at the United States Steel Research Center, Monroeville, Pa.

FIG. 49—36. Creep specimen (bottom) and assembly used at the E. C. Bain Laboratory for Fundamental Research at the United States Steel Research Center, Monroeville, Pa.

held in a steel framework (Figure 49—37). It is anchored at the bottom, and attached to a lever at the top. When the specimen is loaded by hanging weights on the lever, the extension taking place in the specimen is brought to a single point by the indicating arms (Figure 49—36), on each of which is welded a platinum reference surface carrying engraved reference marks in the form of crosses. One surface moves vertically relative to the other, and by measuring the relative vertical displacement of the reference marks with a microscope carrying a micrometer eyepiece, the amount of elongation which has taken place in the specimen may be measured to an accuracy of about ± 0.00002 inch in direct reading. The operator is shown making a test measurement in Figure 49—38.

The temperature of the specimen should be held

within $\pm 1^\circ \text{F}$ over the gage length and from day to day during the 3000-hour ($4\frac{1}{2}$ -month) test period, since a change of as much as 2°F may cause enough thermal expansion or contraction to introduce an error into the readings. Such accuracy is necessary, since the amount of flow which can be tolerated in commercial parts operating at elevated temperature is very small—from a fraction of 1 per cent up to 1 per cent in 10 or 15 years—and accurate measurements of creep rates of 0.1 per cent or 0.01 per cent per 1000 hours must be made within the test period.

When the change of length taking place in the specimen from day to day is plotted against the elapsed time, a creep curve is obtained, whose typical form is shown in Figure 49—39. When the load is first applied, an immediate elastic extension (A) occurs. Then the speci-

FIG. 49—37. Diagrammatic representation of creep and rupture test stand.

FIG. 49—38. Creep test microscope in position for making measurements through window in wall of furnace at the E. C. Bain Laboratory for Fundamental Research at the United States Steel Research Center, Monroeville, Pa.

men stretches gradually, at a decreasing rate, during the "first stage" of creep (B). The rate then becomes constant for a period of time during the "second stage" of creep (C). The slope of the creep curve in this second stage is the creep rate commonly used for design purposes. Finally, if the load or temperature is high enough, or the time long enough, the creep rate increases in the "third stage" (D), leading to fracture of the specimen. At the end of the testing period, if fracture has not occurred, the load is removed and elastic contraction (E) occurs, corresponding approximately to the elastic extension found upon application of the load at the start of the test. Thus, it is apparent that metals creeping under stress at high temperature can and do show both plastic and elastic properties simultaneously. The amount of permanent deformation is represented by (F).

The exact shape of an individual creep curve depends on the stress employed and upon the temperature, as well as upon the composition and structure of the metal. While elastic extension is always found at the beginning and elastic contraction is always found at the end of the creep test, it is rare in any one test to find periods of decreasing, constant, and increasing creep rate. An actual creep curve for a steel at 1000° F under a tensile load of 10,000 lb. per sq. in. is shown in Figure 49—40.

FIG. 49—39. Schematic creep curve. Extension plotted against elapsed time. (A) Elastic extension; (B) creep at decreasing rate; (C) creep at approximately constant rate; (D) creep at increasing rate; (E) elastic contraction; (F) permanent change of length.

THE MAKING, SHAPING AND TREATING OF STEEL

Fig. 49-40. Actual creep curve of alloy steel under stress of 10,000 lb. per sq. in. at 1000° F.

Fig. 49-41. Schematic plot of typical creep curves for seven specimens of the same steel; each specimen tested under a different stress ranging from a very high stress, curve A, to a very low stress, curve G, at a constant temperature. (Taken from "The Interpretation of Creep Tests" by P. G. McVetty, Proc. ASTM, Vol. 34, Part 2, 1934; pp. 105-116.)

Two standards of creep strength are commonly used in this country: (a) the stress producing a creep rate of 0.0001 per cent per hour, often expressed as 1 per cent per 10,000 hours (a little over a year); or (b) the stress per 100,000 hours (about 11 years). The second standard is used in designing moving parts such as steam turbines, in which the total creep must be very small, for example, a fraction of 1 per cent in 20 years.

The stress for a selected creep rate for the material in question must be ascertained by experiment. This is done in the following manner: several creep tests are run under different stresses at a single temperature and the creep curves plotted on the same chart. A family of curves is shown in Figure 49-41. Three or four tests on any given material are usually sufficient to indicate its behavior at a given temperature. The creep rate during the second stage of creep is measured and plotted against the applied stress. On log-log coordinates, the points are found to lie approximately on a straight line as shown in Figure 49-42. The stress for a creep rate of 0.0001 per cent per hour or 0.00001 per cent per hour may then be obtained by interpolation or extrapolation.

In Figure 49-41 the line MN represents the end of a testing period which is too short to show the true long-time behavior of the material, since the later increase of creep rate in curve D, for example, would not have been detected, and the useful strength of the material would have been overestimated. For accurate determination of long-time creep strength, standard testing periods of from 1000 to 3000 hours are now generally employed to overcome this difficulty. Short-time creep tests may tell us that some materials are relatively

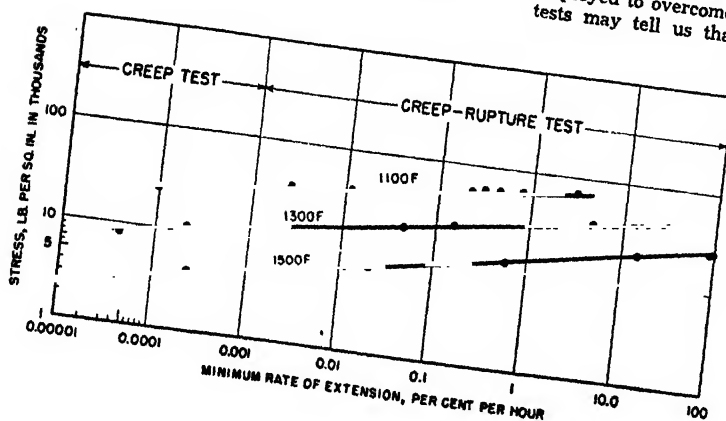

Fig. 49-42. Effect of stress on creep rate of 18-8 Mo (Type 316) steel at various temperatures.

FIG. 49—43. Effect of stress on time for rupture of 18-8 Mo (Type 316) steel at various temperatures.

stronger than others over the period of the test, but they tell little that is not revealed by a high-temperature tension test. Hatfield's time-yield and the standard German creep test, which deal with the amount of creep between the thirtieth and fortieth hours after loading, obviously cannot show the effect of a structural change which would not occur at the test temperature until several weeks after application of the load. Extrapolation from such short-time creep tests generally results in an over-estimate of the creep strength of the material under investigation.

THE RUPTURE TEST

The rupture test (sometimes called the stress-rupture or creep-rupture test) is identical with the creep test, except that the loads and consequently the creep rates are higher, and the test is carried to failure of the material. The apparatus for carrying out the rupture test is usually the same as that employed for the creep test, except that a different instrument is used for measurement of the elongation. In the creep test, the total strain is usually less than 0.5 per cent, while in the rupture test the total strain may amount to as much as 50 per cent or more. The rate during the second stage of creep may be measured as in the customary creep test and when the rate and corresponding stress are plotted on a log-log diagram, extrapolation to a lower creep rate, such as the standard 1 per cent per 10,000 hours, will give a fair prediction of the creep behavior of the material (Figure 49-42). This appears to be about the most reliable method of predicting long-time creep behavior from short-time tests, and has proved to be quite useful in preliminary surveys of the creep behavior of new materials being considered for elevated-temperature service.

In reporting rupture data, it is customary to plot the applied stress against the time for failure on log-log coordinates as shown in Figure 49-43. It has been found that after a certain time, the type of fracture changes from predominantly transgranular to predominantly intergranular, that is, from rupture primarily through the grains to separation primarily along the grain boundaries. Although this change is frequently associated with the increase in the downward slope of the log stress-log rupture time curve, convincing proof of such relationship is still lacking. Because of the change in slope, however, it is desirable to carry the rupture tests out to a considerable time period. Rupture values are usually reported as the stress for fracture in 100, 1000, 10,000, or 100,000 hours.

THE HIGH-TEMPERATURE HARDNESS TEST

The high-temperature hardness test is one of various elevated-temperature mechanical tests which has not

been widely used, but which promises to be valuable as a tool in determining the high-temperature behavior of metals. Two test methods have been developed for determining the hardness at elevated temperatures, one

FIG. 49-44. Schematic sketch of hardness tester used at the Edgar C. Bain Laboratory for Fundamental Research at the Research Center of the United States Steel Corporation.

Fig. 49-45. Relation between hot hardness and ultimate tensile strength for several ferritic and austenitic steels.

employing static loading and the second employing dynamic loading. A certain degree of standardization of test equipment employing static loading has been in evidence recently; in addition, refinements in testing techniques have made it possible to determine high-temperature hardness with the same accuracy and degree of reproducibility as in room-temperature hardness testing. Little attempt has been made to standardize dynamic loading apparatus or techniques. Little correlation is found between static and dynamic results. This lack of correlation is related primarily to the strong dependency of mechanical behavior at elevated temperatures on rate of deformation.

Fig. 49-46. Relation between hot hardness and creep strength of 18 Cr-8 Ni stainless and carbon steels.

The design of hot-hardness apparatus employing static loading has been based essentially on standard room-temperature equipment, including Vickers and Rockwell testers. Inert atmosphere, or a vacuum, have been employed in the test chamber to minimize oxidation. In all instances, small samples are used and a considerable number of hardness impressions are made on each sample at constant temperature or at different temperatures up to at least 1500° F. In hot-hardness apparatus based on the Vickers tester, the diagonals of the impressions are measured after cooling the specimen to room temperature.

A schematic sketch of the equipment used at the Edgar C. Bain Laboratory for Fundamental Research at the Research Center of the United States Steel Corporation is shown in Figure 49-44. In this apparatus the specimen, whose test surface is given a metallographic polish, and a Vickers-type indenter are heated to the desired temperature in a virtually inert atmosphere. The measuring thermocouple is spot-welded on the surface of the specimen. A dead-weight load ranging between 3 and 10 kg. is automatically applied to the indenter while in contact with the specimen. Following a loading cycle of one minute, the load is removed automatically and the sample rotated about its axis, which is offset from the indenter axis, in preparation for making a new impression at the same or at a different temperature. This apparatus has been employed in studying solid-state reactions such as strain-aging, phase changes during tempering and recovery and recrystallization phenomena. Other studies have shown that hardness results on steels at elevated temperatures are closely related to the tensile strength as shown in Figure 49-45, and approximately related to the creep strength as shown in Figure 49-46 and the creep-rupture strength as shown in Figure 49-47.

Fig. 49-47. Relation between hot hardness and creep-rupture strength for 18 Cr-8 Ni stainless and carbon steels.

SECTION 7

USE OF HIGH-TEMPERATURE DATA IN DESIGN

In studying the flow of metals under stress at elevated temperature, it should be noted that, to a much more marked degree than at room temperature, the lower the strain rate, the lower the apparent strength of material. The relation between the strength of carbon

steel as determined from the short-time tension test, and the strength of the same material as determined from creep and rupture tests is shown in Figure 49-48. At the lowest strain rates, permanent deformation occurs at high temperature under stresses less than the

FIG. 49—48. The effect of temperature on the strength of killed, 0.10 to 0.20 per cent carbon steel as indicated by tension, creep, and rupture tests.

yield strength or proportional limit as determined from short-time tension tests. In fact, continuous flow occurs under even the smallest applied stresses and design must be based on a dynamic rather than a static concept of the strength of materials.

Another important effect of the decrease of strain rate is the change in the type of fracture from transgranular to intergranular as the rate is decreased. The change in type of fracture is accompanied by a decrease in the amount of elongation. This behavior is character-

istic of all metals and alloys, and final failure under creep conditions tends to be brittle instead of ductile. The exact amount of elongation accompanying creep failure is usually unknown, since failure under creep conditions does not usually occur for many years. Extrapolation indicates that, in molybdenum steel, the amount of elongation at 1100° F decreases from about 38 per cent in a short-time tension test carried out at a strain rate of about 7.5 inches per inch per hour to less than 10 per cent under creep conditions.

FIG. 49—49. The effect of strain rate on the apparent strength of pearlitic (solid line) and spheroidized (dashed line) molybdenum steel at 1100° F. A and B indicate reported stresses for creep rate of 1 per cent per 10,000 hours in molybdenum steel at 1100° F.

FIG. 49—50. Variation of elastic moduli with temperature for various ferritic and austenitic stainless steels.

A clearer picture of the effect of strain rate on the strength of material is obtained when strain rates are plotted against the applied stress, as shown in Figure 49—49. In this study, a series of controlled strain-rate tests were carried out on spheroidized and pearlitic molybdenum steels at 1100° F. The most rapid test, at a rate of about 7.5 inches per inch per hour, is typical of the strain rates employed in the ordinary short-time elevated-temperature tension test. Tests were also carried out at 1, 0.1, 0.01, and 0.001 inches per inch per hour. Slower strain-rate data from stress-rupture and creep tests of these materials are also represented and show the same trend of decrease of strength. In fact, at a strain rate of 0.000001 inches per inch per hour, about 1 ten-millionth of the strain rate employed in the short-time tension test, the apparent strength of molybdenum steel at 1100° F, has decreased from 37,000 to 2,500 lb. per sq. in. This clearly illustrates the necessity of determining the strength of materials in the creep range from creep and rupture tests rather than from short-time tension tests. High-temperature design stresses, as set by the American Society of Mechanical Engineers, are established on the basis of long-time creep and rupture strength, and the limiting temperature is determined by the scaling resistance of the material. Below 700° to 800° F, the stresses are obtained from short-time tension data. Service experience and the behavior of similar materials are also taken into consideration. Allowable working stresses for the standard ferrous alloys may be found in Sections I and VIII of the ASME Boiler Construction Code and in the API-ASME Code for Unfired Pressure Vessels.

Under certain conditions of design at elevated temperature the permissible strain is of the order of magnitude of the elastic strain. It is necessary in such a case to compute working stresses on the basis of elastic properties of the material. In general, the design of structural members on this basis requires values of three constants of elasticity, the elastic modulus in tension and compression (Young's modulus), the shear

modulus and Poisson's ratio. Of equal importance is the fact that these elastic constants are also needed in computing the magnitude of thermal stresses.

The elastic moduli can be measured under conditions of static or dynamic loading. Under static loading, Young's modulus can be determined from a simple tension or a bend test and the shear modulus can be determined from a torsion test. Poisson's ratio (μ) is then computed from the following relationship:

$$\mu = \frac{E}{2G} - 1$$

where E is Young's modulus and G is the shear modulus. By subjecting a small cantilever beam to simultaneous bending and twisting by application of a single load it is possible to determine both E and G from a single test. Such a method has been employed to determine the variation of the elastic moduli under static loading for a number of commercial, ferritic and austenitic stainless steels up to 1500° F. Average curves for the results obtained are shown in Figure 49—50.

Under dynamic loading, high-frequency cyclic tests of relatively low stress amplitude are generally used. Both E and G can be determined from the measured velocity of longitudinal and transverse waves produced by high-frequency pulses. Dynamic tests on steels have been made up to 1600° F.

Theoretically it is predicted that the variation of the elastic constants, E and G , is linear with temperatures up to nearly the melting point of metals; however, deviations from linearity are caused by various phase and crystallographic lattice changes, magnetic changes and grain-boundary gliding in polycrystalline metals. Because of the low stresses encountered, the dynamic results are not affected by grain-boundary gliding. At temperatures where gliding at the grain boundaries is nil, below 700° F for plain carbon, 900° F for alloyed ferritic, and 1300° F for austenitic stainless steels, the static and dynamic results agree very well.

SECTION 8

MISCELLANEOUS MECHANICAL TESTS

Metals are subjected to a great variety of applications which may involve mechanical properties not directly measured in the more common mechanical tests already described. For this reason, a great many specialized tests have been developed which are usually aimed at a closer approximation to some important aspect of the actual service conditions than the ordinary tests provide. A few of the more important miscellaneous mechanical tests are briefly described in this section, in order to provide some indication of the types of tests which have been developed.

A. Compression Testing—Frequently, in the design of structural members which are to be subjected to compressive working stresses, it is desirable to design on the basis of compressive yield strength rather than tensile yield strength, particularly if there is reason to believe that the compression properties of the material under consideration differ from the tension properties. The data obtainable from a compression test may include the proportional limit, the elastic limit, the yield strength or yield point, and in some cases "compressive strength." The term compressive strength has been defined by the American Society for Testing Materials as the maximum compressive stress which a material is capable of developing. This strength figure has a definite value only for a material which fractures in compression. For other materials, arbitrary compression strength values are sometimes reported which are based on some degree of distortion which is regarded as indicating complete failure of the material.

An ASTM tentative specification for the compression testing of metallic material in other than sheet form has been drawn up and is designated as E9-49T. It is recommended that standard specimens be in the form of circular cylinders, the important feature in specimen preparation being parallelism of the ends and perpendicularity of the planes of the ends to the specimen axis. As in the case of tension testing, axial loading is of great importance. In some instances, a special subpress is used in conjunction with the regular testing machine in order to facilitate truly axial application of the compression load.

Compression members are frequently fabricated from sheet material, particularly for use in aircraft. In the design of such members, it is necessary to use the compression properties of the sheet material. Obviously, edgewise compression tests are not simple on thin sheets because of buckling difficulties. Several methods of testing sheet specimens in compression have been proposed. One of these is the "pack" method, in which a composite specimen is built up of several layers of sheets. In this way, a specimen of sufficient thickness to avoid buckling is provided. Another type of test provides support against buckling by special jigs. One such jig consists of a number of rollers which rest against the faces of the specimen. Another type of fixture which was developed at the National Bureau of Standards simply uses flat tool-steel blocks lubricated with a high-pressure lubricant to support the specimen (Figure 49-51). The specimen is allowed to overhang the supports slightly for loading and attachment of extensometers. Still another type of sheet metal compression test is the cylinder method, in which the flat specimen is formed, by bending rolls, into a cylinder about one and one-half inches in diameter and soldered along the longitudinal joint. This cylinder is very resistant to

FIG. 49-51. National Bureau of Standards jig for compression tests on sheet metals. (Courtesy, U. S. Department of Commerce, National Bureau of Standards.)

buckling and the ends can be accurately machined to insure axial loading. Another advantage of this method is the accessibility of the specimen for strain measurement. The principal disadvantage of the cylinder method is that a small amount of cold work is unavoidably introduced in forming the cylinder.

B. Bend Testing—The bend test, as the name implies, is intended to evaluate the ability of a material to undergo bending during forming operations to which it may be subjected. Generally, the bend test is conducted as a "go-no go" test; i.e., either the specimen meets the desired bend requirement or fails by cracking. In some instances, however, a ductility value is derived from the bend test by placing gage marks on the outside or tension side of the bend and measuring the elongation after completing the bend. This procedure is covered by ASTM Designation: E16-39 and was developed primarily for testing of welds.

Ordinarily the bend test is much simpler, merely involving a determination of whether or not a specified bend can be made satisfactorily. A typical method of stating a bend-test specification for a plate material, for example, is as follows: "The bend-test specimens shall stand being bent cold through 180 degrees without cracking on the outside of the bent portion to an inside diameter which shall have the following relation to thickness or gage of material." A set of bend diameters is then specified for various thickness ranges, the bend diameters increasing with increasing plate thickness. Edge conditions are very important and generally sufficient edge preparation is permitted to avoid an initial edge fracture. The method of bending is not specified and a large number of bending devices have been designed, the design usually being aimed at convenience so that large numbers of tests can be run in a relatively short time.

C. Cupping Tests—A number of so-called "cupping"

FIG. 49—52. Schematic representation of cupping test for sheet metals.

tests have been developed for the purpose of measuring the ductility of sheet metal under conditions where the sheet is stretched in all directions simultaneously. Cupping tests are made on different machines, or testers, known as the Erichsen, the Olsen, the Guillery, the Wazau, etc., of which the first two are the most commonly used. While they differ in many respects, the Erichsen and the Olsen testers are similar in the manner of applying the test. In both, the specimen of sheet or strip is clamped between two rings or dies, and a smooth ball, mounted upon or attached to a plunger, is forced against the flat surface of the specimen enclosed within the area of the ring, as shown in Figure 49—52, thus stretching it into the form of a cup, and continuing until the material is fractured. In the Olsen type of machine, the depth of the cup causing fracture is measured in thousandths of an inch by a recording or measuring device, the indicator of which is actuated directly from the surface of the sample. The end point of the test is indicated by a pressure gage, the pointer of which drops back upon fracture of the specimen. In the Erichsen tester, the plunger is somewhat cone-shaped with a

smooth spherical end; the fracture of the specimen is detected visually by a mirror attachment, and the depth of the cup is measured in millimeters.

In a great many actual sheet-metal forming operations, the blank is required to stretch in all directions. It would be expected, therefore, that a cupping test would prove a better criterion of the behavior to be expected in such forming operations than would a simple tension test in which the material is stretched in only one direction. Actually, the correlation between cupping tests and actual performance has in general been disappointing, except in cases where large differences in formability exist. Cupping tests are widely used for inspection purposes, however, since they provide a quick indication of ductility and some indication of the surface condition to be expected after drawing by the degree of roughness or coarseness developed on the cup during the cupping test.

D. Strain-Sensitivity and Strain-Aging Sensitivity Tests—Steel products are very frequently subjected to cold-forming operations prior to or during fabrication for their final use and may go into service in the cold-worked condition. As discussed in the chapter on plain carbon steels, the properties of cold-worked steel may change progressively with time, this change being known as strain-aging. The question arises, therefore, as to how the changes in properties brought about by cold working and strain-aging will affect the performance of the material in service.

It is well known that straining and strain-aging exert a profound influence on the notch toughness characteristics of certain steels, tending to increase the susceptibility of these steels to brittle fracture. One of the most informative methods of evaluating the effect of straining and strain-aging on notch toughness is the determination of the shift in transition temperature in the notched-bar impact test. The interpretation of the relationship between test results and service behavior is, of course, subject to the same limitations as empha-

FIG. 49—53. Effect of strain aging on transition temperature in the Charpy impact test.

sized earlier in the general discussion of notched-bar impact tests. It is possible, however, to obtain extremely useful comparisons among different steels and to provide relative measures of the extent to which the notch toughness is impaired by straining and strain-aging.

One testing procedure which has proved convenient and useful involves the cold rolling of oversize blanks for Charpy-type specimens. The degree of oversize is based on the desired amount of cold working; for example, if ten per cent reduction is desired, the blank is made about 0.0394 inch oversize and reduced to the standard dimension of 0.394 inch. Two sets of specimens sufficient for the determination of transition temperatures are prepared in this manner. One set is tested as soon as possible after rolling and notching, while the other set is artificially aged for one hour at 550° F. This treatment is believed to produce the maximum effect of strain aging on notch toughness. The shifts of transition temperature caused first by straining, and second by straining and aging give an indication of the extent to which the ability to resist brittle fracture has been impaired. Examples of the types of transition behavior which may be obtained are shown in Figure 49—53.

Another test which is sometimes used to indicate the effects of straining and strain-aging on notch toughness is the Graham tapered-bar test. Varying amounts of cold work are produced by drawing a tapered circular bar through a die so as to produce a uniform cross section. The bar is then notched at various points along its length which correspond to various amounts of cold work and is broken as a cantilever specimen at each notch. The maximum amount of cold work is usually ten per cent. The cold-drawn bar can also be aged before testing. Although this test is relatively fast and simple, it has the disadvantage of not permitting the determination of transition temperatures, and is thus subject to the uncertainties which arise in impact testing at a single temperature.

Steels which exhibit pronounced strain aging show an increase in tensile strength when tested at temperatures in the neighborhood of 400° F over that obtained in room-temperature tests. This increase in tensile strength is sometimes used as a measure of the effects of strain aging, but should not be substituted for a notch toughness test unless a correlation has been established.

Another aspect of strain aging, which is of great practical importance, is the return of the yield point in temper-rolled sheets intended for deep-drawing operations. Such sheets are normally temper rolled after annealing in order to eliminate the yield-point elongation and the accompanying tendency for the formation of stretcher strains or fluting during forming. In steels which are susceptible to strain aging, however, the yield-point elongation and stretcher-strain tendency will return with time. Accelerated aging, in which the temper-rolled material is held at an elevated temperature such as 400° F for some predetermined length of time, is frequently applied in order to indicate the aging tendency. The extent to which the yield point elongation returns in a tension test provides some indication of the manner in which the material can be expected to behave in a drawing operation after a considerable lapse of time at atmospheric temperature.

E. Torsion Testing—In the torsion test, a specimen is subjected to twisting or torsional loads analogous to those encountered in drive shafts, crank shafts, etc. Information on the strength in torsion, particularly the yield point or yield strength, is important in designing for such applications. Torsion tests are not extensively used, since a satisfactory estimate of the yield point in

torsion can generally be made from the yield point in tension. In some instances, however, a direct measurement of torsion properties may be desirable and occasionally may be specified.

Torsion data are usually obtained in the form of a torque-twist curve, in which the applied torque is plotted against the angle of twist. Torsion produces a state of stress known as pure shear, and the shear stress at yielding can be calculated from the torque at yielding and the specimen dimensions. Actually, the stress varies from a maximum at the surface of the specimen to zero at the axis. In the elastic range, the variation is linear, and the maximum stress for a cylindrical specimen can be readily calculated from the following relation:

$$S = \frac{16 T}{\pi d^3}$$

where: S = maximum shear stress (lb. per sq. in.)
 T = torque in inch-pounds
 d = diameter of specimen.

In the plastic range, the calculation of the maximum shear stress is more complicated and the reader is referred to the method developed by A. Nadai, which considers the twisting of a cylindrical bar in the plastic range.

In the elastic range, the shear strain is proportional to the shear stress, the constant of proportionality being known as the **modulus of rigidity**. The modulus of rigidity is about 10,000,000 for steel.

Impact tests utilizing dynamic torsional loads are used to a considerable extent in testing brittle materials such as tool steels. Since the ductility in torsion is greater than in tension, a greater energy absorption is obtained in the torsion impact test than in a beam type of impact test. Sensitivity is thereby improved making separations possible in the torsion impact which are not possible in the notched-bar impact test. The energy absorbed by the specimen in the torsion impact test is measured by the loss in rotational energy of a flywheel which engages one end of the specimen and breaks it.

F. Shear Testing—The term "shear testing" as used here refers to determinations of the resistance of metals to shearing in dies, i.e., cutting by shearing. "Shear test" is sometimes also used to refer to the torsion test, which, as indicated above, measures the resistance to deformation under shear stresses. The sense in which the terms "shear" or "shear strength" are used should always be clearly indicated in order to avoid any misinterpretation.

If a load-penetration diagram is determined while shearing a metal in dies, it will be found to be similar in general shape to the load-extension diagram in tension testing. The maximum load observed during the shearing operation divided by the area being sheared is taken as the shearing strength or shearing resistance of a material. It is necessary to state the exact testing conditions in reporting shearing resistance, since the value obtained will depend markedly on the die arrangement. The clearances, shear angles, and sharpness of the cutting edges will all affect the observed value of shearing resistance. The degree of penetration of the punch into the metal when the fracture begins is also usually reported. It has been generally observed that the shearing resistance of medium carbon steels is from two-thirds to three-fourths of the ultimate tensile strength.

G. Wear Testing—H. W. Gillette has defined the wear of a metal part as "its undesired gradual change in dimensions in service under frictional pressure." Wear generally involves two stages, in the first of which de-

formation occurs, and in the second of which removal of material may occur. Wear of metals may involve the contact of metal on metal, as in shafts and bearings, brakes and wheels, valves and seats; or it may involve the contact of non-metals on metals, as in the case of coke chutes, steam shovel buckets, etc. The phenomenon of wear is so complex that it is extremely difficult to interpret, and is one kind of service for which suitability can be reliably evaluated only in terms of actual service tests. Various wear tests have been used for specific purposes, but are only valid if the test method produces wear in the same manner in which it is produced in service. A more detailed discussion of wear and wear testing can be found in the ASTM "Symposium on Wear of Metals," published in 1937, and in "The Abrasion Resistance of Metals," by R. D. Haworth, published in the ASM Transactions, 1949.

H. Damping Capacity Tests—Damping capacity is a measure of the rate at which a material dissipates energy of vibration, or in other words, a measure of the ability to damp out vibrations. Damping depends upon internal friction in the metal, which is manifested at stresses well below those at which gross yielding occurs. Internal friction probably arises from minute amounts of plastic flow on a submicroscopic scale, a process which results in heating and a loss of vibrational energy. The ability to damp vibrations is of importance in certain structures subjected to vibrations, where there may be a danger of resonant vibrations arising. Resonance can lead to

large amplitudes of vibrations and excessively high stresses. A choice of a material with relatively high damping capacity, which can also satisfy the ordinary mechanical requirements, may be of some benefit in avoiding resonance conditions. High damping capacity materials are also of value in supports for moving machinery, in that the transmission of vibrations to the supporting structure may be reduced.

A commonly used method of measuring damping capacity involves the measurement of the rate of decrease of amplitude of torsional vibrations. One end of a cylindrical specimen is clamped in a rigid base with the specimen in a vertical position. On the other end of the specimen, a heavy inertia bar is clamped. This inertia bar is rotated through an angle corresponding to the desired stress level in the specimen, usually by means of magnets, and then released. The specimen is thus set in torsional vibration, and the rate of decrease of vibration amplitude is measured by some suitable method. In a recently developed machine, a light beam is focused on a mirror on the inertia bar, and the beam is reflected onto a rotating drum carrying a strip of sensitive photographic paper. Measurements of the rate of decrease of vibration amplitude from the photographic record permit a calculation of the damping capacity. Damping capacity is usually expressed in terms of **specific damping capacity**, which is defined as the ratio of the energy loss per cycle to the elastic potential energy at the maximum amplitude of the cycle.

SECTION 9

NONDESTRUCTIVE TESTS

Certain nondestructive tests, although not providing a direct measurement of mechanical properties, are extremely valuable in locating and isolating material defects which could greatly impair the mechanical performance if permitted to remain in a machine element or structural member placed in service. Since the part or article inspected by nondestructive methods is in no way altered or affected, it is possible to inspect the entire article. Furthermore, in many cases, it is feasible to carry out 100 per cent inspection of all product intended for applications which demand especially high quality. In this way, uncertainties as to whether representative sampling has been attained are eliminated. It should also be pointed out that an extremely important function of nondestructive tests is in the examination of parts which have been in service, such examination frequently being possible without removing the part from service. Incipient failures can oftentimes be detected in this manner, thus permitting removal of the part from service before serious damage is done. Since nondestructive testing provides such an important supplement to the conventional mechanical test procedures in evaluating suitability for mechanical service, it is appropriate that a few of the more important nondestructive testing methods be briefly described in this chapter on mechanical testing.

Radiography—Radiography is one of the oldest and most widely used methods of nondestructive testing. Its use is based upon the great penetrating power of X-rays or gamma rays, which, depending on their initial intensity, are capable of penetrating several inches of steel. X-ray tubes operating at voltages as high as three million volts are now in use capable of producing an X-ray beam which can penetrate six to seven inches of steel. Gamma rays, which are given off spontaneously by certain radioactive materials such as radium and by syn-

thetically produced isotopes such as Co^{60} , Ir^{192} and Cs^{137} , are capable of penetrating greater thicknesses than X-rays, and have the important advantage that the equipment required is entirely portable and requires no maintenance. The sensitivity of gamma rays to defects in thinner sections, however, is considerably inferior to that of X-rays, and X-rays are, therefore, more commonly used for radiographic work.

As a beam of X-rays or gamma rays passes through an object, it is absorbed to a degree depending upon the thickness of the object and upon the specific absorbing capacity of the material. Metals are characteristically strong absorbers of X-rays. If a cavity in the object being radiographed lies in the path of the beam, the effective thickness which must be traversed by the beam is decreased and the intensity of the emitted beam is greater in the vicinity of a point opposite the cavity. In this way, an image of the cavity is formed, which can be considered as an X-ray shadow picture. Any large cavity or inclusion which differs in absorbing capacity from the bulk of the test object will act in such a manner as to produce variations in intensity from point to point of the beam as it passes through the object. These variations in intensity or X-ray shadows, so to speak, are generally recorded on photographic film, but may also be observed visually by a fluorescent screen which is activated by the X-ray beam.

Considerable experience is necessary for the expert interpretation of radiographs, particularly in identifying the source of an indication and in judging how harmful the defect may be. A background of practical experience is usually built up by sectioning objects on which certain radiographic indications have been obtained, in order to positively correlate the indication with its source. The principal fields of application of radiography are in testing castings and welds. In castings, defects

such as pipe, shrinkage, hot tears, blowholes, and sand or slag inclusions may be detected by radiographic inspection. In welds, detection of hot tears, shrinkage cracks, blowholes, slag inclusions, lack of fusion, and lack of penetration is possible. One of the principal shortcomings of radiography is its inability to detect very thin defects, unless the plane of such defects lies parallel to the beam. A crack in which the surfaces are very close together is an example of such a defect. Since this type of defect can be very harmful in service, some other method of detection such as magnetic or sonic methods must be adopted.

Magnetic Methods—The magnetic methods of nondestructive testing to be described here are not aimed primarily at an evaluation of actual magnetic properties of a given steel specimen, as carried out for electrical or magnetic steels, but are employed for the measurement of some other characteristic of interest which is reflected by variations in magnetic behavior. Some of the principles of magnetism involved in such methods are discussed in Chapter 2, under "Fundamental Principles of Physics." The magnetic tests of primary interest here are those which are used in detecting physical discontinuities in steel. These methods depend upon establishing a uniform magnetic field around the steel part or test object, either by a magnetizing coil or by passing an electrical current through the part. Any physical discontinuity in the metal creates a magnetic flux leakage which can be detected by the use of magnetic powders or by a pick-up coil.

Magnaflux and Magnaglo are two widely used magnetic powders which are particularly useful in detecting fine surface and subsurface cracks. The Magnaglo powder differs only in that the magnetic particles are coated with a fluorescent material which glows under ultraviolet light. In this way, the contrast of the magnetic powder indication can sometimes be improved. In use, the powders are applied wet or dry to a magnetized part. If cracks are present, the leakage flux causes a local concentration of magnetic particles in the vicinity of the discontinuity.

The well known Sperry rail tester is an example of a magnetic flaw detector utilizing a pick-up coil. In using this device, a heavy direct current is passed through a rail section from a testing car as the car moves along. A uniform magnetic field is thus set up around the rail. If a transverse fissure is present in the rail the magnetic field is disturbed. A small coil moving along just above the track surface detects this disturbance by variations in induced current, which are recorded and used to indicate the location of the defect.

Ultrasonic Methods—Sonic methods have long been used in the detection of flaws or defects in steel. The clearness of the ring given off when an object is struck is well known to give an indication of soundness or freedom from gross discontinuities. The recent development of the ultrasonic testing techniques represents the culmination of much research to improve the sensitivity of sonic methods.

The ultrasonic method of flaw detection depends on the fact that when a beam of ultrasonic waves is projected into the metal object, a small physical discontinuity in the path of the beam acts as an obstacle to the beam. The reflection method, which is the most useful of the various ultrasonic techniques for flaw detection, makes use of the fact that a portion of the incident beam may be reflected from a discontinuity lying in the path

of the beam. By timing the interval between the generation of the initial pulse and the reception of the reflected pulse, the location of the defect can be determined. The ultrasonic waves are generated by a quartz crystal, making use of the piezoelectric effect, which causes the crystal to expand or contract when subjected to an electric charge. By using a rapidly oscillating electric field, the crystal is made to vibrate at the same frequency as the oscillation of the field. This effect is reversible, permitting the same crystal to be employed as a detector, in which case an oscillating electric charge is set up in the crystal as it is subjected to mechanical vibration. Measurement of this oscillating charge provides a method of detecting ultrasonic waves.

The reflection method of ultrasonic inspection has been successful in detecting a large number of types of defects such as pipe, shrinkage, cracks, flakes, fatigue cracks, concentrations of inclusions, segregations, and laminations. The method is rapid and is useful in production line work. As in the case of any nondestructive test, a background of experience must be built up in the interpretation of the indications with respect to the nature of the defect producing a particular type of indication.

Chapter 50

GAGE NUMBERS

In the metal industries, the word gage is used in various systems, or scales, for expressing the thickness or weight per unit area of thin plates, sheets, and strips, or the diameters of rods and wires. Specific diameters, thicknesses, or weights per square foot are denoted in gage systems by certain numerals prefixed to the word gage; for example, No. 12 gage, No. 20 gage, No. 30 gage, or simply 12 gage, 20 gage, and 30 gage. Gage numbers are used only in connection with thin materials; that is, usually when the thickness is not more than one-quarter inch or the weight per square foot is not more than 10 pounds, although most gage tables actually begin at about one-half inch, or 20 pounds per square foot, and one table begins at double these quantities. Heavier and thicker materials are always indicated by weight per unit area or length, or by thickness in English or metric units.

It is advisable, at this point to emphasize the danger of confusion in the use of gage numbers to indicate thicknesses and diameters. This danger is present in domestic as well as in foreign trade, and can be avoided by specifying thickness or diameter in inches, centimeters, or millimeters, or in weights per square foot or per square meter, or by giving other equivalents, in absolute units, of the gage desired. The relations and equivalents of the principal gages are shown in the several tables in this chapter.

Origin of Gages—This custom of indicating thickness and diameter by gage numbers originated in the early days of the metal industries, and the gage numbers were probably first employed to designate the different sizes that could be most readily produced by different stages, or steps, in the processes of manufacture. Inasmuch as these manufacturing processes sometimes varied considerably, not only for different commodities but often among different manufacturers of the same product, and as an individual system of measurement was often considered a trade advantage, a great number of gage systems came into existence. It has been said that at one time there were in use in this country and in England more than fifty different wire gages and several distinct gages for sheets. This condition alone would give rise to considerable confusion, but, as if confusion were to be sought rather than avoided, different names were often applied to the same or practically the same gage system. Also, the same names or symbols were frequently employed to designate different gage systems. All these systems were not only dissimilar with respect to each other in actual thickness denoted by the gage numbers, but the different numbers in the same table seldom bore any mathematical relation to each other.

Relation of Gage Number to Thickness—These gage systems had but one characteristic in common, namely, that the higher the gage number the thinner was the material. This relation of gage numbers to actual thicknesses has always been maintained, and the association of high gage number with thin material or with small

diameter has become fixed, by long custom, in the minds of people associated with the metal industries. With but few exceptions, this relation of gage number to thickness or diameter persists to the present time. The exceptions are the Sheet Zinc Gage, Belgian Zinc Gage, Paris (French) Gage, and Music Wire Gage, in which the gage numbers increase with the thickness of the sheet or the diameter of the wire.

British Gages—Chief among the early gage systems were the Birmingham gages, one for sheets and another for wire, and the Stubs' gages. As Stubs was from Warrington, his most popular gage was often called the Warrington Wire Gage, but was also known as Peter Stubs' Gage. In this country, Peter Stubs' Gage and the Birmingham Wire Gage are considered to be identical. The first attempt at reform in gages was to list the equivalent of the gage numbers in decimals of an inch. This was done first individually by Stubs, and later by organized action of the British Board of Trade, in 1883. In that year, a gage was prepared which was intended as a standard for both wire and sheets but was later found to be unsuitable for sheets. This gage became the legal British standard gage on March 1, 1884, and is now known as the British Imperial Standard Wire Gage, designated in the British Empire by the initials W.G. or B.W.G., and in the United States by the initials I.S.W.G. or S.W.G. When this gage was found to be unsuitable for sheets, a new gage, called the Birmingham Sheet and Hoop Iron Gage, was prepared by revising the old sheet gage. The new gage has since been used in England, merely by common consent until 1914, at which time it was established legally as the British Standard Gage for Iron and Steel Sheets and Hoops, represented by the symbols B.G. Custom gages for galvanized sheets now usually have B.G. suffixed to the gage numbers, but the weights have no systematic relation to the weights of the British Standard Gage (B.G.) for uncoated sheets. The earlier English gages, Birmingham Wire Gage and Stubs' Warrington Wire Gage, are no longer in common use except for telephone and telegraph wire. The relationships between the more common gages mentioned above are given in Table 50—III.

United States Sheet Gages—The next attempt at standardizing gages was made in the United States, in 1892. On March 3rd of that year, the United States Standard Gage for Sheet and Plate Iron and Steel (Table 50—III) was established by an Act of Congress as the only standard gage for these materials after July 1, 1893. This gage is a weight gage based upon weights per square foot in pounds avoirdupois. The gage table as established by Congress began with 20 lbs. per square foot, No. 7/0's gage, and ended with 0.25 lb. per square foot, No. 38 gage, but the light side of the table has been extended by custom to 0.1875 lb. per square foot, or No. 44 gage. In this country the gage is standard for all uncoated iron and steel sheet and plate, and is also used for tin plate in the lighter gages.

Galvanized and Long Terne Sheets have individual

gages based on the U.S. Standard Gage with allowances made for the thickness of the coating in each table. Thus, for the same gage number the weight shown in the Galvanized Sheet Gage regardless of coating weight, is 0.1562 pounds per square foot heavier than the weight shown in the U.S. Standard Gage (uncoated product). In the Long Terne Sheet Gage, each gage number may have various weights depending upon the coating weight. With a commercial coating (6 pounds per double base box) each gage number is 0.016 pounds per square foot heavier than the weight shown for the corresponding U.S. Standard Gage number. (See Table 50—IV).

As stated in the preceding paragraph, the U. S. Standard Gage is based on weights per square foot in pounds avoirdupois. Table 50—III shows the approximate thickness for each gage number adopted by the originators of the gage, who based these thicknesses on the density of wrought iron, which is 480 pounds per cubic foot or

0.2778 pound per cubic inch. Since the adopted standard density for steel is about 2 per cent heavier than that of wrought iron (489.6 vs. 480 pounds per cubic foot), the thickness equivalents for steel are slightly less than those listed in the U.S. Standard Gage. Although this change is legal because the governing factors in the gage schedule are weights and not thicknesses, much confusion occurs in converting from weight to thickness for steel sheets. Consequently, the manufacturers of steel sheets in this country have adopted a new gage, known as the Manufacturers' Standard Gage for Sheet Steel (Table 50—I). The gage numbers and corresponding weights in this gage are identical to those contained in the U.S. Standard Gage, but the equivalent thicknesses are less since they are based on the density of steel, not that of wrought iron. The conversion factor used in determining these thicknesses is actually greater than the density of steel by an amount necessary to allow for the facts that sheet weights are calculated on the basis of ordered width and length with shearing tolerances on the over side, and that sheets are thicker in the center than they are at the edges where thickness is commonly and most conveniently measured.

The factor commonly used in converting from weight to thickness of steel sheets is 41.82 pounds per square foot per inch thick (see Footnote, Table 50—III).

Density of Iron and Steel—In the foregoing discussion, the density of steel was given as 489.6 pounds per cubic foot or 40.8 pounds per square foot per inch of thickness, which figure has been adopted as the standard density of steel of the grades and kinds generally used in plates. The actual density of steel varies slightly with composition and treatment, and thus may be at variance with the adopted standard density as can be seen from Table 50—II, which presents data collected from various

Table 50—I. Manufacturers' Standard Gage for Sheet Steel

Gage thickness equivalents are based on 0.0014945 in. per oz. per sq. ft.; 0.023912 in. per lb. per sq. ft. (reciprocal of 41.820 lb. per sq. ft. per in. thick); 3.443329 in. per lb. per sq. in.

Table 50—II. Approximate Densities of Different Varieties of Iron and Steel.

Material (In Wrought Form)	Density (at 60° F.)		
	Grams per cc.	Lb. per Cu. In.	Lb. per Cu. Ft.
Pure Iron (99.9% Fe)	7.86	0.284	491
Soft Steel (0.06% C) ..	7.87	0.284	491
Carbon Steel (0.40% C)	7.84	0.283	489
Tool Steel (0.90% C) ..	7.82	0.282	487
Wrought Iron	7.40-7.90	0.267-0.285	461-493
Stainless Steel (18% Cr, 8% Ni) ...	8.03	0.29	501
Stainless Steel (17% Cr, 0.12% C) ..	7.75	0.28	484
Stainless Steel (27% Cr, 0.35% C) ..	7.47	0.27	467
High Speed Tool Steel (18% W)	8.75	0.316	546

From these values, it is evident that the weight gage thickness equivalents cannot be applied with accuracy to many of the high alloy steels.

The Tin Plate Gage—For tin plate and short terne plate, long custom has established the Tin Plate Gage, which is practically the same for this country and England. This gage is expressed in pounds per base box, rather than in gage numbers. By base box is meant 112 sheets, each 14 x 20 inches, or other combinations of number and size of sheets that will cover an area of

* Three intermediate fractional gages sometimes used are omitted in this table.
Table above is based on the theoretical weight which make the weight of a plate one foot square and one inch thick 40.8 pounds. Sheets and light plates are gaged on the edges, and the spring in the rolls causes the centers to be slightly thicker than the edges. To have the estimated weights of sheets and light plates equal the actual weight, the average weight of a square foot one inch thick is taken as 41.82 pounds.

Nominal Coating Weights, pounds per double base box

12

15

20

30

40

31,360 square inches. The gages of tin plate were formerly designated by symbols and names, as IC (Common), IX (X or Extra), DC (Double Common), 2X (two-X), ICL (Light), corresponding respectively to 107 lb., 135 lb., 139 lb., 155 lb., and 100 lb. per base box. In these symbols each X represents a specific additional weight and each L a specific decrease in weight. These symbols are falling into disuse, giving way to the more logical method of designation of pounds per base box.

U. S. Wire Gages—The wire gages in general use have never been legally standardized in the United States; the practice had been for each of the steel wire manufacturers to adopt his own gage. Chief among the historical gages are the gage of the American Steel and Wire Company, now a Division of United States Steel, which adopted the Washburn and Moen gage, and the nearly identical Roebling gage. Therefore, upon recommendation of the Bureau of Standards, these manufacturers' gages were merged into one gage designated as the Steel Wire Gage (Stl. W.G.), or the United States Steel Wire Gage (U.S. Stl. W.G.), which was accepted as the standard gage for all steel wire other than music wire. This is now the most commonly used steel-wire

gage in this country. For all sheets and wire made of metals other than iron and steel, the Brown and Sharpe Gage (B. & S. G.), or American Wire Gage (A.W.G.), is recognized as the standard gage in the United States. It was prepared by Messrs. Brown and Sharpe of Providence, R. I., at the request of leading manufacturers of nonferrous wire in this country. Another gage, known as the Edison or Circular Mil gage, is used by electrical engineers to simplify their calculations. This gage is based on the circular mil which is the area of a circle with a diameter of one mil (0.001 inch). Other gages in use are the Trenton Iron Company's gages, and Stubs' Steel Wire Gage. None of the wire gages mentioned above, however, has any legal authorization in this country. The only wire gage recognized in Acts of Congress is the Birmingham Wire Gage (B.W.G.), also known as Stubs' Iron Wire Gage, although it is not used to any extent by the wire manufacturers in the United States, except for telephone and telegraph wire (See ASTM A-111-52). This gage is sometimes used in designating the thickness of hoop and other strip steel products, but the tendency in these fields is to abandon the use of gages entirely and specify all thicknesses in thousandths of an inch.

This volume is printed on a 50-lb. basis special book paper, using the type face known as 8-point Texttype with Italic and Bold Face #2. The text columns are 37 x 55 picas (approximately $6\frac{3}{16}$ x $9\frac{3}{16}$ inches) in size, printed on $7\frac{3}{4}$ x $10\frac{5}{8}$ inch pages. A 120-line screen was employed for all half-tone engravings used in illustrations. The binding cloth is Fabrikoid, and aluminum foil was used for stamping the cover design.

Basic open-hearth process (cont.)			
finishing period	327	production rate	320
finishing temperature	314	Raoult's law applied to	325
flames	311	recarburizing	312
fluorspar as flux	311, 313	refining period	311
flush practice	309, 311	refining reactions related to	
fluxes for	172, 173, 311	slag composition	326
foaming of slag	311	residual elements	324
foundry use for steel castings ..	367	reversal	305, 320
front flushing	311	roll-scale additions	312, 313
fuel consumption	320	run-off slag	323
fuel economy in	83	scrap in charge	308, 309
furnace deoxidation	328	scrap oxidation in	310, 322
hearth area related to produc-		sheet-steel grades of steel	
tion rate	321	made in	585
heat balance	320, 321	silica in slags	322, 323, 326
heat time	313	silicon oxidation in	310, 311, 322
heat transfer from flame ..	311, 312	slags (see "Basic open-hearth	
heat utilization	83	slags")	
Henry's law applied to	325	spectrographic control	
high molten pig iron prac-		analyses	324
tice	309	steel composition control	324
historical	287, 289	steel tapping temperature	314
hot-metal addition	309, 313	steel types produced in	313
hot metal in charge	308, 309	strip-steel grades of steels	
inclusions in steel	329	made in	585
instrumentation	320	sulphur behavior in ..	311, 323, 327
iron ore in charge	309, 322	sulphur in slag	322, 323
iron oxidation in	310, 322	sulphur reactions	
iron-oxide boil	311	in	310, 311, 323, 327
jet tapper	314	sulphur removal in	327
ladle additions	314, 328	tapping	314
law of mass action applied to ..	325	tapping temperature	314
laws of chemical action	324, 325	teeming operations	294
lime boil	311, 313, 323	temperature considera-	
lime in slags	322, 323, 326	tions	322-324
lime ridges on hearth	318	temperature control	324
lime-silica ratio of slags	326	tin behavior in	322
limestone calcination in	323	tin-plate grades of steels made	
limestone in charge	308, 309	in	585
limestone sizing for	173	titanium oxidation in	322
loam applications in	320	tungsten oxidation in	322
magnesia in slag	322, 323	vanadium oxidation in	322
manganese oxidation		van't Hoff's law applied to ..	325
in	310, 311, 322	working period	311, 313, 324
manganous oxide in slag ..	322, 323	zinc oxidation in	322
mass action law applied to ..	325	Basic open-hearth slags (see also	
melting down the charge ..	310, 313	"Open-hearth slags")	
metal control	324	basicity related to oxygen	
mold additions	328	content of steel	326, 327
molybdenum behavior in	322	blast-furnace use of	174, 223
Nernst's law of distribution		compositions	322, 323, 325
applied to	325	control	311, 312, 313,
nickel behavior in	322	323, 324, 326	
nonmetallic inclusions in steel.	329	foaming of	311
ore boil	311, 313, 322	formation of	311
oxidation in	310	iron content	223
oxidation of charge	310, 322	manganese in	223
oxygen-carbon relationships		oxygen content of steel related	
in	328	to basicity	327
oxygen content of steel		pancakes for control	324
related to slag basicity	327	phosphorus in	145
oxygen for rapid oxidation of		run-off slags	309, 311
bath	312, 313, 321	slag-control methods ..	311, 312, 313,
oxygen sources for process ..	309	323, 324, 326	
port roof	302	slag pancakes for control ..	309, 311
phosphoric-acid anhydride		soil conditioners from ..	145, 175, 177
in slag	322, 323	Basic open-hearth steels

 air requirements 223
 alkali-metal oxide behavior
 in 143
 alkalies behavior in 143, 253
 alumina behavior in 143, 253, 254
 amphoteric behavior of
 alumina in 253
 arrangement of plant for 225
 arsenic behavior in 144, 253
 banking the furnace 249
 barium behavior in 253
 basic open-hearth slags in
 charge 174, 223
 beneficiation of raw materials
 for 259
 beryllium behavior in 253
 blast for (see "Cold blast",
 also "Hot blast")
 blast-furnace gas from 223
 blast requirements 223
 blowing in 245
 blowing out 249
 boron behavior in 253
 burdening the furnace 256
 cadmium behavior in 144
 calcination of carbonates in 253
 calcium carbonate behavior
 in 253
 calcium silicates behavior
 in 253
 carbon as reagent 250
 carbon behavior in 250
 carbon content of pig iron
 affected by temperature 251
 carbon in pig iron 251
 carbon-oxygen reactions
 in 254-255
 casting the furnace 237, 247
 charging the furnace 248
 chemistry of 250, 253-256
 chief impurities in charge 254
 chief metallic products of 221
 choking by ore fines 143
 chromium behavior in 253
 chromium-compound behavior
 in 143
 cleaning gas from 225
 cobalt-compound behavior in 143
 coke as fuel for 113, 137, 221,
 223, 254-255
 coke combustion in 254-255
 coke consumption by 221, 223
 coke functions in 225
 coke requirements 223
 cold blast for (see "Cold
 blast")
 columbium-compound behavior
 in 143
 columns for 223, 225, 237
 combustion in 254-255
 control of pig-iron
 composition 225, 245, 249
 control variables 245, 249
 controls for 245, 249
 copper behavior in 144, 253
 direct reduction in 143
 distributor 231, 232
 dolomite as flux in 172
 dolomite sizing for 259
 dry blast for 258
 drying-out methods 246
 dust collection 235
 dust control in 225
 dust in gas leaving top 235
 dust produced per ton of pig
 iron 254
 efficiency of heat utilization 82
 fanning the furnace 248
 ferrosilicon production 172
 filling the furnace 246
 flow diagram of 223
 flue dust from 143
 flue-dust control 223, 225
 flue-dust output 223
 flushing 247
 flushing slag 237
 flux consumption by 223
 flux functions in 225
 fluxes used in 172
 flux requirements 223, 225
 fuel requirements for 82
 fuels for 113, 137
 furnace input 223
 furnace output 223
 gas-cleaning methods 225, 235
 gas consumed by stoves 235
 gas produced by 223
 hanging of furnace 248
 hearth reactions in 254-255
 hearth temperature effect on
 carbon in pig iron 251
 heat utilization efficiency 82
 heating the bottom 246
 heats of formation
 involved in 250, 251
 heavy burden 256
 hot blast (see "Hot blast")
 hot iron from 256
 indium behavior in 144
 iron-bearing materials for
 charge 223
 iron disposal 225, 237, 247
 iron-notch closing 237, 238
 iron-notch opening 237
 iron-ore consumption by 223
 iron-ore impurities always
 reduced in 144
 iron-ore impurities not
 reduced in 143
 iron-ore impurities partially
 reduced in 143
 iron-ore physical require-
 ments 143, 223
 iron-ore requirements 143, 223
 iron ores used in 223
 iron-oxide reduction in 250
 iron removal from
 furnace 225, 237, 247
 iron-silicide formed
 in 252, 254, 255
 irregularities in 248
 instrumentation 245
 kish formation 251
 light burden 256
 lighting the furnace 246
 lime behavior in 143, 172, 254-255
 limestone as flux in 172
 limestone behavior in 254-255
 limestone consumption by 223
 limestone requirements 223
 limestone sizing for 173, 259
 magnesia behavior in 143
 magnesium carbonate behavior
 in 253
 magnesium silicate behavior
 in 253
 manganese behavior
 in 143, 250, 251, 252
 manganese-compound behavior
 in 143
 manganous oxide reduced in 254
 materials charged into
 furnace 223
 metallic products of 221
 mill scale in charge 223
 moisture control of blast 258
 molten pig-iron dis-
 posal 225, 237, 247
 nickel behavior in 144, 253
 nitrogen behavior in 251
 open-hearth slag in charge 223
 operating irregularities 248
 operating problems 143
 operation of (see "Blast-fur-
 nace process")
 ores used in 223
 outline of 223
 output 221, 223
 oxygen role in 250
 oxygen-carbon reactions
 in 254-255
 oxygen enrichment of blast 259
 phosphorus behavior
 in 144, 250, 251, 252
 pig-iron carbon content 251
 pig irons produced in 221
 plant for 223
 potash behavior in 253
 potassium behavior in 253
 potassium oxide behavior in 143
 power consumption per ton of
 pig iron produced 443
 precautions in starting
 operations 246
 pressure operation 259
 production rates 259
 products of 220, 221, 223
 purchased scrap for 205
 rare-earth metal oxide
 behavior in 143
 raw-materials beneficiation 259
 raw materials compositions 256
 raw-materials handling 225

Blast-furnace process (cont.)

raw materials required per ton	
of pig iron.....	254

 hot working contributes to...387
 rolling results in.....821
 steel.....387, 390, 821
 Disc-type filters
 principle of operation.....236
 Disc-type mills.....424
 Discharge
 electric (see "Electric discharge")
 Discoloration
 tin plate.....649, 650, 651
 Dishing
 wheels.....568, 575
 Disintegrators
 high-speed.....236
 rotary.....236
 Theissen.....236
 Dislocations
 crystal.....15
 Dissociation
 carbon dioxide.....58
 chemical.....22, 26
 hydrogen.....58
 Distillate fuel oils.....72
 Distillation
 ammonia recovery by.....117
 azeotropic, pyridine-base recovery by.....122
 batch (see "Batch stills")
 coal, destructive.....113
 continuous (see "Continuous stills")
 control of.....128
 fractional (see "Fractional distillation")
 light-oil recovery by.....125
 progressive, coal analysis.....63
 pyridine-base recovery by....121
 tar-acid refining.....136
 tube, assay test for coal.....63
 Distortion
 alloy tool steels.....839
 austenite grain size influences..795
 quenching stresses cause.....811
 Distribution coefficient
 definition.....23
 Distributor
 blast-furnace.....231, 232
 Divalent atoms.....22
 Dividing wall
 coke-oven heating chambers...95
 Doghouse
 open hearth.....304
 Dolomite
 alumina in.....181
 blast-furnace flux.....172
 burnt (see "Burned dolomite")
 calcined (see "Burned dolomite")
 calcium carbonate in.....173
 characteristics.....194
 chemical nature of.....30
 clinker.....185, 319
 clinkered.....185, 319
 composition.....172, 173, 181
 consumption per ton of steel produced.....184
 crushing.....259
 dead-burned (see "Burned dolomite")
 electric melting furnace use of. 337
 fluxing with.....172
 granular refractories from....184
 impurities in.....181
 kilns for burning.....185
 magnesium carbonate in.....173
 open-hearth refractory.....200, 319
 phosphorus in.....173
 preparation as flux.....173
 raw, uses for.....184
 silica in.....173, 181
 single burned.....319
 sizing.....173, 259
 sulphur in.....173
 Thomas-process consumption per ton of steel.....282
 uses for.....181, 184
 water in.....173
 Dolomite machine
 principle of.....318
 Dominant pool
 duplex process utilizing....360-362
 Door charging
 electric-arc furnaces.....341, 342
 Door cleaners
 coke oven.....108
 Door extractors
 coke oven.....107, 110
 Doors
 basic open-hearth.....200
 coke-oven.....93, 99, 104, 108
 open-hearth.....184, 297, 298, 301
 Dope
 pipe-coupling thread.....780
 Doping
 tubes for Rockriting.....762
 Dormant scrap
 analysis of.....205
 chemical analysis of.....205
 classification of.....204
 consumption of.....205
 sampling of.....205
 segregation of.....204, 205
 sources of.....204
 types of.....204
 DOS
 electrolytic tin plate treated with.....643

INDEX

- Double-acting steam hammers
 - principle of 387
- Double Belgian mills
 - wire-rod rolling 682
- Double bell and hopper
 - blast-furnace 229
- Double-block system
 - beehive coke ovens..... 91
- Double blowing
 - Thomas process 283
- Double collecting mains
 - coke ovens 105
- Double-divided coke ovens..... 98
- Double expanded-end pipe
 - welding of 785
- Double extra strong pipe..... 726
- Double-flange wheels 568
- Double forging
 - wheel blanks 573
- Double-lead process
 - wire patenting by 706
- Double normalizing
 - steel castings 374
- Double-piercing process
 - seamless-tube manufacture. 739, 743
- Double-refined iron
 - definition 214
 - mechanical properties 219
- Double replacement
 - chemical 20
- Double-rolled iron
 - definition 214
- Double shear steel
 - cementation process for..... 262
- Double-slag practice
 - acid electric-arc furnace
 - process 355
 - basic electric-arc furnace
 - process 353
 - steel foundry use of..... 367
- Double torsion springs
 - characteristics of 722
- Doublers
 - breakdown 596
- Doubling
 - packs for hot rolling..... 594, 596
- Down-and-up cut shears
 - primary-mill 472
- Down-cut shears
 - primary-mill 472
- Down run
 - water-gas producers 78
- Downcomer
 - blast-furnace 230, 231, 232
- Downtake
 - blast-furnace 232
- Draft
 - ore boats 242
 - roll-pass design related to..... 433
 - steel-casting molds 367
 - wire-drawing 684
- Draft gages
 - coke-oven 112
- Drafting
 - hot-strip-mill finishing
 - stands 589
- Drag bridle
 - electrolytic-tinning line 641
- Drag-out
 - electrolytic tinning 642
- Drag-over mills
 - two-high, rolling 420
- Drag section
 - foundry molds 370
- Draglines
 - open-pit iron-ore mining..... 161
- Drags
 - mold-car 294
- Drainage
 - open-pit iron-ore mines..... 160
- Draw bench
 - cold-drawing seamless tubes
 - on 757
 - cupping process 767, 769
 - plyer of 757
 - wire-mill 690
- Draw shrinkage
 - iron castings 380
- Drawbar
 - wire-drawing frame 684
- Drawing
 - beehive coke 93
 - cold 390
 - definition in wire industry..... 684
 - heat-treating operation (see "Tempering")
 - hot 389
 - patterns from molds..... 371
 - puddling process 212
- Drawing machines
 - wire (see "Wire-drawing machines")
- Drawing quality galvanized
 - sheets 662
- Drawing temperature
 - ingots 398
- Dresser-type joint
 - pipe coupling with..... 785
- Drifts
 - iron-ore mining 166, 167
- Drill pipe 726, 739, 785
- Drilling
 - billets 772
 - blast holes, open-pit mines..... 160
 - iron-ore mining 146
 - rails 529
- Drive bridle
 - electrolytic-tinning line 643
 - galvanizing-line 672
- Drive pipe 726
- Drives
 - manipulator 461
 - motor-generator sets 593
 - rolling-mill see "Rolling-mill drives")
 - screwdown 460, 592
 - shear 461
 - side-guard 461
 - table rollers 460
- Drop molding
 - refractories 183, 184
- Drop-of-the-beam method
 - yield-point determination 890
- Drop tests
 - rails 528
- Dross
 - galvanizing 666, 708
 - tin 647
 - tin purification 631
- Drum-type filters
 - principle of operation..... 236
- Dry air
 - scaling of steel in..... 596, 597
- Dry blast
 - blast-furnace 258
- Dry-bottom process
 - duplex steelmaking process... 362
- Dry bottoms
 - converters 272
- Dry cleaning
 - blast-furnace gas 235
- Dry drawing
 - wire 684, 688, 697, 698
- Dry finish
 - long ternes 657
- Dry granulation
 - blast-furnace slags 374
- Dry ice
 - coolant for impact testing..... 905
- Dry pressing
 - refractories 183
- Dry processes
 - coal preparation 67
 - portland cement manufac-
 - ture 178, 179
 - wire-drawing 684, 688, 697, 698

- Drycolene 414
- Dryers
 - ammonium sulphate 119
 - centrifugal 119, 120
- Drying
 - bars after pickling..... 555
 - basic brick 184
 - blast-furnaces 245
 - bottoms for converters..... 270, 272
 - cores 371
 - electric-arc furnace charge
 - materials 342
 - electrolytic tin plate..... 643
 - hot tops 343
 - ladles 343
 - molds for steel-base rolls..... 435
 - organic coatings 629
 - pickled flat-rolled prod-
 - ucts 599, 601
 - steel ladles 343
 - stopper-rods 343
 - stoves 245
- Ductile
 - definition 6
- Ductile iron (see "Nodular iron castings")
- Ductile-iron rolls
 - rolling-mill 439, 440
- Ductility
 - aging decreases 823
 - cold working decreases.... 821, 822
 - definition 881
 - significance in design..... 895
 - tempering to improve..... 811
 - tension test for determining
 - properties involving 891
 - wrought iron 219
- Ductility transition
 - impact testing 907-908
- Dummy block
 - hot-extrusion
 - process 774, 775, 776, 777
- Dummy pass
 - rail-mill 526
- Dumpers
 - car 242
- Dumps
 - waste (see "Waste dumps")
- Dunkard series
 - coal 66
- Duplex pig iron
 - composition ranges 221
- Duplex processes
 - acid-Bessemer converters
 - for 360, 361
 - advantage of 363, 364
 - continuous process main-
 - taining a dominant pool... 360-362
 - converters for 360, 361
 - disadvantages of 362, 363, 364
 - dry-bottom process 362
 - heat times 363

THE MAKING, SHAPING AND TREATING OF STEEL

Inch	definition	15	Northrup type	335	big-end-down	295
Inclusions			primary coil of	337	big-end-up	295
non-metallic (see "Nonmetallic inclusions")			steelmaking	334	bleeding of	394
Incubation period			Induction heating		bloomed-down	471
isothermal transformation	798		heat treatment by	412, 413	blowholes in	391, 393, 394, 395
Indene			melting electrolytic tin		bottom pouring of	398
light-oil constituent	123, 126, 132		coatings by	643	bridges in	393, 394
Indenter			principle of	334	burning of	398, 494
Knoop	902		Induction stirring		butt cracks in	396
Rockwell hardness test	898-900		electric-arc furnaces	340, 353	capped-steel	393, 394, 396
Vickers hardness test	900		Industrial-car wheels	568	casting of	391
Independent-arc furnaces			Industrial locomotive wheels	568	characteristics of	391
steelmaking (see "Indirect-arc furnaces")			Inert coatings		cinder patch on	494
India			characteristics of	618	columnar structure in	391, 398
iron-ore reserves	140		Infiltration		control of structure	396
iron ores	142		air, control of	86, 88	cooling of	391
Indicators			Inflammability (see "Flammability")		cracking of	354, 396, 493
chemical, definition	21		Ingot buggy		crucible-steel	254
direction	13		blooming-mill	472	delivery facilities at soaking pits	404
Miller	12		function of	401, 404, 405, 472	delivery to rolling mills from soaking pits	405
Indirect-arc furnaces			Ingot coverage		dendritic structure in	395
Rennerfelt type	335		soaking pits, definition	402	direct-rolling to rails	523, 526
Stassano type	335		Ingot cracks		drawing temperature	398
steelmaking	334, 335		causes of	396, 493	electric-furnace steel	343
Indirect firing			crucible steel	264	fissures in	391, 395
heat-treating furnaces	413		hanger cracks	354	folds in	396
Indirect pouring			ingot phenomenon	391	handling at soaking pits	401-404, 405
basic electric-furnace steel	354		seams related to	493	hanger cracks in	354
Indirect primary coolers			thermal shock contributes to	397	heating for rolling	391, 397, 401-406
coal-chemical recovery	116		Ingot defects		heating furnaces for	401-406
Indirect processes			minimization of	277	heating time for	406
ammonia recovery	117		Ingot molds		height of	318
wrought-iron manufacture	206, 209		acid-Bessemer plant	276	honeycomb blowholes in	393, 394
Indirect resistance furnaces			additions to steel in (see "Mold additions")		hot tops for	354, 394, 395, 493, 586
electric	334		big-end-down	391, 392	ingotism in	395
Indium			big-end-up	391, 392	ingot pattern in	395
atomic number	8		blast-furnace iron for	383	internal bursts in	395
atomic weight	8		bottle-top big-end-down	391, 392	internal fissures in	391, 395
iron-ore constituent	144		buggies for	276	killed-steel	393, 394, 397
melting point	8		cap for	391	molds for (see "Ingot molds")	
symbol	8		characteristics	317, 318	nonmetallic inclusions in	391, 395
Induced-draft fans			closed-bottom big-end up	391, 392	overheating	398
open-hearth	291, 297, 306		coatings for	354, 396	pipe in	391, 393, 394
Induced electrostatic charges	38		composition of iron for	384	port-marked	398
Induction			core of	276	pot car for handling	401, 404, 405
electromagnetic (see "Electromagnetic induction")			electric-furnace steels	354	pouring rate affects quality	396
magnetic (see "Magnetic induction")			hot tops for	186, 318, 354	pouring temperature affects quality	396
Induction electric-furnace pro-			metal for casting	391	power consumed per ton produced	442
advantages	357		open-bottom big-end-up	391, 392	products rolled from	463
atmosphere melting	358		open-top big-end-down	391, 392	rimmed steel	393, 394, 396
charge selection	356		plug-bottom big-end-up	391, 392	rolling of	463-479, 586
charging methods	356		preparation	343	scabs on (see "Ingot scabs")	
disadvantages	357		stools for	276, 391, 392	scaling in soaking pits	402, 406
melting the charge	356, 357		stripping from ingots	295, 296	seamless-tube steels	740
melting under controlled atmospheres	358		types of	391, 392	segregation in	391, 395
melting under vacuum	357		wall thickness	318	semikilled steel	393, 394, 396
motor effect on bath	357		Ingot pattern		size limitations for rolling	465
power consumption	357		ingot phenomenon	395	skin blowholes in	393, 394, 395
slags	356		Ingot pit cranes		skin of	392
vacuum melting	357		soaking-pit auxiliaries	404	soaking pits for heating	401-406
Induction furnaces			Ingot-receiving table		solidification pattern	392
Ajax-Northrup type	335		blooming mill	472	solidification time	354
capacity range	337		Ingot run		stainless steels, rolling	860
construction	337		open-hearth	291	step heating	406
coreless	334, 335, 356		Ingot scabs		stripping	276, 295, 296, 404
Ferranti type	335		ingot phenomenon	391, 395	structures of	393, 394, 396
foundry use of	366, 374, 375		Ingot strippers		surface defects	277
high-frequency coreless	334, 335, 356		principles of	205, 276, 296	taper of	392
Kjellin type	335		Ingot turner		teeming	391
low-frequency type	334, 335		blooming-mill	472	temperature equalization in	391
			Ingotism		time required for solidification	393
			ingot phenomenon	395	topping	264
			Ingots		track time	354, 397, 406
			acid open-hearth steel	332		
			air gap between ingot and mold wall	392		
			axial porosity in	396		

INDEX

impurities affecting refractoriness 193

Refractories (cont.)

intermediate-duty fireclay	
brick	182, 188
iron-oxide attack of	194
iron oxides in	182
kaolins	181
kilns for firing	184
kyanite	181
ladle	276
ladle brick	182, 188
lead attack of	205
lime-alumina-silica system	
phase diagram	193
lime in	182
lime-magnesia-silica system	
phase diagram	198
lime-magnesia system phase	
diagram	198
lime-silica system phase	
diagram	196
linear expansion of	187, 189
top-blown oxygen steelmaking	
converters	285
load-bearing ability	188, 189
load-test data	189
low-duty fireclay brick	182, 188
magnesia	181, 194
magnesia-dolomite ramming	
mixtures	185
magnesia-ferrous oxide system	
phase diagram	198
magnesia in	182
magnesia-lime group	181
magnesia-lime-silica system	
phase diagram	198
magnesia-lime system phase	
diagram	198
magnesite	181
magnesite brick	182, 187, 188
magnesite-chrome brick	182, 188
magnesite in ramming	
mixtures	185
magnesium-silicate group	181
manganous oxide-alumina-silica	
system phase diagram	196
massive (see "Massive refractories")	
mechanical spalling	191
mica schist	180, 182, 183
mining raw materials for	183
mixer lining	274
mixing raw materials for	183
modulus of rupture	188
molding	183, 184
mortars for brick laying	185
mullite	184
neutral	180
nodular fireclay	181
olivines	181, 183
open-hearth	288, 296, 298, 299, 300, 301, 303, 304, 319, 320, 321
periodic kilns for firing	184
permeability	187
physical characteristics	185
physical properties	188
plastic (see "Plastic refractories")	
plastic flow	189
pneumatic ramming	183, 184
porosity	187
potassium oxide-alumina-silica	
system phase diagram	195
pouring-pit	200, 201
power pressing	183
preparation of	183
pressing	183
puddling furnaces	211
purifying raw materials for	183
pyrometric cone equivalent	186

quartzite	180
ramming types	183, 184, 185
raw-material mining	183
raw materials for	180
raw-materials purification	183
raw state	183
refractory concrete	184
reheating furnace	201
requirements of	180
sandstone	180, 183
screening raw materials for	183
secondary expansion	189
selection for steel plant use	199
semi-silica brick	182, 188
serpentine	181
service requirements	185
Sharon conglomerate	180
side-blown process	284
silica-alumina-ferrous oxide	
phase diagram	192
silica-alumina-lime system	
phase diagram	193
silica-alumina-manganous	
oxide system phase diagram	196
silica-alumina-potassium	
oxide system phase diagram	195
silica-alumina-sodium oxide	
phase diagram	194
silica-alumina system phase	
diagram	191
silica in	182
silica brick	182, 187, 188, 193, 194
silica-ferrous oxide-ferric	
oxide system phase diagram	197
silica-lime-magnesia system	
phase diagram	198
silica-lime system phase	
diagram	196
siliceous fireclay brick	187, 188
siliceous group	180, 187, 188
sillimanite	181
soaking pit	200, 201
sodium oxide-alumina-silica	
system phase diagram	194
softening temperature	186
spalling of	191
spalling resistance	188
specific gravity	188
steel-plant uses	199
stiff-mud process for	
shaping	183
structural spalling	191
super-duty fireclay	
brick	182, 188
super-duty silica brick	182, 188
tempering	183
testing of	199
thermal capacity	190
thermal conductivity	190
thermal expansion	189
thermal properties	188
thermal shock resistance	191
Thomas-process	281, 282
titanium oxide in	182
total porosity	187
true specific gravity	187, 188
tunnel kilns for firing	184
uses of	199
vibration for molding	184
voids in	187
volume changes	189
zinc attack of	205, 253

Refractory concrete	
calcium-aluminate cement	
for	184
constituents of	184
Refractory shapes (see "Massive refractories")	

Refrigerants

impact-test specimen cooling	
in	905
Refrigeration	
blast drying by	258
Regenerative chambers (see "Regenerators")	
Regenerative single-divided	
coke ovens	94
Regenerators	
applications of	87
basic open-hearth	200
blast-furnace stoves	232
checkerwork for	305
coke ovens	93, 95-99, 100, 102
heating-furnace	401
historical	287
insulation	305
open-hearth	200, 287, 296, 297, 298, 303, 304, 305
peeling of checker-brick	189
principle of	87
roofs for	305
sealing	305
soaking-pit	401, 402
Regular lay	
wire rope	720
Regulators	
electric-arc furnace	348
Reheater	
ammonia-recovery process	118
Reheating furnaces	
barrel-type	410, 411
batch-type	406, 407
billet-mill	479
burner locations	407-411
capacity	411
combustion control	411
continuous-type	406-411
fuel consumption	85, 411
fuel economy in	85
fuels for	589
function of	399
hearth area	399
heat losses in	411
heat utilization in	85
heating capacities	411
hot-strip mill	589
insulation of	411
operating statistics	411
plate mill	503, 507, 509, 514, 519, 520
radiant-type burners for	410, 411
scaling of steel in	411, 414
skids for	589
thermal efficiency of	411
types of	406-411
Reid vapor pressure	73
Reinforced angle bars	529
Reinforcing bars	
bar-mill product	559
Rejects	
long-terne	657
Relative viscosity	
liquid fuels	72
Relay system	
direct-current motor speed	
control	451
Reluctance	
magnetic (see "Magnetic reluctance")	
Rennerfelt furnace	
indirect-arc type	335
Repeaters	
rolling-mill	420, 543, 681
bar-mill	543
rod-mill	681
Rephosphorized steels	
composition ranges for	818

- Replacement
 - double (see "Double replacement")

 addition agents for making 396, 397
 aging in 822
 allotropic transformation 386
 alloy (see "Alloy steel")
 aluminum capping of 586
 aluminum-clad 623
 ancient processes for making... 261
 annealing (see "Annealing")
 antiquity of 1-2
 austenite in 789
 axle 578
 banding in 387
 Bessemer steel (see "Acid-Bessemer steel")
 blackening processes for 625
 blister (see "Cementation process")
 bluing processes for 625
 brown color produced on... 625, 626
 burned 494
 capped (see "Capped steel")
 carbon (see "Carbon steels")
 carburizing of 814, 815
 cast (see "Steel castings")
 cement (see "Cementation process")
 cementite in 788
 cladding 623
 cleaning of (see "Abrasive cleaning," also "Electrolytic cleaning," also "Pickling")
 cold extrusion of 390
 cold working of (see "Cold working")
 coloring processes for 625, 626
 constitution of 788
 controlled cooling of (see "Controlled cooling")
 converted (see "Cementation process")
 copper-clad 623
 corrosion of (see "Corrosion")
 critical temperatures for 792, 793, 794
 crucible (see "Crucible process")
 crystalline nature of 385
 Damascus 261
 decarburization during reheating 411
 deep-drawing 825
 deformation of 385
 deformation resistance 444
 density of 929
 deoxidation of (see "Deoxidation")
 deoxidized Bessemer 740
 directional properties 387, 390
 double shear 262
 elasticity of 385
 electric-furnace (see "Electric-furnace steels")
 emissivity factors 59
 eutectoid 793
 eutectoid carbon content 794
 eutectoid structure 790
 eutectoid temperatures 793
 extra-deep-drawing type 586
 extrusion of 388, 390, 770-778
 ferrite in 788
 fiber 387
 finishing temperature 387
 flat-rolled (see "Flat-rolled steel products")
 forging 387, 388
 full annealing of 560
 furnaces for making (see "Steelmaking furnaces")
 galvanized sheet and strip bases 662, 666, 667
 gases in 393, 394
 grain growth in 386
 graphite in 791
 hammering 387
 heat absorption by 400
 heat- and corrosion-resistant castings of 374-377
 heat-resisting (see "Heat-resisting steels")
 heat treatment of (see "Heat treatment")
 heat-treating furnaces for (see "Heat-treating furnaces")
 heating for hot working 399-411
 heating for rolling 399-411
 heating furnaces for (see "Heating furnaces," also "Reheating furnaces," also "Soaking pits")
 heating rates for 400
 high-strength low-alloy ... 841-847
 hot extrusion of 388, 770-778
 hot scarfing of 498
 hot working of 386
 hydrogen in 501
 hypereutectoid 794
 hypo-eutectoid 793
 inclusions in 329
 ingots of 391
 ingot-structure control ... 396, 397
 iron carbide in 788
 iron-carbon equilibrium diagram for 791, 792
 iron-iron carbide equilibrium diagram for 791, 792
 isothermal annealing of 560
 killed (see "Killed steel")
 killed Bessemer 740
 long-terme base metal 635
 magnet steel 835
 magnetic properties lost on heating 794
 making (see "Steelmaking")
 mechanical properties 816, 819
 mechanical treatment 396
 metallographic constituents. 788-792
 nickel-plated, emissivity factor 59
 nitriding of 815
 nonmetallic inclusions in 329
 normalizing of (see "Normalizing")
 open-hearth (see "Open-hearth steel")
 oxide coatings for 625
 overheated 398
 passivity of 615
 pearlite in 790
 phase changes in 792-794
 pickling (see "Pickling")
 plain carbon (see "Carbon steels")
 plastic deformation of 385
 plasticity of 385
 pneumatic processes for making 266
 power consumption per ton of ingots produced 442
 press forging 387, 388
 process annealing of 561
 production, annual 269
 proeutectoid constituents 790
 protective coatings for 620-629
 quenching of 561, 562
 rail-steel 523
 recarburizing 312
 recovery after strain hardening 386
 recrystallization of 386
 rephosphorized 818
 residual elements in 324
 resulphurized 818
 rimmed (see "Rimmed steel")
 rivet steel 819
 sand blasting of 621
 scaling of 406, 408, 411, 414
 scarfing of 498
 seamless-tube 739, 740
 semifinished (see "Semifinished steel")
 semikilled (see "Semikilled steel")
 shot blasting of 621
 side-blown converters for making 284
 single shear 262
 spheroidization of 561
 stainless (see "Stainless steels")
 stainless-steel clad 623
 structural 819
 subcritical annealing of 561
 surface side-blown acid process for making 284
 sweating during heating 400
 tempering of 562
 thermal sensitivity of 501
 Thomas process for making... 281
 tin coatings on (see "Tin plate")
 tin-plate base 632, 644, 645, 646, 652
 tinned, emissivity factor 59
 tool (see "Tool steel")
 top-blown oxygen steelmaking process for 285, 286
 top killing of 586
 transformation of 792-794
 vitreous enameling of 627
 wheel 568
 wild 267
 wire-making types 676
 wootz 261
 wrought 365

- Steel-base rolls**

 inspection of 701
 kinds of 712-717
 lead annealing of 705, 706
 Liquor-Finished 685, 712, 713
 manufacture of 674-717
 market wire 713
 mechanical properties 694, 695, 701

- Wire (cont.)
- mechanical properties
 - affected by drawing.....694, 695
 - medium classifications 712
 - medium-hard temper 678
 - metal-stitching wire 715
 - metallic coatings for707-712
 - metallic hardening process
 - for 706
 - muffle annealing of..... 705
 - music wire 714
 - nails (see "Wire nails")
 - normalizing of 702
 - old-process patenting of..... 706
 - one-minute wire 711
 - O.P. patenting of..... 706
 - patenting 701, 706
 - pay-off reels for..... 694
 - piano wire 714
 - pin of 686
 - pointing for drawing..... 695
 - pot annealing of..... 705
 - prestressed-concrete applica-
 - tions of 718
 - principal uses of..... 674
 - process annealing of...701, 702, 704
 - process wire 684
 - products fabricated from...717-723
 - properties of patented wire... 706
 - protective coatings for.....707-712
 - rods for (see "Wire rods")
 - roll straighteners for..... 700
 - rope made from (see "Wire rope")
 - rope wire 714
 - salt-bath annealing of..... 705
 - Scratch-Brush 713
 - shapes (see "Wire shapes")
 - single-draft coarse 697
 - six-draft 698
 - size tolerances for..... 700
 - sizes of 676
 - soft 678
 - special wires 698, 613-715
 - spoke wire 714
 - springs made from (see "Wire springs")
 - stainless-steel 715
 - steels for 676
 - stem pay-off for..... 694
 - stem of 686
 - straightening 700
 - stretching machines for
 - straightening 700
 - surface finishes of..... 677
 - temper of 677
 - tempered 714
 - tempering 701, 706, 707
 - testing 701, 710
 - three-draft 698
 - tinned 713, 715
 - tinned armature-binding wire.. 715
 - tinning of 711
 - tire wire 714
 - tolerances for 700
 - tube annealing of 705
 - two-draft 698
 - two-minute wire 711
 - types of 685
 - valve-spring wire 714
 - Weaving 712
 - Welding-rod 712
 - whirls for straightening..... 700
 - wrought-iron 675, 676
 - zinc-coated (see "Galvanized wire")
 - Wire drawing
 - auxiliary equipment for..... 694
 - blocks for (see "Wire-drawing blocks")
 - borax coatings for.....684, 688
 - bridge wire 723
 - coarse wires 697
 - coatings for684, 685, 688, 698, 699
 - copper wire 699
 - diamond dies for..... 689
 - die alignment in..... 699
 - dies for (see "Wire-drawing dies")
 - draft defined 684
 - dry process 684, 688, 697, 698
 - effects of 695
 - equipment for 689
 - fine wire 698, 699
 - five-draft wire 698
 - four-draft wire 698
 - frames for 684, 693
 - hard-drawn wire 698
 - heat generated in..... 695
 - high-carbon wire 698
 - historical development 675
 - lime coatings for.....684, 688
 - limitations of 697, 700
 - lubricants for 684, 685
 - machines for (see "Wire-drawing machines")
 - mechanical properties
 - affected by 694, 695
 - microstructure affected by.. 696, 697
 - pointing stock for..... 695
 - precautions in 699
 - processes for 684, 685, 688, 697, 698
 - results of 695
 - rod-drawing 684
 - rod-preparation for 684
 - safety precautions in..... 695
 - single-draft coarse wire..... 697
 - six-draft wire 698
 - size tolerances in..... 700
 - soap as lubricant for..... 685
 - structural changes pro-
 - duced by 696, 697
 - sull coating for..... 684
 - three-draft wire 698
 - tolerances for 700
 - tungsten carbide for dies..... 689
 - two-draft wire 698
 - wet process for..... 684, 698, 699
 - wire temper controlled by
 - extent of 677, 678
 - Wire-drawing blocks
 - bull blocks 684, 691
 - coarse wire 677
 - fillet of 690
 - fine wire 677
 - historical 675
 - motor blocks 684, 691
 - operation of 690
 - wire-drawing frame 684
 - Wire-drawing dies
 - alignment of 699
 - diamond dies 689
 - hole contour 689
 - materials for 689
 - nib of 689
 - tungsten-carbide nibs for..... 689
 - types of 689
 - wire-drawing frame 684
 - Wire-drawing frames
 - blocks for 684
 - die for 684
 - drawbar for 684
 - operation of 684
 - principle of 693
 - Wire-drawing machines
 - bull blocks (see "Bull blocks")
 - circular tandem type for fine
 - wire 693
 - continuous-type 692, 693
 - drawbench 690
 - fine-wire drawing 693
 - intermediate-type 693
 - motor blocks (see "Motor blocks")
 - safety devices for..... 695
 - step-cone-type for fine wire... 693
 - tandem type for fine wire..... 693
 - Wire electrogalvanizing
 - advantages of 710
 - equipment for 710
 - operation of process..... 710
 - Wire fence
 - historical 675
 - kinds of 717, 718
 - woven-wire 675, 717
 - Wire galvanizing
 - advantages of 707
 - coiling equipment for..... 709
 - cooling coated wire..... 709
 - dross formed in..... 708
 - methods for 707
 - pickling for 707
 - processes preliminary to..... 707
 - spelter pan for..... 708
 - wiping methods 708
 - zinc skimmings from..... 708
 - Wire nails
 - finishing 717
 - forming operations on..... 717
 - historical 675
 - machines for making..... 717
 - Wire products
 - manufacture of 717-723
 - Wire resistance strain gages
 - tension-test applications
 - of 883, 885
 - Wire rods
 - baking 689
 - billets for 679, 680
 - blocks for drawing..... 684
 - borax coating 684, 688
 - C-hooks for handling..... 685, 686
 - characteristics of 678
 - cleaning 684, 685, 687, 688
 - coating for drawing..... 684, 688
 - coils of 678
 - cranes for handling..... 686
 - defects in 683
 - dry drawing 684, 688
 - historical 675
 - lime coating 684, 688
 - pickling 684, 685, 687, 688
 - pin of 686
 - pointing for drawing..... 695
 - preparation for drawing..... 684
 - production of, annual..... 674
 - reels for 683
 - rinsing after cleaning..... 688
 - rolling of (see "Rod mills")
 - sizes of 678
 - stem of 686
 - sull coating 684
 - time required for pickling.... 688
 - Wire rope
 - closing 720
 - cores for 719, 720
 - fabrication of 719, 720
 - hemp cores for..... 719, 720
 - historical 674
 - Lang lay 720
 - laying 720
 - regular lay 720
 - stranding 720

- Wire rope (cont.)
types of 719, 720
wire for 714
- Wire shapes
sections of 676
Turk's head for forming 695
- Wire springs
active coils of compression
springs 720, 722
bluing 722
clock springs 722
compression springs 720, 722
double torsion springs 722
end finishes for 720-722
extension springs 721, 722
free length of compression
springs 720
helical springs 722
historical 675
inactive coils of com-
pression springs 720, 722
initial tension 722
jig springs 722
motor springs 722
pitch of compression springs 720
scale testing 722
tested spring 722
testing 722
torsion springs 722
types of 720-722
upholstery springs 722
- Wisconsin
iron ores 142, 153
- Wobblers
roll 431
- Wolf furnace
wrought-iron production in 208
- Wolf oven
wrought-iron production in 208
- Wolhaupter rail joint 529
- Wollastonite
lime-silica system component .. 196
- Wood charcoal
blast-furnace fuel 113
- Wootz
manufacture of 261
- Work
definition 33
- Work hardening (see also "Cold-
working")
stainless steels 860, 863
- Work rolls (see "Working rolls")
- Working
cold (see "Cold working")
hot (see "Hot working")
- Working period
acid electric-arc furnace
process 355
acid open-hearth 331
chemistry of working period in
basic open-hearth 324
dry-bottom duplex process 362
open-hearth 311, 313, 324, 331
single-heat duplex process 362
- Working rolls
cluster-mill 420
cold-reduction mills (see
"Cold-reduction mills")
four-high rolling .. 420, 510, 514, 519
function of 420
plate-mill 510, 514, 519
- Working volume
blast-furnace 228
- Worms
yield-point phenomenon 889
- Wound-rotor induction motors
hot-strip mill applications 456
- motor-generator sets driven
by 454
rolling-mill drives 447, 455
three-high mill drives 455
- Woven-wire fence
manufacture of 718
- Wrought iron
American bloomery for
making 207, 208
antiquity of 1-2
Aston process for making .. 211, 215
balling furnaces for bushel-
ing 213
bauernofen for making 208
Bessemer process used in
production of 216
best bar 214
blasofen for making 208
blau furnace for making 208
blauofen for making 208
blooms of 206-213
blown metal for making 216
blue furnace for making 208
Burden squeezer for puddle
balls 213
busheling 213
carbon in 218
carburization of surface 261
case hardening 261
Catalan process for making 207
cementation-process raw
material 262
charcoal-hearth processes for
making 209
composition 218
crucible process use of 263
density of 929
direct processes for making .. 206, 207
double-refined iron 214
double-rolled iron 214
dry puddling process for
making 210
ductility of 219
Ely mechanical puddler for
making 211
etch testing 218
fagoting for rolling 214
fracture test for 218
furnaces for making 206-217
grain size of matrix 218
hand puddling process for
making 210-214
historical background 206, 207
indirect processes for
making 206, 209
Lancashire process for making .. 210
loup furnace for making 208
luppenofen for making 208
macroscopic structure 218
manganese in 218
manufacture of 206-219
mechanical properties 218
mechanical puddling processes
for making 211
merchant bars 214
microscopic structure 218
muck-bar mill for rolling 213
muck bars 213
No. 2 iron 214
No. 3 bar 214
osmund furnace for making ... 208
pearlite in 218
phosphorus in 218
pig-boiling process for making .. 210
pig iron for making 221, 223
piling for rolling 213
plates 219
properties of 218
- puddle balls of 212
puddling furnaces for
making 210-213
puddling process for
making 209-215
rolling 213, 217
salamander furnace for
making 208
shingling puddle balls 213
silicon in 218
single-refined iron 214
single-rolled iron 214
slag in 218
slag used in making 216
South Wales process for
making 210
specific heat 54
squeezing puddle balls 213
structure of 218
stuckofen for making 208
sulphur in 218
tensile properties 219
Walloon process for making ... 209
welded-pipe properties 219
wire made from 675, 676
wolf furnace for making 208
wolf oven for making 208
wolf's oven for making 208
- Wrought steel
definition 385
- Wrought-steel wheels (see
"Wheels")
- Wulf's oven
wrought-iron production in 208
- Wüstite
ferrous oxide-alumina-silica
system component 192
ferrous oxide-ferric oxide-
silica system component 197
ferrous oxide-silica system
component 197
- Wyoming
iron ores 145, 149
- X
tin-plate symbol 932
- X-rays 529
- X-rays
nondestructive-test methods
employing 373, 377, 926, 927
steel castings examined by .. 373, 377
- Xanthosiderite
iron ore 139
- Xenon
atomic number 8
atomic weight 8
boiling point 8
melting point 8
symbol 8
- Xylenes
boiling range 127
distillation for recovery 136
light-oil constituents .. 115, 122, 123,
126, 127, 128, 131
protective coatings utilizing ... 127
recovery from light oil 126-131
tar constituents 132
uses for 127, 138
- Xylenols
tar constituents 132
- Yellow phosphorus
specific gravity 30
- Yield point
definition of 889-891
determination of 889-891
phenomena associated with .. 889-890
- Yield-point elongation
definition of 889

Yield strength						solution potential in various	
definition	888	Zinc	atomic number	8		solutions	622
determination of	888, 889		atomic weight	8		surface treatments for	
Young-blown heats			blast-furnace refractories			coatings of	626
acid-Bessemer process	275, 279		affected by	144		symbol	8
Young's modulus (see "Modulus			blast-furnace behavior of.....	253		wire coated with.....	707-711
of elasticity")			boiling point	8	Zinc-iron system
